3. Disarticulation of the Knee Joint.—F. J. Gaenslen describes his method of disarticulation of the knee joint, devised for the purpose of securing a broad weight-bearing surface, utilizing the patella in addition to the condyles. In common with other disarticulating operations there is no necessity for carrying the artificial limb to the tuber ischii for support as in thigh amputation. The principal points in the technique are the preservation of the patella and the extensor apparatus by division of the patellar ligament close to the tibial tubercle; lengthening of the quadriceps tendon to allow the patella to be brought down into apposition with the lower surface of the femur, and the performing of an arthrodesis between the patella and the femur in the intercondyloid space at such a point that the pressure bearing point of the patella will lie on a level with the condyles. In this way weight will be distributed equally between these three large smooth surfaces, thus affording an eminently satisfactory weight bearing surface. Furthermore, the skin covering the patella is more or less thickened and therefore suited for bearing purposes. The muscular balance of the limb is little interfered with. The various methods of amputation in this region are discussed. The author thinks that when one has a choice, disarticulation with lateral flaps seems to have its advantages when used as in the operation of Stephen Smith. His own procedure differs from Smith's in the lengthening of the quadriceps tendon, allowing the patella to be brought down between the condyles; arthrodesis between the patella and the intracondylar surface and its fixation in this position by suturing of its ligament to the hamstring tendon and capsular tissue behind.

4. End Results of the Baldy-Webster Operation.—By J. O. Polak. (See MEDICAL RECORD, July 1, 1913, page 45.)

5. Membranous Dysmenorrhea and Endometritis.—K. J. Sanes believes that membranous dysmenorrhea does not depend on endometritis for its occurrence. The inflammatory appearance of the lining membrane of the uterus is physiological, and if the picture of menstrual membrane could prove a endometritis, then all menstruating uteri have endometritis. The author quotes from Van Herwerden that in certain monkeys a membrane is always cast off during menstruation, and if this is considered physiological in the monkey, why should it be considered unphysiological in the human species? Is it because it is rare in the human female? It is, however, a great deal commoner than is generally supposed. It is not always accompanied by pain and naturally such cases are not reckoned as membranous dymenorrhea. Dysmenorrhea is common and there is no reason why it should not occur in cases in which a membrane is cast off. A number of authorities are quoted to show that a menstrual membrane is not inconsistent with fertility and a suggestion is made that the formation of the membrane may be due to a more excessive stimulation of the process by the ovarian hormones.

6. Radium in Internal Medicine.—L. G. Rowntree and W. A. Baetjer present a summary of the physiological and pharmacological effects of radium as observed by European authors. Its value is unqestionably established in chronic and subacute arthritis (luetic and tuberculous excepted), in rheumatism, gout, sciatica, neuralgia, polyneuritis, lumbago, and the darting pains of tabes. In certain other diseases it is said to be of some value, though more data are required. These include chronic bronchitis and pharyngitis, pneumonia, myocarditis, arterial sclerosis, vasomotor disturbances, scleroderma, chronic lymph-node enlargements and chronic constipation. Certain authors have warned against its use in hemorrhagic diathesis and purpura, gastric ulcer, pregnancy, marked neuroses, especially if involving the vegetative system, also in advanced tuberculosis and polycythemia, but these last two are queried by the authors. Nephritis was at first considered a contraindication, but this is not now accepted. As regards methods of administration, baths have been in use for many years, the benefits of which are now credited to the radium emanation. It is sometimes used now as a local application to the skin, but the best method is by inhalation. This, however, is also the most expensive, requiring a special air-tight room or cabinet. The author's patients were treated entirely by drinking water activated with radium emanation, and were under observation for periods varying from two weeks to three months. The daily dose was from one-half to forty microcuries. The series of eighteen cases included five of infectious arthritis, three of which seemed to be temporarily benefited; five cases of muscular rheumatism and neuralgia, one apparently cured and another temporarily benefited, and three cases of tabes were unaffected, as well as one of acute rheu-

matism and one of sciatica with the same result. One case of Parkinson's disease was slightly improved for a time; one of nephritis and high blood-pressure showed rather marked improvement. In one case of gout a severe exacerbation followed the treatment. The most favorable results were in the arthritis cases, in which there was a slight definite lasting improvement after the first relapse.

7. **Rupture of a Lymph-Node into a Bronchus.**—By A. L. Goodman. (See MEDICAL RECORD, June 28, 1913, page 1186.)

8. **Roseola Infantum.**—By J. Zahorsky. (See MEDICAL RECORD, June 28, 1913, page 1191.)

9. **Infectious Arthritis.**—J. W. Cokenower holds that failures in treating joint disease are due more to wrong diagnoses of the cause than to improper treatment, and back of this is a lack of knowledge of the anatomical structure of joints as well as of the pathology of the disease. It will often be necessary to have the help of regional experts and the aid of roentgenography and bacteriology. One must not forget, omitting trauma, that arthritis is only a symptom of a disease or diseases whose real nidus is in some distant part of the body. A urethritis or suppurating antrum may either cause the same symptoms, but we must treat one as gonococcal and the other as septic. The diagnosis in children is mainly between tuberculosis on the one hand and sepsis, rickets, congenital syphilis, and coxa vara on the other, and in early adult life special forms of septic infection from the gastrointestinal and genitourinary tracts are most common, while in still later life chronic septic infection of the mucous tracts of nearly all parts of the body must be considered. The author specially emphasizes the importance of the mouth as a source of arthritis. Absence of all the teeth without replacement by artificial ones is a sure proof of oral sepsis. The tonsils and the teeth should be carefully inspected in all nontraumatic cases where there is any doubt as to infections from other parts of the body. No diagnosis is complete in such cases without this examination.

10. **Injection Treatment of Tuberculous Joints.**—L. W. Ely traces the employment of injections of tuberculous joints back to Mikulicz in 1881, who used iodoform, which has been the substance most persistently advocated by those who recommend this treatment. Many other substances, however, have been used, such as iodine, phenol, formaldehyde, etc. The author has gone over the literature relating to the use of iodoform and finds that the evidence for iodoform, after thirty-two years of trial, consists almost exclusively of unsupported clinical opinion. While this does not necessarily condemn it, an approximately equal weight of unfavorable clinical opinion would point in the direction of some other method of treatment. Iodoform is not widely used in this country at present except by those who possess an extreme reverence for foreign authority. The claims for the other substances are just about as well supported. They are at first vigorously advocated and then abandoned. Formaldehyde is at present still being tried. It is as rational to attempt the cure of tuberculous joints by injections as it would be to attempt to cure the disease in the lung by injecting the pleura. One should simply attempt to aid nature in its reaction against the presence of the tubercle bacillus and discount the ability of any substance injected into a joint to destroy the infection.

1. **Fever in Pulmonary Tuberculosis.**—F. J. Wethered states that it may be assumed that a rise of temperature, apart from accidental factors, may be considered an indication of activity, and that the most reliable means for reducing activity is rest. If, therefore, a patient who has been progressing favorably exhibits a rise of temperature, it must be accepted as a sign that rest must be insisted on. In other words, a patient suffering from pulmonary tuberculosis must live in accordance with his temperature chart. Any increase of cough and expectoration, headache, general malaise, and so on, should always be regarded as calling for a record of the temperature for a few days, and should a rise be found, the necessary measures should be taken in accordance with the general features of the case.

2. **Examinations and the Medical Student.**—Sir William Osler presents an interesting paper on this subject. He concludes that the student needs more time for quiet study, fewer classes, and fewer lectures, and, above all, the incubus of examinations should be lifted from his soul. To replace the Chinese by the Greek spirit would enable him to seek knowledge for itself, without a thought of the end, tested and taught day by day, the pupil and teacher working together on the same lines, only one a little ahead of the other. This is the ideal towards which we should move. The pity of it all is that we should have made an intolerable burden of the study of one of the most attractive of the professions, but the reform is in our own hands and should not be far off. A paragraph in an address of the late Dr. Stokes contains the pith of the author's remarks: "Let us emancipate the student, and give him time and opportunity for the cultivation of his mind, so that in his pupilage he shall not be a puppet in the hands of others, but rather a self-relying and reflecting being."

7. **Arteriovenous Anastomosis for Impending Gangrene.**—C. Goodman finds that arteriovenous anastomosis is applicable in angiosclerosis and in arterial thrombus, where the integrity of the limb may be preserved by this means until collateral circulation is established. In regard to methods, end-to-end anastomosis offers the most simple technique and is least likely to be followed by thrombosis. The author has tried the operation in 15 cases, and in this series noted that the foot, previously cold and cadaverous in appearance, took on a feeling of warmth and a healthy pink color. The valves of the veins were only a temporary barrier to the course of the blood against the constant pounding of the heart. The pain due to ischemnia was relieved shortly after the operation in all these cases. Strongly presumptive evidence of establishing a reversal of the circulation are the following facts: Improvement of color, increase of warmth of the affected part, relief from pain, filling of the superficial veins, pulsation of veins below the site of anastomosis, and the return of the part threatened with gangrene, or the actual seat of gangrene, to the normal. All writers seem to agree that angiosclerosis of the lower extremity is an ascending process and leads eventually to gangrere. A review of the author's cases shows six successes. Several of these cases which promised success required amputation later, but even these had temporary relief from pain. In his experiments upon animals he tried all the usual methods of anastomosis—end-to-end, side-to-side, end-to-side, intubation, and invagination. In his operations upon human beings he used the end-to-end method in all excepting one case, as he found it the simplest in execution and least likely to cause thrombosis. The operation should not be undertaken in the presence of

sepsis, or advanced or fulminating gangrene. The opportune time for intervention is in the pregangrenous stage before mortification has set in, in order to prevent its inception. In non-septic gangrene the improved nutrition of the limb may be hoped for, permitting lower amputation than would otherwise be possible, as is shown in several of the cases. The utmost delicacy and skill in minute detail must be observed in order to avoid the formation of thrombi; a most rigid asepsis is required throughout the operation, or the object of the operation will be defeated. To reduce the dangers of thrombosis to a minimum the author practised the following precautions: Before the sheath of the vessel is opened the wound must be absolutely freed from, and dried of, any visible signs of blood, and then covered with sterile wound protectors. For this purpose the author used various materials and found that a thin, black, oriental silk gives the best results; this material adapts itself to the wound without encroaching upon the operative field, and the color removes the glaring and trying effect of the open wound upon the eyes of the operator during the more minute details of the operation.

7. Electrargol in Smallpox. R. Denman.

1. **Action of Strophanthin Upon Cardiac Tissue.**—A. J. Clark discusses the action of strophanthin upon the heart. The action can be divided into two stages—a first or therapeutic stage, in which the force of contraction of the auricle, and to a less extent that of the ventricle, are increased, and a second or toxic stage, in which the force of contraction is diminished, the rate of conduction is impaired, and the diastolic relaxation is imperfect. In the action of strophanthin upon the hypodynamic heart the increase in the force of the ventricular contraction is much greater than in the fresh heart; this difference suggests a possible parallel to the difference in the action of cardiac glucosides upon the healthy heart and the diseased heart in mammals.

4. **Fatal Purpura Following Scarlet Fever.**—J. Biernacki and A. L. Dykes note that relatively rarer than the mild purpura chiefly affecting the lower extremities which occurs after scarlet fever is a malignant form with extensive superficial lesions in various parts of the body. The authors report a case that belongs to the latter type, but is unique in that the purpuric areas showed a definite inflammatory element. The inflammation was revealed not only by an undue degree of tenderness, but by marked swelling of the loose tissues, and a certain amount of induration. Early in the attack it seemed likely that the lesions would become gangrenous, but the patient died before any breaking down had occurred; also it was noticed before death that at points on the right leg and left arm the purpura was beginning to recede.

Nature of Human Diabetes.—Frank, assistant of Minkowski, discusses the two leading views of the nature of diabetes. These do not exclude each other necessarily, while it is possible that they repose on a common basis, to wit: the pathology of glycogen. The latter is often regarded as a dead reserve, but Ehrlich has shown that it is united with a "carrier substance"—according to Arnold the "plasmosomes" of the liver cells. We know of two ways in which glycogen leaves the liver: one, the ordinary type, is the result of hyperglycemia, while the other is seen only in certain intoxications (phosphorus, etc.), in which the sugar content of the blood remains unchanged. The toxic substance uses up the glycogen rapidly and completely, so that some of it enters the blood. Embden has shown that if a liver rich in glycogen is completely bled, large quantities of lactic acid are formed, while when blood rich in glucose is infused through the liver, but little lactic acid is formed. Numerous other finds of this type appear to show that glycogen is more readily attacked in the liver cells than is glucose. Since bodies which act vitally must be bound with other substances we look upon glycogen as vitally bound with protoplasm; perhaps with a phosphoric-acid-holding complex. From this viewpoint the pancreas yields a something which may be able to vitalize glycogen into the chemistry of the living cell. Should this intermediary be absent the glycogen, set free from its combination, is quickly transformed by cell diastases into glucose, a subject much less readily utilizable. The liver cells which need glycogen for their own metabolism strive to form glycogen out of their protein content, but in vain. It is quite possible that these protein fragments by accumulating in the cell damage its power to fix new glycogen. Glucose now escapes into the blood, because it can no longer be fixed as glycogen in the liver cells, and in itself cannot be but slightly utilized. It is to be hoped that we may be able to demonstrate the nature of the process by which the pancreatic hormone "vitally fixes" the glycogen.

Treatment of the Cardiac Weakness of Pneumonia with Venesection and Saline Infusion Containing Suprarenin.—Lonhard, a military surgeon, relates in great detail a case in which life was saved by this treatment. The patient was a soldier of none too good physique and heredity, who developed a fulminant type of pneumonia as a result of catching cold on parade. On the second day he was unusually ill and grew worse until the fourth day when he seemed to improve a little without the intervention of a crisis. He soon became worse again, evidently from extension to a new lobe and complicating nephritis. On the seventh day, after he had long been taking digalen, camphor, cognac, and a pneumococcus serum, he was pronounced moribund. On account in part of the indication furnished by his extreme cyanosis he was bled to the extent of 300 c.c. and with marked temporary benefit, his sensorium becoming clear. The venesection had at once been followed by saline infusion containing suprarenin. The improvement lasted a full day when the grave symptoms returned. No more blood was withdrawn but the infusion was repeated on several occasions and the usual cardiac stimulants were kept up, the disease ending by lysis. The pneumonia had been asthenic in type with tendency to migration. After the failure of analeptics alone, venesection, followed by the renewed use of cardiac stimulants prevailed over the disease.

Etiology of Bone and Joint Tuberculosis.—Möllers concludes his paper as follows: In the pus or in diseased portions of tissues in twelve cases of human tuberculosis of the bones and joints from which fifteen pure cultures were cultivated we were able to distinguish all the characteristics of tubercle bacillus. Fifteen preceding authors on this subject had collected 163 similar cases, in but four of which bovine bacilli were present, all the others presenting only the human type. But Fraser, of Edinburgh, has recently published a similar series, in nearly two-thirds (61 per cent.) of which the bovine germ was present. Fraser should subject his material to a more general analysis in order to bring out possibilities of fallacies—*Deutsche medizinische Wochenschrift.*

Insurance Medicine.

A Study of Rejections.—Statistics as to the future of rejected applicants are few and information is meager. Dr. Frank W. Foxworthy, medical director of the Commercial Life Insurance Company and the Majestic Life Assurance Company, Indianapolis, Ind., in his President's Address, American Association of Medical Examiners, Minneapolis, Minn., June, 1913, speaks of some of the cases which have come under his observation and which have proved beneficial to him. In many cases a complete knowledge of the applicant, imparted confidentially to the medical director, will cause a rejection without further investigation. In other cases, special information secured by the medical director has changed a first-class recommendation by the examiner to a declined risk; the medical director wondering if the examiner was blind or deaf to facts that stood out prominently to the applicant's associates and yet were not elicited by the examiner in his examination. The first case is designated as the "Cured Tuberculous." In July, 1912, Mr. C. applied for life insurance and the examination by a trained physician was first class in every particular, including family history. A confidential report on him was first class, except a rumor that the applicant had at one time been treated at a tuberculosis camp. Through the agent who wrote the application and the applicant himself, it was found that the applicant had worked in a minor capacity at a tuberculosis camp, but he denied, under affidavit, ever having been treated for tuberculosis, not suffering from it. The medical director of the sanitorium was written to and confirmed the rumor, as the applicant had had tuberculosis and had been treated for it. The information was referred to the legal department, with the result that the policy was taken up. Information not long ago received stated that Mr. C. had died of acute tuberculosis in June, 1913. As the medical examiner is a conscientious and honest man, he could not be blamed for failing to find the lesion of tuberculosis. One of the lessons from this case is that healed consumptives are not cured, but that the disease remains in abeyance, only to break out under favorable conditions for its development. The next case was one of rheumatism in a woman of apparently perfect health. Mrs. S. applied for insurance in 1909, with an excellent family history and a good physical examination; the only history of illness being an attack of acute rheumatic fever which lasted five or six months, leaving her with a slight limp, due to a little stiffness in one knee. This attack had occurred two years previous, and the applicant had been in excellent health ever since with no heart involvement. The medical director at that time accepted the risk. Five years after her rheumatic attack and three years after the acceptance of the risk, Foxworthy was employed to examine the applications of the company, and laid aside this risk as suspicious. The applicant was re-examined by a competent physician and reported in first-class condition, with recommendation that the policy be reinstated. Foxworthy then sent for the woman and made an examination of her heart, but no lesion could be found. Believing, however, that acute rheumatism of several months' duration must leave an indelible mark upon the constitution of the individual, the risk was declined. Mrs. S. died of some acute heart disease within three months of her last examination. Among several other classes which are exceedingly difficult for the medical director to pronounce judgment on are those in which the impairment is not recognized by the applicant himself. Courts have held that an applicant, not being cognizant of any physical impairment, answering questions in the negative relative to a condition he may have, no misrepresentation is intended. One young man of nineteen applied for insurance, and just as the physical examination was completed had an epileptic fit. He had had one a year before, but had no idea as to the cause of his condition and was not informed, but was not accepted as a risk. The question arises, Should these applicants, ignorant of their impaired condition, be informed by the examiner? On the whole, it seems wiser not to enlighten them, as often the shock and the mental condition produced work more harm than good. Another class may come under the heading of the "graveyard" insurance. In this class are the applications made out for people, most often widows, who upon investigation are found to be on their deathbeds or else many years older than the application blank stated and liable to die in a short time. The agents who caused this condition were eventually sent to the penitentiary. The next class are those rejected risks who should be accepted. This class is usually caused by the examiner, who, though honest and conscientious, may lack experience, or delegate his work to others. Young examiners, out of college but a short time, often magnify slight imperfections. Ofttimes a pulse will be taken after violent exercise and passed on the examination as normal, or after the applicant has just smoked a cigar, either of which will cause a variation from normal. Or an office girl, ignorant of some of the results expected in urine analysis, doing the tests for a physician, may give a wrong report, and unless care is exercised higher up the applicant may be rejected. Blood-pressure rejections form still another class. Foxworthy considers that the standardization of blood-pressure tests is in its infancy, and that it would be worth while to have a committee of experts compile statistics with regard to the normal blood pressure at different ages. Blood pressure is almost a prophet. Foxworthy, in the course of his examinations, found a farmer aged fifty-five, retired, whose physical examination was perfect. This man at the time of the examination was a teetotaler, but in his earlier days had drunk considerable liquor. His blood pressure was between 158 and 160 m.m., and he was declined as a risk solely on account of the high blood pressure, which was not sufficiently high, however, to be detected at the radial pulse. Within the year the applicant died from cerebral hemorrhage. The last class is that of family history, which also has not received sufficient standardization, the personal equation of the medical director being apparently the leading factor as to the acceptance or rejection of an applicant. As a result of his excursion into the question of rejections, Foxworthy is more firmly convinced than ever that there should be a standardization of the application blank, as well as of blood pressure, family history and several other problems which daily come before the medical director. It would not only induce longevity in the medical directors as well as the medical examiners, but would be a protection to the company, and, in many cases, the applicant would benefit by being warned in time to conserve his health.—*Lancet Clinic*, July 19, 1913.

Book Reviews.

Ophthalmoscopic Diagnosis, Based on Typical Pictures of the Fundus of the Eye, with Special Reference to the Needs of General Practitioners and Students. By Dr. C. Adam, Assistant at the Kgl. Univ.-Augenklinik, Berlin. Translated by Matthias Lanckton Foster, M.D., Ophthalmic Surgeon to the New Rochelle Hospital; Member of the American Ophthalmological Society; Member of the American Academy of Ophthalmology and Otolaryngology. With 86 colored pictures on 48 plates and 18 illustrations in the text. Price $6.00. New York: The Medical Art Agency, Herald Square Building, Rebman Company, 1913.

This volume is one of 229 pages and is a good example of the printer's art. Part one is devoted to a description of the technique of ophthalmoscopy. Then follows a brief description of the anatomy of the eyeball. The author then takes up the description of the ophthalmoscopic appearance of the normal fundus oculi, following this with descriptions of the fundus oculi in disease. The work is abundantly illustrated by excellent cuts in the text and numerous excellent colored plates. Special stress is given to the differences in the appearance of the fundus ophthalmoscopically in diseases affecting like structures with a view to differential diagnosis. The signs and symptoms of the various disease conditions observed by means of the ophthalmoscope are carefully analyzed to this end. Some of the rarer forms of disease of the retina and chorioid have been omitted. Works of this nature are very helpful to the student. The work has been ably and conscientiously done and deserves wide recognition from ophthalmologists. The translation is most excellent.

Die Augeneiterung der Neugeborenen (Ätiologie, Pathologie, Therapie, und Prophylaxe). Von Dr. C. A. Crede-Horder, Frauenarzt in Berlin. Mit 33 Abbildungen im Text. Price 5 marks. Berlin, 1913. Verlag Von S. Karger, Karlstrasse 15.

This monograph is one of 140 pages. It is a comprehensive review of the subject in the light of the more recent careful studies of the affection. Etiology, clinical history, and treatment are quite fully prophylaxes exhaustively considered. The author states the lamentable fact that at the present time 12.39 per cent. of the blind in Germany owe their conition to ophthalmia neonatorum. The monograph is worthy of careful perusal.

The Ophthalmic Year-Book, Volume IX, Containing a Digest of the Literature of Ophthalmology for the Years 1911 and 1912. Edited by Edward Jackson, M.D., Professor of Ophthalmology in the University of Colorado. Assisted by Theodore B. Schneideman, M.D., of Philadelphia; William Zentmayer, M.D., of Philadelphia; William H. Crisp, M.D., of Denver; Casey A. Wood, M.D., of Chicago; Wendell Reber, M.D., of Philadelphia; Harry S. Gradle, M.D., of Chicago; Robert Henry Elliot, M.D., of Madras, India; Hugo W. Aufwasser, M.D., of Denver; Meyer Weiner, M.D., of St. Louis. Illustrated. Published with Assistance from the Knapp Testimonial Fund of the Section on Ophthalmology of the American Medical Association. Herrick Book and Stationery Company, Denver, Col., 1913.

This volume of the Ophthalmic Year-Book presents a most excellent digest of ophthalmic literature for the years 1911 and 1912. This publication has been very helpful to ophthalmic surgeons from its beginning, each volume being an improvement over its predecessor. Much credit is due to Dr. Jackson, the very talented editor, for the logical arrangement, development and execution of the work, all of which has been ably forwarded by the excellent corps of collaborators. The digests of the articles and the exhaustive bibliography enable the student to obtain a comprehensive knowledge of the work done on any subject in ophthalmology during the period covered by the volume with the least possible expenditure of time. The publication should be in the hands of all surgeons who are actively engaged in the practice of ophthalmology.

Selected Papers by Dr. Carlos J. Finlay. Havana: 1912.

This book is a compilation of most of the papers of the illustrious Scotch Cuban. Dr. C. J. Finlay, the greater portion contributions which have appeared in national or foreign scientific publications. The work of this intrepid and untiring investigator has opened the heretofore closed path of progress and civilization in tropical America. The confirmation of his theory of the transmission of yellow fever by the mosquito was one of the most important steps taken in these regions since their discovery by Columbus. The gigantic work of the Panama Canal, which will revolutionize geographical conditions in the world, could never have been done without his investigations and their confirmation by the U. S. Army Commission. This book is an exposition of his ideas. The biographical notes are very interesting. Part I deals with yellow fever; a paper on the mosquito hypothetically considered as an agent in the transmission of yellow fever read August 14, 1881; a paper reprinted from the *Am. Jour. of Med. Sciences*, "Yellow Fever, Its Transmission by Means of the Culex Mosquito," October, 1880. Then follow some papers in Spanish which are not translated. There is an interesting chapter in English on Yellow Fever before and after the Discovery of America, another on a Plausible Method of Vaccination against Yellow Fever. The most recent contribution, dealing with atmospheric temperature as an essential factor in the production of yellow fever, was read at the International Congress for Hygiene and Demography, Berlin, September, 1907. A smaller second portion of the book deals with the transmission of cholera and filariasis.

Tuberculin Treatment. By Clive Riviere, M.D., F.R.C.P., and Egbert Morland, M.B., B.Sc., M.D. Second Edition. Price $2.00. London: Henry Frowde and Hodder & Stroughton; New York: Oxford University Press, 1913.

In the interesting introduction to this volume the authors give the history of tuberculin in England, and although they call it strange and eventful, to the mind of the reviewer it does not differ from the history of tuberculin in the United States and in other countries. At first, over-enthusiasm, then entire abandonment by most phthisiotherapeutists and internists in general, and then a gradual taking up of the culture product as a therapeutic means, but in much smaller doses. Wright's discovery of the opsonic index seems to have given tuberculin therapy, particularly in England, a great impetus.

In Part I the authors discuss the general lines of tuberculin administration and give a very interesting subchapter on the relation of tuberculin to anaphylaxis. The many tuberculin preparations are a little bewildering. The authors do not commit themselves as to their choice, but very pertinently say "All the better known tubreculins have led to good results in various hands, and this is the true significance of the number of preparations on the market and not the deduction of Sobotta that "the actual specific preparation has not yet been discovered."

Part II of the volume deals with the immunization method as a curative procedure, that is to say, immunization by means of tuberculin given in increasing doses with a view to producing tuberculin tolerance. The authors claim this to be the treatment particularly indicated in the large majority of pulmonary cases in adults of the type in which the tubercle products are poured into the general circulation.

The last chapter speaks of the immunization without tolerance, as particularly indicated in localized tuberculosis. This chapter closes with a refreshing note of warning not to neglect the auxiliary treatment: "Tuberculin is no passive immunizer to neutralize the poisons of disease. Its action presupposes a power of response on the part of the body; it is a stimulus to the defensive mechanism, a call for active effort on the part of the tissues. Consequently no measures must be neglected which may help to put the body in the best possible condition to respond to this call."

The book on the whole is up-to-date. It deserves the most careful perusal by the tuberculosis specialist as well as the general internist and the surgeon called upon to treat local tuberculosis.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; Assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia, June 1, 1913. Price $6 per annum. Philadelphia and New York: Lea & Febiger, 1913.

The present number of "Progressive Medicine" contains five contributions. The article on Hernia is supplied by W. B. Coley; that on Surgery of the abdomen, exclusive of hernia, by J. C. A. Gerster; that on Gynecology by J. G. Clark; that on Diseases of the blood, diathetic, and metabolic diseases, diseases of the thyroid gland, nutrition, and the lymphatic system, by A. Stengel; and that on Ophthalmology, by E. Jackson. As usual, all of the contributions are of a high order of merit; and it is hardly necessary to do more than mention the appearance of the June number of this publication.

Acute Abdominal Diseases, Including Abdominal Injuries and the Complications of External Hernia. By Joseph E. Adams, M.B., M.S. Lond., F.R.C.S. Eng.; Senior Assistant Surgeon, East London Hospital for Children; Hunterian Professor, Royal College of Surgeons of England; Demonstrator of Anatomy, St. Thomas's Hospital Medical School; and Maurice A. Cassidy, M.A., M.D., B.C. Cantab., F.R.C.P. Lond.; Physician with Charge of Out-Patients, St. Thomas's Hospital; Honorary Physician, The Putney Hospital. Price $4.50 net. New York: William Wood & Company, 1913.

The real and fundamental unity of surgery and medicine is recognized in the joint authorship of this book. A surgeon and an internist here cooperate, just as they do in everyday practice. They aim "to discuss, compare and contrast all the various acute diseases and injuries to which the abdomen and its contents are liable, treating these conditions from the point of view of both physician and surgeon." This volume is unique in its plan and in the comprehensive and thorough manner in which the entire range of acute abdominal disorders is dealt with. The first chapter comprises a review of the essentially surgical features of the anatomy of the abdomen. In the next chapter are detailed the various steps in the investigation of acute abdominal cases. The significance of the various symptoms is clearly described. This chapter contains a number of admirable illustrations, such as one showing the areas of referred visceral pain, and the series portraying various forms of peristalsis. Chapter III describes the technique of laparotomy and its postoperative management. The authors believe that morphine has no place in the treatment of peritonitis and that this drug should be given in other acute abdominal lesions only when the decision to operate has already been reached or when one is certain that operation will not be required. The next chapter discusses the acute diseases of the peritoneum and omentum, such subjects being included as pneumococcal and gonococcal peritonitis, subhepatic, subphrenic, perirenal and perisplenic abscesses, acute pericolitis, abscess of the lesser sac, perigastric abscess, and diseases of the omentum, such as torsion and epiploitis. A most exhaustive and lucid exposition of the subject of intestinal obstruction is given in the one hundred pages which comprise Chapter V. Fourteen varieties of intestinal obstruction are described in detail. The next chapter deals with the stomach and duodenum. The large and small intestine form the heading of Chapter VII. Here are discovered intestinal diverticula, the various forms of colitis and enteritis, uremic ulceration, intestinal neuroses, idiopathic dilatation of the colon, and perforation of typhoid ulcers. Chapter VIII consists of full presentation of the subject of appendicitis. Of particular interest and value is the careful and exhaustive manner in which the differential diagnosis of this condition, on the one hand, and of a host of other acute abdominal diseases, on the other hand, is dealt with. The succeeding chapters discuss the liver and bile passages, the pancreas, the spleen and kidneys, the female genitalia, the vascular abdominal diseases, the complications of external hernia, abdominal injuries, and diseases which may simulate acute abdominal lesions. The careful perusal of the last chapter will repay every practitioner, who may be saved from some of the pitfalls of diagnosis that are of daily occurrence. Indeed, one may state without reserve that this book will be of inestimable value to the general practitioner no less than to the surgeon; in fact, more so, for it is the general practitioner who is the first to see the case of acute abdominal disease, and whose good judgment and prompt action are of such vital importance to the patient. The authors are to be commended for their profound knowledge of the subjects about which they write, and for their excellent literary style. Of particular value are the brief case reports which bring many of the topics concretely before the reader's eye. The excellent typography, paper, and binding are fully in keeping with the importance of this work.

John Barleycorn. By Jack London, Author of "The Call of the Wild," "The Abysmal Brute." "Smoke Bellew." "The Night-Born," etc. Illustrated by H. T. Dunn. Price $1.30 net. New York: The Century Company, 1913.

This is a remarkable human document. It is the autobiography of one, who, hating the taste of alcohol, nevertheless acquired a craving for it in a long battle with this insidious foe extending over a period of twenty years. It mirrors the adventurous life history of the author, who as newsboy, oyster-pirate, sailor, factory hand, coal-heaver, high-school and university student, newspaper and magazine writer, and finally as the successful novelist, was under the domination of "John Barleycorn," the lure of alcohol in its myriad phases. When no more than fifteen he learned the social attraction of the saloon, the clubroom of the workingman. It was only after the lapse of many years that John Barleycorn appeared to him in another light. He no longer drank for bravado or for camaraderie. He drank for the "kick" which alcohol gave him, for the mental stimulation which it produced, for its power to unlock the reserve forces of mind and body. The heroic part of the author's career came when in three years of intense study, with the robbing of sleep, he was transformed from the sailor with a common school education to the successful writer, who was publishing stories in the *Atlantic Monthly*. The author makes an eloquent plea for the control of the saloon evil, for it is this that makes alcohol so readily accessible, and because of its social associations, so alluring to the youth of the land. It is for the sake of them that he would control the sale of alcohol, just as the sale of strychnine is controlled, and just as China is stopping the traffic in opium. He has written a powerful indictment of alcohol, powerful because it is a personal confession, a penetrating insight into the physiological and psychological aspects of alcoholic indulgence, made by one whose miraculous physique and mental equipment enabled him to survive the onslaughts of, and adequately to size up, his foe. He would still continue to drink, however, "more skilfully, more discreetly, than ever before." He is therefore, not a prohibitionist, but an advocate of temperance.

Diseases of the Ear. By Philip D. Kerrison, M.D. Price $5.00. Philadelphia and London: J. B. Lippincott Company, 1913.

This new text-book comes as a significant addition to the notable advances in otology, crowded into the last decade. There are twenty-five chapters and three hundred and thirty-three, chiefly original illustrations. The first three chapters cover the anatomy and physiology of the sound-conducting apparatus; physical examination of the patient and functional examination of the Cocklear apparatus, with hearing tests, air conduction, and bone conduction of sound. Chapters on diseases of the external ear immediately follow. The most important features of the book, in the reviewer's estimation, are the chapters on the anatomy and physiology of the labyrinth. The chapters on the suppurative affections, eight in number, form the chief feature of the work: they will be read with retentive interest by the student of physiological acoustics, as also by the aural and general surgeon. There are two chapters on salvarsan and serumtherapy in aural disease, and others on dental lesions, deaf-mutism, and adenoids. It is very evident that aural surgery is no longer confined to the tympanum and mastoid, but includes the domain of the cochlea, labyrinth, and intracranium.

One excellent feature of the book is the plan of illustrating successive steps of important operations. The author has a clear, convincing, if also argumentative, style of writing which makes his methods easy to follow, quick to grasp. The reviewer notices very few references to the pioneers in aural work—Politzer of Vienna, Lucæ of Berlin, and Blake of Boston, while Gruber of Vienna and Roosa and Buck of New York are not mentioned.

Diseases of the Stomach Including Dietetic and Medicinal Treatment. By George Roe Lockwood, M.D., Professor of Clinical Medicine in the Columbia University; Attending Physician to Bellevue Hospital, New York. Illustrated with 126 engravings and 15 plates. Price $5.50. Philadelphia and New York: Lea & Febiger, 1913.

This is a very complete work on diseases of the stomach, and is based almost entirely on the author's personal experience. This gives to the volume a value and an individuality which will be much appreciated by the practitioner. Where the author's views and experience are at variance with those of other writers the fact is duly noted, full discussion of opposing opinions is given, but no attempt is made to reconcile contrary theories and figures. Throughout the book the reader is struck with the author's honesty of purpose, and a perusal of the various chapters confirms the conviction that to this volume the physician can safely turn for advice and guidance on any point in connection with diseases of the stomach. The subjects discussed are: Acute gastritis; chronic gastritis; cirrhosis of the stomach; acute and chronic ulcer; erosions and rare ulcers; cancer; sarcoma; benign tumors and foreign bodies; tuberculosis and syphilis; atony; acute dilatation; pyloric spasm and pyloric stenosis; congenital pyloric stenosis; hour-glass stomach; diaphragmatic hernia; eventration; volvulus; gastroptosis; hyperacidity; achylia; hypersecretion; neuroses, and various diseases and their gastric relations.

Hygiene and Sanitation. A Text-Book for Nurses. By George M. Price, M.D., Author of "A Hand-Book on Sanitation," "Tenement House Inspection," "Epitome of Hygiene and Public Health." Director Joint Board of Sanitary Control, Director of Investigation, New York State Factory Commission. Price $1.50 net. Philadelphia and New York: Lea & Febiger, 1913.

The author of this little book has performed a useful task in a most satisfactory manner. Most of the books on hygiene, written for nurses, try to cover too much ground, and at the same time leave some of the essentials untouched or insufficiently explained. This work avoids these faults, and should prove of value not only to nurses but also to the average lay reader. The book is well printed and handsomely bound.

A Text-Book of Midwifery for Students and Practitioners. By R. W. Johnstone, M.A., M.D., F.R.C.S., M.R.C.P.E., Assistant to the Professor of Midwifery in the University of Edinburgh; Physician Accoucheur, New Town Dispensary; Extern Assistant Physician, Royal Maternity Hospital; University Clinical Tutor in Gynecology, Royal Infirmary; Gynecologist, Livingstone Dispensary; Fellow of the Obstetrical Society of Edinburgh. Contains 264 illustrations. Price $3.25 net. New York: The MacMillan Company, 1913.

This is a small but very complete text-book of obstetrics. It is evidently intended for the junior student, and it certainly is an admirable introduction to the subject. It is concise, practical, fairly complete, and should be a popular book with medical students. The first section is on Anatomy and physiology; the second, on Physiology of pregnancy; the third, on Labor in the various presentations; the fourth, on Physiology of the puerperium; the fifth, on Pathology of pregnancy; the sixth, on Pathology of labor; the seventh, on Pathology of the puerperium; and the eighth on Operative obstetrics. There are numerous illustrations, most of them original, and all of value. The book gives the impression of being the work of one who is not only a master of his subject but also a practical teacher who knows what the student wants and knows also how to supply that want.

The Reduction of Domestic Flies. By Edward Halford Ross, M.R.C.S. England, L.R.C.P. London; of the John Howard McFadden Researches, the Lister Institute of Preventive Medicine, London; late of the Liverpool School of Tropical Medicine; and Sometime Health Officer, Port Said, the Suez Canal District, and Cairo; Author of "The Reduction of Domestic Mosquitoes," "The Prevention of Fever on the Suez Canal." With Illustrations. Philadelphia: J. B. Lippincott Company, 1913.

This is a timely little volume on an important subject, and there are few households in which the information contained herein will not be welcome. There is no longer any doubt about the possibility of these insects being directly concerned in the spread of certain diseases; and the prevention of disease and discomfort appeals to all. The practical conclusions reached by the author are, that Fly-reduction (1) means a saving of life and therefore of money; (2) reduces sickness, sorrow, and misery; (3) results in the riddance of a pest; (4) entails better sanitary inspection; (5) improves our knowledge of certain diseases; (6) and all this can be done at a small cost. The book is well printed in large type, and is amply illustrated.

Collected Papers by the Staff of St. Mary's Hospital, Mayo Clinic, 1912. Philadelphia and London: W. B. Saunders Co., 1913.

This is the sixth volume by the staff of the Mayo clinic, and contains articles written and presented for publication to the various medical journals during the year 1912. Almost all fields of surgery are touched upon and the most modern theories and technique discussed. There are fourteen papers on the alimentary canal, including ones on gastric ulcer, jejunostomy and radical operation for carcinoma of the rectum, three papers on hernia, 15 on urogenital organs, 10 on ductless glands, 7 on the head, spinal column, thorax and extremities, besides miscellaneous papers on technique and general subjects. The topics range from laboratory investigations such as the glycyltryptophan splitting agent in human saliva, to practical surgery such as involvement of regional lymph glands in carcinoma of the stomach.

Several well illustrated articles are written by William J. Mayo, including jejunostomy, the operative results in carcinoma of the gastrointestinal tract, radical operation for carcinoma of the rectum, prolapse of the uterus and walls of the vagina, nephrectomy without drainage, etc. Papers are also written by Chas. S. Mayo on surgery of single and horseshoe kidney, surgical importance of the thymus, posterior gastrojejunostomy, etc.

The book is well illustrated, excellent references to literature are appended to almost all articles and the publication is one the surgeon cannot afford not to read.

Massage, Manual Treatment, Remedial Movements, History, Mode of Application, and Effects; Indications and Counter Indications. By Douglas Graham, M.D., Consultant and Instructor in Massage, Boston, Mass.; Member of the American Association for the Advancement of Sciences of the American Medical Association, the Massachusetts Medical Society, etc.; with a Chapter on the Massage of the Eye by Dr. A. Darier, Paris, formerly President of the Ophthalmological Society of Paris, Chevalier of the Legion of Honor, etc. Fourth Edition, Revised and Enlarged, with 75 Illustrations. Philadelphia and London: J. B. Lippincott Co., 1913.

This book is largely a record of the experiences of the author, combined with that of the best writers and practitioners of massage both here and abroad. It partakes of the nature of a text-book and a reference book at one and the same time. There are forty interesting pages on the history of massage. The book is written from the standpoint of the physician and practical masseur.

Its range of usefulness is increasing all the time and has long since extended into every special and general branch of medicine. The effects of massage in fractures and upon the opsonic index are surprising. The chapters deal in a bright and spirited manner with the mode of applying massage, its physiological effects on the skin, muscles, circulation; influence of baths, massage and exercise on the blood pressure; effects of massage on the number and hemoglobin content of the R. B. C. on the flow of lymph, upon the secretions of the glands, upon the nervous system; massage of in neurasthenia and anemia of women, local massage for local neurasthenia, massage of internal organs, uterus, and surroundings, with report of 239 cases; relative value of massage, exercise, and baths in the treatment of heart affections; effects of massage on internal organs, upon simple chronic hyperemia of the liver, upon atony of the stomach and intestines, in chronic diarrhea, etc.; massage in the affections of the central nervous system, massage and movements in hemiplegia in infantile paralysis; in locomotor ataxia in progressive muscular atrophy, in chorea, risks of massage in diseases of the central nervous system, etc.; massage in Raynaud's disease, angina pectoris and arteriosclerosis; massage in writers' cramp and allied affections; in lateral curvature of the spine, flat foot; treatment of spring and synovitis by massage with report of over 1900 cases, recovery in one-third of the usual time in other methods of treatment. There are various chapters dealing with many phases of this interesting subject.

Le Mal de Tête, Les différentes formes, Nature, Diagnostic et Traitement par le Docteur Siegmund Auerbach. Traduction française par le Dr. A. Françon, d'Aix-les-Bains. Price 3.50 fr. Paris: Vigot Frères, 1913.

Of original ideas the result of clinical experience of Dr. Auerbach, this book is claimed to have profited by translation. After a short treatise on the anatomy of the brain there follow successively studies of migraine, rheumatic headache, etc. Chronic intoxications and constitutional diseases are given their place in the discussions.

Vaccine and Serum Therapy, Including also a Study of Infections, Theories of Immunity, Specific Diagnosis and Chemotherapy. By Edwin Henry Schorer, B.S., M.D., Dr.P.H., Assistant Rockefeller Institute for Medical Research, New York City. Second Revised Edition. Price $3.00. St. Louis: C. V. Mosby Company, 1913.

The first edition of this work was published four years ago and in that time the necessity for revision has been so great that the book has been practically rewritten for its second edition. In its present form it is a very complete and exhaustive work. There is a clear discussion of the principles of immunity and a very complete chapter on specific diagnosis. The section of specific therapy is naturally the main portion of the book and in it the author does not hesitate to say exactly what he thinks. The reader is warned against the reckless use of various proprietary preparations and the author's views are sane and rational. A brief appendix presents the subject of chemotherapy in syphilis and malaria. It is quite surprising to see his statement that "a mother free from syphilis on bearing a syphilitic child becomes immune." In view of present diagnostic methods it is more probable that she is also infected. The press work is excellent. The book can be highly recommended.

Society Reports.

MEDICAL ASSOCIATION OF THE SOUTHWEST.

Eighth Annual Meeting, Held at Kansas City, Mo., October 7 and 8, 1913.

THE PRESIDENT, DR. W. T. WOOTON, HOT SPRINGS, ARK., IN THE CHAIR.

Prophylaxis of Syphilis and Professional Ethics.—DR. ALFRED SCHALEK of Omaha said that syphilis must be attacked in two directions: in its relation to society and to the individual. Syphilis was contracted directly by sexual contact and indirectly through a virus carrier. Sexual functions were indulged in legitimately in marriage and promiscuously outside of it. Prostitution contributed the greatest factor in spreading infection. It was only a question of time before every prostitute became diseased. The problem how to deal with prostitution was not solved. Official regulation had proven a failure wherever attempted. Absolute suppression was the only relief. While seemingly a Utopian dream, it was feasible with the honest co-operation of everybody concerned. It could not be achieved by the closing of the bawdy houses alone. It necessitated measures to stop all other sources leading to prostitution, such as strict enforcement of the white slavery laws, and the protection of the poor. When the time came that syphilis was looked upon only as a pathological condition, in no way different from others, when its stigma of disrepute had been removed, when our therapy would destroy the microorganisms and eliminate their toxins and not only secure a symptomatic but a real cure, our ambition to make syphilis a disease of the past would be realized.

DR. WILLIAM FRICK of Kansas City, Mo., emphasized the fact that a great many cases of syphilis were innocently contracted. He recalled the case of a young woman, who developed a chancre on the upper lip. How it occurred was a mystery for some time. It was finally learned that she was having her teeth repaired, but this particular dentist was not clean about his instruments, and during the time of repair of the teeth injury was done to the upper lip, and in about the proper length of time a chancre developed. She had a secondary eruption, not knowing what it was. This was one phase of the subject that deserved great stress. He had seen quite a number of such cases.

Dr. J. D. KERNODLE of Boyle, Okla., believed ignorance was at the bottom of the trouble. There was not a boy or girl who did not know right from wrong, but they did not know the tremendous consequences following a wrong. They needed education along these lines.

Dr. E. H. MARTIN of Hot Springs, Ark., said if every house of prostitution was raided and the inmates all treated regardless of symptoms, there would be less danger than now. If we admitted we could cure syphilis, we would admit that the best method was prophylaxis. He stood almost alone in believing from observation and practical experience that salvarsan would cure syphilis. He had had more than fourteen cases of reinfection after having treated cases with salvarsan. He had one patient who had had three primary lesions in eighteen months. His method was to give one dose of salvarsan in proportion to the patient's weight every week until there was absolutely no reaction from the dose. In the secondary stage, after the chancre colony was broken up, and the organisms were expelled, after the chancre had softened, the average number of doses was three, given ten days apart.

Dr. R. H. T. MANN of Texarkana, Tex., asked if it was possible to eradicate syphilis from America. It was, and that such a thing could be done and done only when the medical profession awakened to its full responsibility and got the assistance of various communities and state governments. Whether this task could be performed in this generation, or whether it would fall upon future generations to drive syphilis out of America, depended wholly upon the activities of the physicians now living, but it was a task that could be accomplished. The medical profession owed it to humanity to eradicate syphilis from this country.

Dr. E. G. MARK of Kansas City, Mo., stated that in the prevention of venereal disease we must take the stand as physicians that prostitution could not be eradicated. It was the oldest profession in the world. You could not eradicate it, but you could segregate and control it. It had been brought to our attention in the last few weeks that Minneapolis, Chicago and other cities had eradicated prostitution, but the facts were it was not so. With proper segregation, proper inspection, venereal diseases could almost be eradicated; but prostitution could never be suppressed.

Dr. ROSS GROSSHART of Tulsa, Okla., said that in doing away with the segregation of prostitutes these were driven into various districts and were living in the midst of respectable people. Venereal diseases and their dangers should be taught to the pupils of high schools, and when this was done sexual evils would be lessened and much done toward the wiping out of syphilis.

Dr. SCHALEK, in closing, said he did not agree with Dr. Mark regarding the suppression of prostitution. Fifteen years ago he read a paper in which he stated that the suppression of prostitution was impossible, but he did not believe it now. He believed it was possible to wipe out prostitution. Most women were driven to prostitution; others wanted to lead a lazy life; they wanted to enjoy luxury, but these were few in number as compared with those who were driven to it for money.

The Operative Treatment of Glaucoma.—DR. R. H. T. MANN of Texarkana, Tex., said that the conjunctival flap should be made large. Care should be taken not to let the trephine enter the eye too far back. Should the piece which had been removed with the trephine fall into the anterior chamber, this could either be removed or left in the anterior chamber, as it did no harm when it was left in the anterior chamber. It seemed with a permanent opening in the eye, that infection might take place, but so far as the records went there was no danger of this. He did not believe that any one of the operations for glaucoma would be the operation permanently adopted for the cure of chronic glaucoma. He felt sure, however, that the operation finally adopted would be an operation which produced a filtering cicatrix, and until a better operation was devised, the Elliott operation should be the one adopted in chronic glaucoma.

Dr. C. L. WILLIAMS of Topeka, Kan., said as to this trephining operation for chronic glaucoma, the consensus of opinion was in making an opening through to include a portion of the sclera and a portion of the iris, going down through the cornea and corneoscleral incision, and by a mixture of the different formations of tissues permanent drainage would be established, thus relieving tension. However, we had not sufficient data at present to know the permanent value of this operation in chronic glaucoma.

DR. J. ELLIS JENNINGS of St. Louis, Mo., said he had had a set of these trephines sent to him from London and had done four or five of these operations recently. He had had one case of late of a very rapidly advancing chronic glaucoma in which he did the LeGrange operation and removed quite a bit of the sclera, and that case had turned out beautifully. He had to use eserin in that eye for several months, but since that time no eserin had been used. The tension was fine and the sight had improved. This trephining operation was very delicate, but one from which we could hope for very beneficial results.

Dr. JOSEPH S. LICHTENBERG of Kansas City, Mo., said glaucoma was not a disease, but a symptom, and since we did not know what glaucoma was, all this work was, more or less, done from the standpoint of treatment of the symptoms, and not from a clinical point of view. The operation of trephining was simple and efficacious.

Tumor of the Nasopharnyx.—Dr. C. L. WILLIAMS of Topeka, Kan., said the points of interest he desired to emphasize were: 1—Persistent growth in the nasopharnyx, with a tendency to occur when removed. 2—Frequent hemorrhages difficult to control and threatening the life of the patient. 3—The difficulty in arriving at the true pathology of this tumor.

Dr. JOSEPH C. BECK of Chicago, Ill., said the tumor was undoubtedly a small spindle cell sarcoma. These growths arose from the posterior naris in the region of the ostium tubæ and extended to the postnasal space and also into the nose. The literature was teeming with reports of these cases, so there was nothing to be said in regard to that. The method of removal of these tumors was that of Pynchon, of Chicago. When the doctor removed the adenoids, if he had made an examination it would have shown the sarcomatous nature of the tumor.

Dr. W. T. BLACK of St. Louis, Mo., said it looked very much like a small spindle cell sarcoma. The fact that the doctor was able to shell it out so easily was another indication that it was a sarcoma. We knew that fibroma of the nasopharynx was a difficult tumor to remove.

Dr. R. H. T. MANN of Texarkana, Tex., said that a good many years ago he operated on five or six of these tumors in one year. One tumor was a very large fibroma. If one knew he was going to have a severe hemorrhage, it

was best to ligate the external carotid artery on the side on which the tumor was situated. If this was done before the operation, one would have little or no trouble from hemorrhage.

Dr. M. F. Jarrett of Fort Scott, Kan., said he had one of these cases at his office the day before; he had been treating the patient for three or four months. It was probably six months since he removed the last adenoid tissue. He did not examine the tissue under the microscope, but supposed it was the adenoid tissue. The patient was 35 years of age. The growth had returned slowly. The slowness of the growth led him to think it was malignant.

The Complete Removal of the Tonsil in Its Capsule (Sluder Method) by Means of a New Tonsillotome.—Dr. J. Ellis Jennings of St. Louis, Mo., said that Sluder had described a method of removing the tonsil in its capsule complete by means of the guillotine or tonsillotome. The essential and distinctive feature of this method was removing the tonsil completely out of its normal bed and upwards onto the eminence of the lower jaw produced by the last molar tooth, and the utilization of this prominence in putting the tonsil through the aperture of the guillotine. For this operation a tonsillotome of great strength and leverage power was essential. Dr. Sluder used a Mackenzie guillotine which he had modified by doubling the thickness of the shaft, shortening its length and making the handle longer. The blade was driven home by pressure with the thumb. He had resigned an instrument for this operation with a ring knife to cut on the pull. The instruments necessary for the operation were the tonsillotome, the mouth gag, tongue depressor, several sponge forceps, and tonsil hemostat.

The Tonsil, with Especial Reference to the Sluder-Ballenger Operation.—Dr. Eugene Dixon of Oklahoma City, said the Sluder-Ballenger operation could be done with either local or general anesthesia; personally he preferred the latter, and would only mention the local in a way of warning against the too concentrated adrenalin solution, as many sudden deaths were being reported from tonsillectomies by its use, but it was safe with the weaker solution and just as effective in controlling hemorrhage. In this operation above all others, it was essential to have a competent anesthetist, one who knew at all times just in what stage of anesthesia his patient was, as it was very important not to begin the operation until the patient was thoroughly anesthetized and to have given one two-hundredth grain of atropine sulphate one-half hour before the anesthetic was started. Following the Sluder method of removal of tonsils, there was less trauma, and consequently less cicatricial tissue. If one examined his cases three months after operation he would not find both pillars bound together, obliterating the sinus tonsilaris, nor would he find contractions and shortening of the muscles interfering with the action of the throat and soft palate, thus impairing the singing voice. If those who insisted upon using the angular knife and snare would follow their cases up for several months and make a record of the condition of each throat they would soon be convinced.

Surgical Treatment of Tonsillitis.—Dr. T. L. Higginbotham of Liberal, Kan., said that tonsillitis was just as much a surgical disease as was appendicitis, a carbuncle, an osteomyelitis or a blind infected eye, and should receive the same determined and energetic treatment as the conditions named, and just as early, that the dangerous complications might be prevented. Since November, 1909, he had operated upon 142 cases of tonsillitis, in all stages of inflammation from the onset to bilateral quinsy, and with the results obtained he felt perfectly free to condemn methods that were inefficient and deceptive. With the vast number of men doing the perfected enucleating operation, this method of treatment could be extended to the most remote rural districts, just as was emergency surgery in other lines.

Dr. A. E. Hertzler of Kansas City, Mo., said he had not found a general practitioner yet who was not enthusiastically in favor of removing the tonsils soon after the beginning of the disease. He had been skeptical as to the correctness of the reports regarding the sudden dropping of the temperature and rapid convalescence. It would seem that the laryngologist had been behind the general surgeon in recognizing the acute lymphatic inflammations in this region as a proposition for prompt and radical surgery. He had a number of specimens of these acute tonsils, and it was exceedingly interesting to lay them side by side with acute appendices removed in the early stages of appendicitis.

Dr. Joseph C. Beck of Chicago, Ill., said that with his tonsillotome Dr. Jennings removed, but did not cut the tonsil. In a paper he had described the method of using Mathieu's tonsillotome, and the technic did not vary one particle, so far as the use of the instrument was concerned from that described by Dr. Jennings. He did not agree with Dr. Hertzler. The anatomical structure of the tonsil was different from that of the appendix; it did not matter at what time one operated on the tonsil, but it did on the appendix.

Dr. E. M. Sevdell of Wichita, Kan., said in a few instances he had removed acutely diseased tonsils. Patients had come to him and wanted the work done at once, and he had taken the chances of removing their tonsils, but at times had felt sorry he had taken these chances for fear of Ludwig's angina developing.

Dr. D. L. Shumate of Kansas City, Mo., had operated on acute tonsillar cases when they came to him from the outside and had not seen any bad effects follow. In removing tonsils if one removed all tonsillar tissue, one would have good results no matter what method one adopted.

Dr. F. B. Tiffany of Kansas City, Mo., said he had had the privilege of studying with Lennox Browne and Morell Mackenzie many years ago, and they never hesitated to operate when the tonsils were acutely inflamed. That had been his practice and he had not seen any bad results from it.

Dr. J. F. Shelley of Elmdale, Kan., said he had been in practice for twenty years and had hesitated to remove tonsils when they were acutely inflamed and when there was slight catarrh of the mucous membrane. In removing the tonsils when they were acutely inflamed one opened the raw surfaces for infection that came from surrounding tissues, and furnished a good basis for a damage suit. He would not do it under any circumstances.

Dr. C. L. Williams of Topeka, Kan., said it had been his practice in the past two or three years to watch the effect of operating in acute tonsillitis, or when patients were getting over the attack, and he was firmly convinced that if one operated on an acute case the wound would take longer to heal and the patient would be kept away from his work longer.

Dr. William E. Jones of Oklahoma City, Okla., said that at first he had some fear in operating on acute cases of tonsillitis, but with increased experience that fear had passed away. While the symptoms in a few cases were alarming from operating on acute cases of tonsillitis, they soon subsided.

Dr. J. H. Barnes of Enid, Okla., said he had seen Sluder do the operation, and in 10 per cent. of the cases he failed in getting the tonsils out. Ten years ago, when he first described the operation, he failed in one-third of the cases in children to remove the tonsils entirely.

Dr. W. T. Black of St. Louis, Mo., said he had the pleasure of seeing Dr. Sluder operate at different times, and he removed the tonsils intact in 28 per cent. of the cases.

Dr. D. D. McHenry of Oklahoma City, Okla., had never used the Sluder method; it might be all right but he had been having success with the old methods of removing the tonsils. Any method by which one could remove all of the tonsil would be followed by success.

Surgical Constipation.—Dr. A. L. Blesh of Oklahoma City, Okla., said that aside from various stenoses, congenital or acquired, constipation had principally to do with the colon, or (to better express his meaning) the colon had most to do with constipation. Coprostasis was the *fons et origo* of a train of pathological sequences ranging from the misnamed "biliousness" to true organic nephritis and other organic degenerations which had long been treated as entities. The field of so-called idiopathic or purely functional constipation was becoming more and more circumscribed, and more and more we were coming to realize that mechanical interference was at the bottom of the condition. These mechanical causative factors frequently consisted in embryological deviations having their origin in evolutionary processes, i.e., reversions to some remote ancestral type. Many of these deviations existed without symptoms being fully compensated in one or more of the several ways. They might exist symptomless for a time and then be brought to the surface by some grave physical crisis, such as reducing illness, and especially so by labor, in which hitherto compensating elasticity of a tense abdominal wall was lost by overstretching. That compensation, when it consisted in muscular overdevelopment of the colon itself, might be lost, as was the case with any other overmuscularization of a hollow viscus.

He had anchored the colon in eight cases, with complete relief of constipation and sequences in four, partial relief in two, and no improvement in two: ileosigmoidostomy with separation of ileum was performed in five cases, of

which three were completely relieved and two were unimproved. Cecosigmoidostomy two, completely relieved two. Lane short-circuiting, severing of the ileum with implantation low in the sigmoid, in three; all were much improved, but all had had attacks due to regurgitation mentioned above. This work covered the periods comprised between the dates of November 1, 1912, to August 1, 1913.

Operative Treatment of Constipation.—Dr. W. J. Frick of Kansas City, Mo., stated that the operative treatment of constipation was indicated when some degree of organic obstruction of the intestine existed. He was not an advocate of surgical interference in this condition except after all efforts at a medical cure had failed, and the patient was threatened with a permanent invalidism. Undoubtedly there were intraabdominal and intrapelvic conditions, purely surgical in nature, which were clearly responsible for the constipation. He referred to the recently much talked of developmental bands, membranes, adhesions, etc., with the resulting kinks in the intestinal tube, tumors in the intestinal wall, tumors of other abdominal and pelvic organs, and displaced viscera, many of which might be the direct or indirect cause of constipation by inhibiting in some degrees the normal peristalsis of the gut. Such cases were clearly operative, as there was no other method of dealing successfully with the primary cause of the trouble. Concerning the bands, membranes, adhesions and kinks as described by Treves, Jonnesco, Jackson, Lane, and others, we could not yet be certain whether they were the cause or the result of constipation. According to the available evidence, it would seem that they were the cause rather than the result, since the most recent researches appeared to support the theory that they were developmental in origin rather than the result of inflammatory processes. But that they might bear neither causal nor resultant relationship to constipation was shown by the clinical experience of competent observers. Certainly much improvement followed the division of these structures in some cases; just as certainly this treatment had given not the slightest benefit in other cases. Another of the causes of constipation was the result of chronic pelvic peritonitis. He had in mind the fixation of the pelvic colon to the pelvic floor or to the rectum. Tuttle recommended in this condition division of the adhesions and, if necessary, the fixation of the pelvic colon to the abdominal wall to prevent a recurrence of the angulation of the gut. In a series of fifteen operations of this kind he declared there was no case in which bowel movements were not free and comfortable after operation. In this series the operation was not always done solely for constipation; however, all of the patients operated for no other reason than constipation were completely relieved. Some fibroids of the uterus, retrodisplacements of the uterus, and tense cysts were capable of exerting such pressure upon the pelvic colon as to cause difficult, painful, and inefficient deflection. After removal of the tumor, or correction of the displacement, these patients recovered from their constipation. Among other short-circuiting operations was one done for exclusion of the splenic flexure, that is, anastomosis between the ascending limb of the transverse colon and the descending colon. Gant successfully established an anastomosis between the pelvic colon and the rectum after a division of the adhesions and fixation of the prolapsed pelvic colon to the anterior abdominal wall had failed. Mr. Lane was very enthusiastic about the more radical operation colectomy. It was safe to say that this operation relieved all the trouble that might have existed in the colon; however, the removal of the colon was a formidable operation and was not without danger even in the hands of such a great abdominal surgeon as Mr. Lane. It was not an operation for one who had not had a large experience in abdominal surgery. It must ever be borne in mind that all short-circuiting operations of whatever type were contraindicated in cases in which the cause of the trouble lay distal to the lower portion of the pelvic colon. In such cases ileosigmoidostomy could not relieve, but on the contrary might even aggravate the trouble.

Hookworm in the Middle States.—Dr. Estill D. Holland of Hot Springs, Ark., said the treatment of hookworm was not as simple, safe or satisfactory as one might have been led to believe, but if one could start treating a patient who had had two hundred hookworms and even get half of them with each course of thymol, it would not be long before he would either be cured or else have so few remaining that they would not cause him any inconvenience—providing he didn't get a reinfection. Any physician who made more or less of a specialty of digestive troubles, as he did, or who treated digestive troubles in the course of his general practice, would find that the examination of the stools of his patients would explain a great many of his chronic cases. There was no way to diagnose a moderately severe case of hookworm except by examining the stool, and if a patient had the disease it would practically always show on such an examination.

Prolapse of the Uterus and Bladder.—Dr. J. T. Antell of Newton, Kan., stated that: (1) The old cystocele operation should be discarded. (2) Replacement of the uterus alone was not satisfactory. (3) Hysterectomy alone was worse than useless. (4) The Watkins-Wertheim operation was good and satisfactory in most cases. (5) Where there was great atrophy or disease of the uterus calling for its removal, or in most severe cases the Mayo or Montgomery operation was better. (6) Vaginectomy gave excellent results where it was not objectionable.

The High Short Incision for Cesarean Section.—Dr. H. S. Crossen of St. Louis, Mo., said the high short incision in suitable cases had two distinct advantages. First, there was less extensive handling of peritoneal surfaces—hence less peritoneal shock and less danger of infection from handling. Second, the incised uterus dropped away from the abdominal wall, thus preventing adhesion and firm fixation of the incised uterus to the abdominal wall, which had proven a serious matter in some cases operated on by the usual incision. The dropping away of the incised uterus from the abdominal wound was well shown in this case. The abdomen was everywhere resonant down to the pubic bone, showing that the uterus had entirely dropped away from the incision and that the intestines occupied all this region as in the normal condition. On deep palpation, the fundus uteri was felt in the pelvis. Of course the high incision was suitable only for clean cases, where it was permissible to open the uterus within the peritoneal cavity. When the uterus was infected, the long incision should be used so that the uterus might be turned out before being opened. Again, when there was a probability that the uterus would have to be removed, on account of a tumor or other complication, the low incision should be employed. For example, in one of his cases, the indication for the Cesarean section was a fibroid blocking the pelvis and there was a strong probability that hysterectomy would be necessary. He made the usual hysterectomy incision, opened the uterus *in situ*, delivered the child and then brought the uterus outside of the cavity. A careful examination was then made to determine if myomectomy were practicable. Finding that it was not, the uterus was at once removed by supravaginal hysterectomy. Such a case, though clean, was not suitable for the high incision. But in the majority of clean cases requiring Cesarean section, the high incision would be found decidedly advantageous.

A Study of Epilepsy Based on One Thousand Admissions to the Kansas State Hospital for Epileptics.—Dr. M. L. Perry of Parsons, Kan., said to be effective, systematic treatment should be begun early in the course of the disease and must be long continued. There were few cases in which individual treatment was so important. Every case of epilepsy presented distinctive features which had a bearing on its proper and scientific handling. A very large number of patients would show temporary improvement under a change of treatment. In all head injuries a careful examination should be made for fractures of the skull and for evidence of depressed bone or meningeal hemorrhage. Any of these conditions called for immediate operation as a prophylactic measure. All cases of Jacksonian epilepsy should be operated on if seen early. In long standing cases due to cortical irritation, and in chronic epilepsy from other causes, little might be expected from intracranial surgery. As a routine measure a search should be made for peripheral irritations to the nervous system and if any were found appropriate remedies, either surgical or medical, should be instituted for their relief. The attention should not be too strongly concentrated on merely checking the convulsive attacks, but it should be borne in mind that they were only symptoms of a general nervous disease. There was no drug which of itself would effect a cure. Of all the drugs used in the treatment of epilepsy the bromide preparations were the most effective. The bromide of sodium was the most satisfactory as a usual thing. There was no advantage to be gained by combining a number of bromides. Comparatively small doses of bromides usually yielded better results on the disease as a whole than did large ones. Bromides should never be given except in proper doses determined for the individual case and where the patient was under the frequent observation of a physician. He was convinced that most of the

disrepute into which the bromides had fallen in recent years was directly due to their indiscriminate and unscientific administration. Any form of medical treatment would be limited in its effectiveness unless reinforced by hygienic and dietetic regulations.

The Surgery of Jackson's (Jonnesco's) Membrane, Naturally a Normal Ligament, Mechanically Considered.—Dr. JOHN E. SUMMERS of Omaha, Neb., said that most of the cases he had observed where abdominal symptoms were dependent upon defective or excessive development of the bowel in a so-called Jackson membrane, were in people over thirty years of age, and in several they had been between fifty and sixty years of age. The intestinal wall lost its tone just as the bladder might lose its tone from the various causes that produced it. Therefore, two lines of procedure might be required for the relief of intestinal stasis and the accompanying symptoms—the *one* to release the bowel so as to permit of freer function, the *other* to support the bowel, thereby increasing its muscular tone. Further experience had convinced him that the so-called "white line," which he believed to be the line of fusion of the colonic peritoneum with the parietal peritoneum after the rotation of the colon had been completed, was always demonstrable whenever the pericolic membrane could be shown, and it was the line of attachment of the pericolic membrane to the parietal peritoneum. It was demonstrated by rotating the attached hollow viscus in a direction continuous with the course of the blood vessels and fibers of the membrane. He had called this "white line" the *ligamentary attachment* of the pericolic membrane to the parietal peritoneum or to the peritoneal investment of a solid viscus. Usually, when it might be deemed best to release the intestine from the investment of this ligamentary support,—the pericolic membrane,—it should be divided along its loosest line of attachment; however, greater mobility might be obtained in some instances by dividing the membrane at its base,—the "white line" when this line is short, as it frequently was in the hepatic region and in the sigmoid region, the raw space left by the division of the line in the direction with its course, could be closed by sutering at a right angle to the line of division. If the "white line" was a long one, as was sometimes the case in an extensive membrane enveloping the ascending colon, this was not practicable. When, in addition to the presence of a Jackson membrane, there was a marked ptosis of the hollow viscera, particularly the cecum and transverse colon, the membrane should not be divided, but some of the methods advocated by Coffey and Connell were indicated. He had found, however, in women, that a properly fitted, front-laced, straight front corset would relieve many of the symptoms that depended upon these ptoses, provided proper habits of life were observed.

Gastric and Duodenal Ulcer.—Dr. FRED H. CLARK of El Reno, Okla., said gastric and duodenal ulcer might be roughly considered as a circumscribed loss of tissue on the inner wall of the stomach or duodenum beginning with the mucous membranes and extending in depth through the various layers of the stomach wall. They might be roughly divided into two general classes, viz: acute and chronic. While other and more delicate classifications might be made, these would suffice for a brief paper. As to the causes bringing about this condition, much had been written by various authors, and the purpose of the writer would be to consider this subject rather as a clinical study than a theoretical one, so he would consider, first, the cause of an acute ulcer as some hypertoxicity or poisoning or some direct bruise, such as a fall, the patient striking with force over the region of the stomach, which might cause the sudden destruction of the tissues; and, secondly, as the cause of a chronic ulcer a lowered vitality of the tissues causing them to become weakened so that either they broke down or became so softened that they were digested by the ordinary processes of stomach digestion. Mention had been made recently of the fact that this condition might be expected more frequently in the Spring and Fall than at any other time of the year. Probably more than 90 per cent. of patients suffering with gastric ulcer sought the physician for relief from what they termed indigestion. This was true especially in one of the cases he cited. This was caused by the fact that one of the earliest, if *not* the earliest symptom of gastric ulcer, was a sence of fullness in the stomach after eating. Another symptom often complained of was the desire to partake of food more frequently than usual and more or less pain when the stomach was entirely empty. One writer had described this condition by saying that many of these patients when presenting themselves for examination would be found to have a cracker in their pocket, so they could have something to eat whenever they began to feel this discomfort when they described as a gnawing sensation in the stomach. The writer mentioned, said that when that condition was met with one might always make a positive diagnosis of gastric ulcer without further examination. These were the early symptoms of what was usually termed a latent ulcer and which might go on for years or which might bring on at any time a crisis which would call for heroic treatment. Hyperchlorhydria was nearly always present in this condition also. The one symptom which should always be considered serious, especially in chronic ulcer, was the presence of blood, either in the vomitus, in the water, if lavage was practiced, or in the stools, the latter could oftentimes be found only by careful microscopical examination. With the positive diagnosis at hand what should we say of the treatment? He quoted the opinion of the largest number of men, and with which he coincided, that the acute form of either gastric or duodenal ulcer called for medical treatment if we would avoid complications which might be briefly summarized as early hemorrhage so severe as to be fatal, adhesions which caused great discomfort and more or less danger; the complete closure of the pylorus from cicatrization, an abscess with a fistulous opening and cancer which seemed practically to always have, or at least in a very large majority of instances to have, an ulcer for its starting point. Surgery, if done early, offered excellent results for this condition in the large majority of cases.

Acute Nephritis in Children, with Special Reference to Etiology and Treatment.—Dr. H. M. MCCLANAHAN of Omaha, Neb., stated that his personal observation was based upon twenty-one cases of nephritis in children ranging in age from two to twelve years, all except one having been treated in the home. All of these cases had been under his observation within the last five years. In all but three nephritis occurred as a complication of some acute infection. Five followed scarlet fever, five as a result of grip, three an attack of tonsillitis, one within a week after diphtheria, one after chicken-pox, one in the course of a severe enterocolitis, one after measles, and one occurred in a child recovering from general furunculosis. In the other three there was no history of any preceding acute infection. He was not able to secure in any of these any evidence of suppuration in any part of the body. Two of these came to his office because of the dropsy. The other one he saw at the home, the mother calling him because she noticed a peculiar shortness of the breath. In this case he suspected a pre-existing scarlet, but found no clinical proof. It was a reasonable inference that acute nephritis was usually induced as a result of some general infection. It seemed probable, therefore, that some toxin circulating in the blood acted as the exciting cause. Of the twenty-one cases, three had died; eighteen recovered; two died with uremic symptoms, and the other one apparently from heart failure.

Pseudomembranous Angina of the Nose and Throat.—Dr. HUGH B. CAFFEY of Pittsburgh, Kan., stated that (1) pseudo-membranous angina or Vincent's angina affecting the nose and throat resulted from an infection with the fusiform bacillus, developed a membrane, and presented clinical symptoms resembling those of diphtheria which could be positively diagnosticated only by the microscropic examination of a smear taken from the seat of the disease. (2) The ordinary cultural tests would always fail to show the fusiform bacilli, hence the necessity of examining the fresh smear taken from the patient's nose or throat. (3) The disease was not limited to the tonsils and mouth, but might affect the nose independently of any other infection.

The Use of Pig Skin in Extensive Grafts.—Dr. C. S. VENABLE of San Antonio, Tex., pointed out the value of pig skin for grafts where large surfaces were to be covered. A young pig from two to six months old was selected, as at about that time the tissues were at their heighth of cell metabolism; and etherized. The site from which the grafts were to be taken, preferably the rump, was shaved and cleansed with soap and water, using friction with a rag, instead of a brush, as this did not contuse the epidermis. Strong antiseptics were to be avoided, as their use interfered with cell growth and in their stead he sponged the area with gasolene, and finally with 50 per cent. alcohol, or a 1-2000 solution of bichloride of mercury; none of these coagulated albumin, which was the reason for their selection. The field was now surrounded by sterile drapery, maintaining the same surgical cleanliness as though a laparatomy were to be done. To remove the graft the skin was put on the stretch with hooks or clamps in the direction in which it was to be slided, and with a thin bladed razor folded on its handle by a sawing movement, strips of epidermis were cut of

the desired length and width after the manner of Thiersch. These strips were now carried on the blade to the area to be grafted and transferred by holding two fixed points with needles to the denuded area while gently withdrawing the blade which left the graft evenly spread, when any irregularities were teased out with the needles, avoiding at all times touching the graft with the fingers or handling in any way. When sufficient grafts had been applied the rubber impregnated open mesh of Davis or a freshly prepared parafin mesh was placed over them and held by adhesive beyond the edges and by multiple interrupted sutures throughout the area. This was covered with a simple dry gauze dressing, which was to be changed as often as soiled by excreted fluids. If this dressing was only four to six thicknesses of gauze it would be found that the excretions were less and the area remained dry better than should a heavier dressing be applied which more effectually excluded free access of air. About the third to the sixth day the sloughing superficial epidermis was to be gently clipped away and the area exposed to the sun for half an hour or so two or three times daily. The mesh splint was removed in ten or twelve days, and thereafter the site freely exposed for as much of the time as practical. The superficial layers of squamous epithelium were going to die and slough as in any graft, so one should not be discouraged at about the fifth to the eighth day when disappointment seemed certain, as in a few more days this would change to first a creamy white surface and then a healthy pink, and it would be found that the grafts had taken. He would mention here, lest one be deterred through fear of the patient becoming part swine, that this was not a source of such acquirement; the pigment soon disappeared and no bristles were grown, as the grafts were cut above the hair follicles. However, should such an unforseen catastrophe as the advent of bristles obtain, the prognosis even then was good, as the follicles would atrophy in a very short time. He had practised this method as one of election since 1905, and had found that he was able to attain from 85 to 100 per cent. of takes as against 50 to 75 per cent. of takes by using heterografts or other zoo-grafts.

The Preparation of Surgical Patients and Operating Room Technique.—Dr. Merrill K. Lindsay of Topeka, Kan., stated that on the morning of operation tea or coffee or wine and water might be given not later than two hours prior to the anesthetic, unless the upper alimentary tract was the field of operation. Cathartics should be dispensed with two days before operation. The reason for this is that the bacterial content of the bowel was increased in direct proportion to the fluid nature of the contents and the absorption was increased by removal of the protecting mucus. Lavage of the lower bowel with either warm water or soapsuds, or if this was not sufficient, soapsuds and glycerine or soapsuds and turpentine (soapsuds 8, turpentine 2) would remove the contents. This could be given on the evening preceding and the morning of operation. Stirring in the white of an egg with the turpentine before mixing would prevent separation of the oil. Every patient should be thoroughly bathed with warm water and soap the night before and the skin in the region of the operation shaved. The ease of removing the hair with a depilatory was evident after using, and the following formula might be found useful: Powdered calcium oxide, 10 grams; sodium sulphide, 3 grams; starch 10 grams. Mix and add water to make a thin paste and apply for five minutes. Wash off with water. Adjacent mucous surfaces should be protected with oil before applying the paste. The skin should next be washed thoroughly with soap and water, the water and other fluids being poured, not dipped. The soap was then washed off with sterile water and the parts sponged with Stewart's and Harrington's solution. The bladder should be empty in all cases before going to the operating room. The operating room should be gone over with warm water and soap, every piece of furniture washed, special care given to the removal of dirt from overhead fixtures, and the room tightly closed from dust. The operator and his assistants should appear in the wash room in freshly laundered garments and after preparing the hands and arms in one of the approved ways should present themselves to the nurse, who supplied them with a fresh sterile towel and then with gown and gloves. The application of tincture of iodine over the site of operation was not interfered with by the preparation mentioned.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. S. S. Glassock, Kansas City, Kan.; *Vice-President from the State of Missouri*, Dr. J. D. Griffith, Kansas City; *Vice-President from the State of Texas*, Dr. J. E. Dawson, Vernon; *Vice-President from the State of Arkansas*, Dr. L. R. Ellis, Hot Springs; *Secretary-Treasurer*, Dr. F. H. Clark, El Reno, Okla.

Galveston, Tex., was selected as the place for holding the next meeting.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held October 3, 1913.

Dr. Clarence A. McWilliams, Chairman pro tem.

Spina Bifida.—Dr. Joseph P. Hoguet read this paper in which he spoke of the comparative rarity of this condition, and the small experience that individual operators had in it on that account. He said that its etiology was unknown; the theory that an intrauterine hydrocephalus was responsible for it was not probable. The embryology of the condition was then spoken of so that the pathology might be better understood. The four varieties under consideration were: 1. Meningocele. Here there was a defect in the posterior osseous wall with a hernia of the dura with possibly the arachnoid. 2. Spina bifida occulta, really a variety of meningocele, with a cleft in the neural arch, which might be closed with a dense fibrous membrane, with no bulging of the external skin. The only external sign generally being hypertrichosis. 3. Syringo-myelocele, where there was a defect in the neural arch and generally in the dura, the posterior portion of the cord being thinned out by distention of the central canal. 4. Myelocele, where there was also a deficiency in the posterior portion of the cord, so that it ended directly externally, and was generally represented as a raw granulating area. This condition was incompatible with life and these children were practically always stillborn. The symptoms and physical signs were then brought out, with the means for a differential diagnosis between a meningocele and a syringo-myelocele. The different paralytic complications were then spoken of. It was generally conceded that this condition occurred most often in the lumbar and lumbosacral regions. There was a very bad outlook without operation, and spontaneous cure was rare. The inefficiency of the injection treatment was referred to, and the mortality of the open operation was put at from 20 to 30 per cent. Operation was urged in all cases, especially those with paralytic symptoms, and where nerve tissue was expected to be found in the sac. The surgical proceeding was then discussed and the writer showed a method of closing the cleft by means of a fascial flap. He reported six cases, one of which had not been operated upon; of the five operated upon, none had died as a result of the operation, although the youngest case, a baby of 16 days, had died two weeks after operation from marasmus. The paralytic complications had disappeared in one case, and had very much improved in another.

The Localization of Foreign Bodies within the Tissues, with a Description of a Method of Localization.—Dr. Alfred J. Brown read this paper, in which he stated that a review of the methods thus far described allowed them to be divided into two classes: 1. The localizing of the foreign body, if metallic, by the electric searcher, and, 2, localization by stereoscopic radiography. The electric probe was of value only in cases in which there was an open tract leading down to the foreign body. As a result the instrument was useful chiefly in gunshot wounds. Thomas made use of a telephonic searcher consisting of three needles mounted on a handle and so wired that contact of any two of the needles with a metallic object completed an electric circuit and rang a bell, the sound being transmitted to the ear of the operator through a telephone receiver. The current was turned off, the searcher left in place, and the foreign body cut down upon using the needles as a guide. Dr. Brown then described the Cole method of radiographic localization which embodied the principle of the triangulation of the planes of the shadows cast by the foreign body with the tube in two different positions. He also referred to the methods used by Brickner, Sweet, and Fürstenau. These methods left nothing to be desired in the way of theoretical accuracy, but were very exacting technically, and because of the special instruments required it was not always feasible to carry them out. Measurements were usually made from fixed bony points and this allowed for the possibility of two forms of error. The distance from the shadow cast by the bony point to that cast by the foreign body did not correspond to the distance between the actual objects in the living body. There was also the error due to the personal equation between the radiologist and the surgeon in taking the measurements. A further diffi-

culty for the surgeon was that in some of the methods there was no mark upon the surface of the body to follow at the operation, and in others there was only the small silver nitrate spot. The following method was suggested as being simple, accurate, and requiring no special apparatus beyond the usual *x*-ray outfit. A preliminary radiographic examination for the purpose of substantiating the diagnosis was made and the approximate position of the foreign body noted. The area of the skin over the foreign body and the surrounding area of a few inches was then prepared in the following manner. Vertical and horizontal lines running at right angles to each other were painted on the skin with silver nitrate solution, thus laying the skin out into squares. The size of the squares could easily be made to bear a proper relation to the size of the foreign body on the one hand and that of the part to be prepared on the other. As a rule 1 inch squares would be found very convenient. The component lines of this checker-board were numbered. The area thus painted should include one-half the circumference of the part. As an example, in the knee the first vertical line should run along the antero-internal margin of the knee and the last along the postero-external. The horizontal lines should connect the vertical. If the entire circumference was laid out in squares, the lines of one-half the circumference should be solid and those of the other half dotted. The silver solution was allowed to turn black and the skin thus stained. The lines were then painted over with white lead paint and this allowed to dry. Two radiographs were then taken, one antero-posteriorly and one laterally, the target of the tube being placed directly over the position of the foreign body as shown in the preliminary skiagraph. The resulting skiagraphs showed the shadow of the foreign body with relation to the squares painted upon the skin. By projecting imaginary lines from the shadow of the body in the two positions with relation to the overlying lines its approximate depth from the surface was easily calculated. If the entire circumference of the part had been painted, the position of the body was noted accurately by projecting the point of intersection of the shadow with the solid lines on one surface to its points of intersection with the dotted line on the opposite surface. If desired a tracing of the lines and shadows of the body might be made on a transparent paper and this tracing laid upon the skin so that the lines of the squares corresponded accurately. The shadow of the foreign body might then be marked upon the skin with silver nitrate to be used as a guide at operation. This method had been used in three instances on the First Surgical Division of Bellevue Hospital, in the services of Drs. John B. Walker and Lucius W. Hotchkiss. In each case the foreign body, a needle, had moved a considerable distance from its point of entrance and in none of the cases could it be palpated. In certain cases the position of the foreign body might be such that the painting of the part over the entire circumference would prove of value as it would allow of through and through projection of the shadow from a fixed point on one surface to a fixed point on the other.

Dr. Walter M. Brickner said that the method brought forward by him was rather crude; the triangulation method gave more definite information.

Dr. A. S. Vosburgh reported an interesting case in which he removed a bullet from the orbit, its position being estimated by *x*-ray plates. In another case he removed a bullet from the middle fossa of the skull, the opening being made as in decompression operations. In each of these cases the location of the foreign body was carefully estimated by means of the *x*-rays.

Dr. William Henry Luckett said he always obtained the exact location of a foreign body after but two pictures had been taken at right angles. Palpation should not be neglected especially when there was some foreign body, as a bullet, in the hand in the thenar or hypothenar group of muscles.

Philadelphia County Medical Society.

At a stated meeting held October 8 Dr. James Hendrie Lloyd read a paper entitled "Acute Syphilitic Infection of the Pons, Medulla and Upper Spinal Cord." He pointed out the importance of the discovery of the pallid spirochete as the causative factor in the development of syphilis and the bearing of this discovery on the pathology of various diseases of the nervous system. The finding of the spirochete in the brain in cases of general paresis and in the spinal cord in cases of tabes proves that these diseases also are syphilitic and that the terms parasyphilis and metasyphilis have lost their previous doubtful validity. At the same time explanation is wanting of the fact that in some instances it is especially the membranes and the blood-vessels of the nervous system that bear the brunt of the morbid process, while in others especially the parenchymatous elements suffer.

Dr. Francis X. Dercum presented a communication entitled "The Clinical Forms Presented by Nervous Syphilis; Significance of and Necessity for Their Differentiation." While admitting the identity of etiology with respect to so-called syphilis of the nervous system, general paresis, and tabes dorsalis, he contended that each of these affections presented individual features that differentiated them one from the other. For example, syphilis of the nervous system is amenable to antisyphilitic treatment, whether in the form of mercury or in that of arsenobenzol, while tabes and paresis respond little if at all to such measures. The one exhibits interstitial lesions through an impression exerted especially on the blood-vessels and the meninges, while the others are represented particularly by parenchymatous changes of a destructive nature. There must be some special reason why a given source of infection may give rise to a number of cases of paresis or tabes respectively, and also in explanation of cases of tabes and paresis in husband and wife. Also as between tabes and paresis, while at times there is an overlapping of symptoms each usually is distinct, with a number of differentiating features.

Dr. Milton B. Hartzell discussed "The Cutaneous Manifestations of Syphilis," illustrating his remarks by lantern demonstration. He pointed out that while it is perhaps the prevalent belief that the primary lesion is almost exclusively of genital origin, statistical investigation in many countries has shown that in a considerable proportion of cases extragenital infection takes place. He illustrated a number of unusual sites for the primary lesion, for example, the cheek and the lip, and also a number of unusual types of lesion. The primary lesion may simulate epithelioma, and there is scarcely any exanthem the cutaneous manifestations may not imitate.

Dr. Theodore H. Weisenburg exhibited a slide showing the *Spirochæta pallida* from the spinal cord of a paretic. He discussed various aspects of the subject in the light of recent discoveries.

Dr. Judson Daland discussed "The Diagnosis, Prognosis and Treatment of Syphilis." He dwelt on the utility of the Wassermann test in diagnosis, and of the globulin test, and of lymphocytosis when syphilis of the nervous system is suspected. He pointed out that while salvarsan is probably the most effective remedy in the treatment of syphilis in its various stages, it is advantageous to conjoin with its administration also that of mercury. The best mode of introducing salvarsan is through the blood-stream, while mercury is most effective when introduced by deep intramuscular injection.

Lieutenant-Commander George A. Lung, U. S. N., spoke of The Control of Venereal Diseases in the U. S. Navy."

The discussion was participated in by Dr. Jay F. Schamberg, Dr. George E. Price, Dr. Charles K. Mills, Dr. Henry W. Cattell, Dr. B. Alexander Randall, and Dr. W. Egbert Robertson.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Ohio State Medical Board.

June 2-5, 1913.

ANATOMY.

1. Locate and describe the scapula.
2. Give the course and relations of the brachial artery.
3. Give the boundaries of the fourth ventricle.
4. What structures pass through the jugular foramen?
5. Describe the urinary bladder of a male and give its relations.

PHYSIOLOGY.

1. Name the principal varieties of connective tissue, where are they found, and what purpose do they serve?
2. State the disposition of the fat principles of food after digestion; carbohydrate principles; effect of alcohol in small quantities with food.
3. What is understood by absorption?
4. Name four forces concerned in the circulation of the blood.
5. What effects do extremes of temperature have on respiration? What effect has age?
6. Describe the suprarenal capsules. What is their function?

7. What is the influence of the nervous system in the production of sweat?
8. Name the five laws of reflex action (Pfluger). How do they work?
9. Describe the process known as ovulation.
10. Describe the function of the tympanic membrane: eustachian tube.

CHEMISTRY.

1. Give properties and chemical formulæ of (*a*) carbon dioxide; (*b*) carbon monoxide.
2. Give a test for indican and state its clinical significance when found in urine.
3. Define (*a*) aldehyde; (*b*) alkaloid; (*c*) glucosid.
4. Name and differentiate the three classes of sugar.
5. What are proteins and from what are they derived?

MATERIA MEDICA AND THERAPEUTICS.

1. Briefly discuss the serum and vaccine theories.
2. Name four principal serums, give mode of administration, dose, and use of each.
3. What drugs would you use in anemic conditions? Write two prescriptions using the drugs named.
4. Mention two intestinal antiseptics. Give therapeutic use and dose of each.
5. Name three hypnotics; indicate use and dose of each.
6. State the physiological action, use, and administration of hot and cold water.
7. Name two cardiac stimulants and sedatives, and indicate dose of each.
8. Give the composition of Dover's powder. State its action, use, and dose.
9. Give the physiological action of nux vomica, name its principal alkaloid, and state its use and dose.
10. Give the range of indications for the use of galvanism and high frequency currents.

ANSWERS.

ANATOMY.

1. The *scapula* is a large, flat, triangular bone situated at the back and side of the thorax, between the second and seventh ribs. Its anterior surface contains the subscapular fossa for the subscapularis muscle. The dorsal surface is divided by the spine; above the spine is the supraspinous fossa for the supraspinatus muscle, and below it is the infraspinous fossa for the infraspinatus muscle. To the spine, the trapezius and deltoid muscles are attached. At the outer end of the spine, and overhanging the glenoid cavity is the acromion process. The superior border of the scapula has the suprascapular notch and the coracoid process. The axillary border gives attachment to the teres major and minor and triceps muscles; the vertebral border gives attachment to the rhomboideus major and minor and the levator anguli scapulæ; the biceps is attached to the apex of the glenoid cavity and to the coracoid process; to the latter are also attached the pectoralis minor and the coracobrachialis. The scapula articulates with the humerus and the clavicle.

2. *The brachial artery* is the continuation of the axillary, begins at the lower margin of the insertion of the teres major, passes down the anterior aspect of the arm, and terminates about half an inch below the bend of the elbow, where it bifurcates into the radial and ulnar arteries. It passes along the inner borders of the coracobrachialis and biceps muscles, it is superficial throughout its course, is accompanied by venæ comites, and at about its center is crossed by the median nerve, which passes from the outer to the inner side of the artery.

Relations. In front: The skin and fascia, the bicipital fascia, median basilic vein, and median nerve. *Behind:* Triceps, musculospiral nerve, superior profunda artery, coracobrachialis and brachialis anticus. *Externally:* Median nerve (above), coracobrachialis and biceps. *Internally:* Ulnar nerve, internal cutaneous nerve, median nerve (below) and basilic vein.

3. The fourth ventricle is the expanded portion of the central canal of the spinal cord; it is a diamond-shaped cavity situated between the cerebellum behind, and the posterior surface of the pons and medulla in front. It is bounded: *Above*, by the valve of Vieussens and the cerebellum. *Below* by the pons and medulla. *Laterally*, by the superior peduncles of the cerebellum, restiform bodies.

4. The *jugular foramen* transmits: The inferior petrosal sinus; lateral sinus, meningeal branches from the occipital and ascending pharyngeal arteries; and the glossopharyngeal, pneumogastric and spinal accessory nerves.

5. The *bladder* is a musculomembranous sac situated in the pelvis, behind the pubes and in front of the rectum. The superior surface is covered by peritoneum. The anterior surface is separated from the body of the pubic bone by the prevesical space of Retzius; the lower part of this surface is uncovered by peritoneum, the upper part being covered according to the degree of distention of the bladder. The lateral surfaces are covered behind and above by peritoneum. The ureters enter the bladder at the upper part of the base. The neck of the bladder is surrounded by the prostate. The trigone is a triangular smooth surface situated at the base of the bladder immediately behind the urethral orifice; it is bounded at each posterior angle by the opening of a ureter, and in front by the opening into the urethra. The lower part of the base is in relation with the rectum, seminal vesicles and vasa deferentia. The bladder is retained in its place by ten ligaments; five of these are called *true ligaments*, these are the two anterior ligaments, two lateral, and the urachus; the five false ligaments are formed by folds of the peritoneum.

PHYSIOLOGY.

1. The *principal varieties of connective tissue* are: Areolar, adipose, elastic, fibrous, retiform, lymphoid, cartilage, and bone. They all serve to connect and support other tissues. *Areolar tissue occurs* under the skin, beneath serous and mucous membranes, in glands, and ensheathing muscles, vessels, and nerves. *Adipose tissue occurs* almost everywhere in the body except in the cranium and liver. *Elastic tissue occurs* in the ligamenta subflava, vocal cords, bronchi, lungs, arteries, and some ligaments. *Fibrous tissue occurs* in ligaments, tendons, fascia, periosteum, perichondrium, dura mater, capsule of the kidney. *Retiform tissue occurs* in mucous membranes. *Lymphoid tissues occur* in lymphatic glands, the thymus, Peyer's patches, tonsils. *Cartilage occurs* in joints, at the articular ends of bones, trachea, nose, external ear, Eustachian tube, intervertebral discs.

2. *Absorption of fat.* "Fat is not absorbed as fat, but as glycerin and fatty acid or soap. It is generally accepted that the fatty acid set free in the intestine is dissolved by the bile salts, and in this way, together with the glycerin, is absorbed by the columnar cells, but that during absorption a lipase which is contained in the columnar cells re-synthesizes, by reverse action, the glycerin and fatty acid. In this way minute fat particles are found near the bases of the columnar cells, and these may be demonstrated by staining with a 1 per cent. solution of osmic acid. The fat globules are further taken up from the columnar cells by some of the lymphocytes, which are capable of exhibiting ameboid movements, and which are found in the lymphoid tissue between the columnar cells and the central lacteal. The fat is then deposited in the central lacteal by these ameboid cells, and in this way it gets into the general lacteal stream, and thence into the thoracic duct. The bile salts, which have been absorbed by the columnar cells, in all probability get into the portal vein radical, and in this way are taken back to the liver to be excreted again in the bile. After a fatty meal minute globules of fat may be demonstrated in the blood plasma of an animal; but they disappear rapidly, possibly existing in a soluble and invisible form absorbed to the blood proteins before they are deposited in the fat depots of the body."

Absorption of carbohydrate. "During digestion the greater part of the carbohydrate of the food is converted into the glucoses. These are comparatively small molecules which are readily dissolved, and easily passed through the columnar cells into the portal vein radical which lies beneath. It is possible that some maltose may be absorbed by the columnar cells, and that during its passage through those cells it is converted into dextrose before it enters the portal vein radicals. It is possible that in these columnar epithelial cells the glucose, which is being absorbed, is linked to the cell protein, and that, farther down the cells, this loosely combined substance is split into two, the dextrose passing into the portal vein radical and the protein molecule remaining intact in the columnar cells and ready to combine with fresh glucoses to be passed through the cells. A small portion of the dextrose, which is carried to the liver, goes on unchanged to the tissues to be assimilated, but the greater portion of the absorbed glucose on arriving at the liver is stored there by the liver cells as glycogen." (Lyle's *Manual of Physiology.*)

A small quantity of alcohol with the food is believed to slightly increase the digestibility of the proteids.

3. *Absorption* is the process by which the food, after it has been digested, is taken to the blood current and tissues of the body.

4. (1) The force of the contraction of the heart, (2) the

muscular coat of the arterial walls; (3) thoracic aspiration; and (4) the action of the valves in the veins.

5. A high temperature causes a diminution in the amount of oxygen consumed and carbon dioxide expired; a low temperature has the contrary effect.

6. The *suprarenal capsules* are ductless glands, situated in the back part of the abdominal cavity, behind the peritoneum, one on the upper extremity of each kidney, and extending slightly on the inner and anterior surfaces. They are generally from one to two inches in length, and weigh about a dram to a dram and a half. They consist of a cortical portion and a medullary portion.

The *function of the suprarenals* is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body.

7. *The nervous mechanism of perspiration.* "The sweat centers, one for each side, are situated in the medulla oblongata, but probably subsidiary sweat centers exist in the cord. They may be excited directly by (1) a venous state of the blood—hence the cold, clammy sweats seen in the later stages of certain diseases, as croup and pneumonia; (2) by hyperpyrexia, as when the temperature of the blood reaches 105° F. the sweating is profuse; (3) by certain drugs, such as pilocarpine, muscarine, nicotine, and ammonia salts. Atropine appears to inhibit the sweat centers. There appear to be secretory nerves which, when stimulated, increase the activity of the sweat glands. Vasomotor nerves regulate the supply of the blood to the skin; they act in connection with the secreting nerves. Sweating may be produced in the following ways: (1) By direct stimulation of the sweat centers. (2) By stimulation of the secretory nerves and vasodilator blood-vessels, as by the action of certain drugs, as pilocarpine, warmth to the surface, warm drinks, alcohol. (3) Reflexly by stimulation of certain sensory nerves. (4) By mental stimuli. (Ashby's *Notes to Physiology.)*

8. PFLÜGER'S LAWS OF REFLEX ACTION. "(1) *Law of unilaterality.*—If a feeble irritation be applied to one or more sensory nerves, movement takes place usually on one side only, and that the same side as the irritation. (2) *Law of symmetry.*—If the irritation becomes sufficiently intense, motor reaction is manifested, in addition, in corresponding muscles of the opposite side of the body. (3) *Law of intensity.*—Reflex movements are usually more intense, on the side of irritation; at times the movements of the opposite side equal them in intensity; but they are usually less pronounced. (4) *Law of radiation.*—If the excitation still continues to increase, it is propagated upward, and motor reaction takes place through centrifugal nerves coming from segments of the cord higher up. (5) *Law of generalization.*—When the irritation becomes very intense it is propagated in the medulla oblongata; motor reaction then becomes general, and it is propagated up and down the cord, so that all the muscles of the body are thrown into action, the medulla oblongata acting as a focus whence radiate all reflex movements." (Brubaker's *Physiology.*)

9. *Ovulation.* "In the process of development in the ovary, the individual Graafian follicle increases in size and gradually approaches the surface of the ovary. When fully ripe or mature, it forms a little projection on the exterior. Coincident with the increase in size, which is caused by the augmentation of its liquid contents, the external envelope of the distended vesicle becomes very thin and eventually bursts. The ovum and fluid contents of the vesicle escape on the exterior of the ovary, whence they pass into the Fallopian tube. In man and mammals ovulation apparently occurs only at certain periods." (Kirke's *Physiology.*)

10. The *function of the tympanic membrane* is to receive the vibrations of the atmosphere which are transmitted to it.

The *function of the Eustachian tube* is to equalize the air pressure on both sides of the tympanic membrane, and to aid in preventing echo.

CHEMISTRY.

1. *Carbon monoxide,* CO, is a colorless, odorless, tasteless gas, lighter than air, slightly soluble in water and in alcohol; it unites readily with oxygen to form carbon dioxide. It is very poisonous, uniting with the hemoglobin to form a stable compound which cannot carry oxygen to the tissues.

Carbon dioxide, CO_2 is a colorless, suffocating gas; it will neither burn nor support combustion; it is soluble in water; if inhaled pure it causes spasm of the glottis and death.

2. *Test for indican in the urine:* The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chloride, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.

Indicanuria is found in hypochlorhydria; in hyperchlorhydria of gastric ulcer; in conditions in which there is diminished peristalsis of the small intestines, as in ileus and peritonitis, not in simple constipation; also in conditions in which putrefactive changes occur in the body elsewhere than in the intestine, as in empyema, putrid bronchitis, gangrene of the lungs, etc. (From Witthaus's *Essentials of Chemistry.)*

3. *Aldehydes* are the first oxidation products of primary alcohols; they are intermediate between the alcohols and organic acids; they are readily converted into alcohols by reducing agents, or into acids by oxidation.

Alkaloids are, as a rule, solid bodies; contain carbon, hydrogen, nitrogen, and oxygen; have very complex constitution; react with acids to form salts in the same way that ammonia does; are of vegetable origin, as a rule; are extremely poisonous; are optically active, generally levorotatory.

Glucosides are substances which, under the influence of heat or dilute mineral acids, split up into glucose and some other substance.

4. CLASSES OF SUGARS. "(1) *Monosaccharides, or Monoses*—which do not yield any other sugar or sugars by the action upon them of dilute acids (glucose, fructose, galactose, etc.). (2) *Disaccharides, or Saccharobioses*—which, under the influence of dilute acids, take up H_2O and yield two other sugar molecules (saccharose, lactose, maltose, etc.). (3) *Trisaccharides, or Saccharotrioses*—which, under the same influences, take up $2H_2O$ and yield three other sugar molecules; and (4) *Polysaccharides*—which, under the same influence take up more than $2H_2O$, and yield more than three sugar molecules (starches, gums, celluloses, etc.). The disaccharides, trisaccharides and polysaccharides may be considered as produced by the fusion of two or more monosaccharide molecules with elimination of one or more molecules of water." (Witthaus' *Essentials of Chemistry.)*

5. *Proteins* are substances of very complex composition and of unknown constitution; they constitute the greater part of animal and vegetable tissues. They all contain carbon, hydrogen, oxygen and nitrogen; some also contain sulphur, phosphorus, iron, or some other element. They are derived from plants and animals.

MATERIA MEDICA AND THERAPEUTICS.

1. "*Serum-therapy proper* is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood-serum containing an antibody (antitoxic, bactericidal, etc.) which is specific to the particular disease. As generally used, however, the term includes also the treatment of some of these affections by vaccines and by the toxic products (toxins) of attenuated cultures of their respective microbes; but these toxins, though sometimes grown on blood-serum, may be produced on other media, and are never administered in a blood-serum, as the antibodies invariably are."

"*Bacterial Vaccines.* The term vaccine was originally applied to the infective virus or antigen of vaccinia (cowpox), but in modern usage has been extended to include the antigens of all infectious diseases. In the preparation of stock vaccines the pathogenic bacteria are grown in pure culture, then killed by heat, suspended with their toxin in sterile physiological salt solution, protected from contamination by an antiseptic, and standardized to contain a definite number of bacteria in each cubic centimeter. They are used by injection, subcutaneously or intravenously, to develop in the patient's body a condition of active immunity against the corresponding pathogenic germs or their toxins by raising the opsonic value of his blood and thereby promoting the phagocytosis of invading bacteria. The advantage of this active immunization for prophylactic purposes depends on the facts that these vaccines are incomparably cheaper and simpler to prepare than the sera, and that the active immunity conferred by them is more durable than the passive immunity produced by the latter. On the other hand their immunity does not set in immediately as is the case with the passive form, but only after 8 to 14 days of treatment." (Potter's *Therapeutics and Materia Medica.)*

2. Four serums. (1) *Antidiphtheritic serum* (against diphtheria); administered subcutaneously; dosage, average about 3,000 units, immunizing dose for a well person about 500 units. (2) *Antitetanic serum* (against tetanus); administered subcutaneously, or into the spinal subarachnoid space; dose, 10 to 20 c.c. repeated if necessary. (3) *Meningococcus serum* (against cerebrospinal meningitis); administered into the spinal canal after lumbar puncture and withdrawal of about 40 c.c. of the spinal fluid; dose about 20 or 25 c.c. (4) *Antirabic serum* (against rabies); administered subcutaneously; for about two weeks several injections are made daily with viruses of gradually increasing strength.

3. In *anemic conditions* iron, arsenic, nux vomica, and manganese are recommended.

(1) ℞.

Massæ ferri carbonatis 5ji.

Divide in pilulas no. xxx.

Signa: Take one after each meal.

(2) ℞.

Liquoris potassii arsenitis ℥j.

Signa: Take five drops in water, after each meal. Increase the dosage according to directions.

4. *Two intestinal antiseptics:* Salol, dose 5 to 20 grains; and sodium phenolsulphate, dose 5 to 20 grains. They are used to control fermentation and putrefaction in the stomach and intestines.

5. *Three important hypnotics:* (1) Chloral hydrate; dose, gr. xv to xx. (2) Sulphonal; dose, gr. xv to xxv. (3) Trional; dose, gr. xv to xxv.

Indications: They are all used to produce sleep (when no pain is present.)

Chloral hydrate produces a natural sleep, acts promptly, but is of no service if pain is present; it also lowers the body temperature. It can be given for a long time without deleterious effect, but it may irritate the tissues and weaken the heart.

Sulphonal produces a natural sleep, but is of slow action, requiring 3 or 4 hours to take effect; it is of no use if pain is present, does not irritate the tissues and weaken the heart, but is probably not so good for continuous use as chloral hydrate, though the two may replace each other for a time.

Trional is very similar to sulphonal, but is more soluble, and acts quicker. Both sulphonal and trional are supposed to be safer than chloral.

6. *Therapeutics of water:* "Cold baths are employed in the treatment of febrile diseases, more particularly typhoid fever. It is important that frictions should be maintained all the time the patient is in the water. Various modifications of the full cold bath are also employed. Ice-water baths are of great service in sunstroke or thermic fever, and cold water may be injected into the bowel when the skin is cold but the central temperature high. Large injections of cold water are also useful in dysentery. Ice bags are sometimes applied to various parts of the body for the purpose of controlling inflammatory action and also for the hemostatic effect of the cold. Warm baths are employed to soothe pain, alleviate muscular and mental fatigue, promote sleep, and relieve spasmodic conditions and internal congestion. Hot baths and the hot pack are useful in renal disease and uremia, and in commencing colds, on account of the free diaphoresis they induce. Localized hot baths aid in the same way as general ones, but are less pronounced in their effects. In various painful affections of the eye much relief may be afforded by the application of hot water on cotton pledgets frequently renewed, or by allowing the water to drop continuously on the eye. Internally water is of great service in keeping the urine diluted, and its free use tends to prevent the formation of gallstones, as well as of gravel or urinary calculi. A glass or two of water swallowed upon rising often has the effect of causing an evacuation of the bowels. Tepid water, sometimes with the addition of mustard, is very commonly used as an emetic." (Wilcox's *Materia Medica.)*

7. *Two cardiac stimulants:* Alcohol, dose 1 ounce of whiskey; aromatic spirit of ammonia, dose 30 minims.

Two cardiac sedatives: Aconite, dose 10 minims of the tincture; diluted hydrocyanic acid, dose 1 minim of a recent preparation.

8. *Dover's Powder* consists of 10 parts of ipecac, 10 parts of powdered opium, and 80 parts of sugar of milk. Dose gr. vijss. It is an expectorant, and diaphoretic; often, an early dose may avert a threatened cold; it is also of sedative action, and is useful in cases of irritative cough.

9. Nux vomica. *Official alkaloid:* Strychnine, dose gr. 1/60 of the sulphate. *Physiological action:* It excites the digestive secretions, increases the appetite, increases peristalsis, and improves the digestion; it is a vasoconstrictor, it raises blood pressure, and is a cardiac stimulant; it is also a respiratory stimulant; hearing and sight are rendered more acute. *Therapeutic indications:* As a general tonic or bitter; in indigestion, cardiac depression, impaired peristalsis, pneumonia, phthisis, amenorrhea, dysmenorrhea, impotence, some forms of paralysis, chorea, epilepsy, neuralgia, alcoholism, and urinary incontinence.

10. *"Electricity* is employed in medicine to restore functional activity to peripheral nerves and muscles when conduction has not been completely cut off by some irreparable lesion; to promote general nutrition; to arouse the nerve-centers in states of depression; to combat various sensory disturbances which are of a functional character or which depend upon minor lesions of the peripheral nerves or their centers; to effect the rapid passage of drugs through the unbroken skin (cataphoresis); to bring about the coagulation of blood in aneurysmal sacs; to favor the absorption of inflammatory or degenerative products; and in the form of the galvanocautery, to excise or destroy hypertrophied tissues or morbid growths." (Stevens' *Modern Materia Medica.)*

"General applications of high frequency currents are indicated in rheumatism, rheumatoid arthritis, gout, diabetes, anemia and general debility. Local applications are employed with success in some disease of the skin and mucous membranes—such as pruritus, psoriasis, lupus, acne, eczema, obstinate ulcers, alopecia areata, etc." *(Essentials of Medical Electricity.)*

(To be continued.)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†
Alabama*	W. H. Sanders, Montgomery	Montgomery
Arizona*	J. W. Thomas, Phoenix	Phoenix
Arkansas	F. T. Murphy, Brinkley	Little Rock . . Nov. 11

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Virginia State Board of Medical Examiners.—Of 101 applicants who took the full examiantion at the June meeting, 77 passed, 21 failed, and 3 were incomplete or withdrew. Nineteen non-graduates took the partial examination, of whom 15 passed, 2 failed, and 2 withdrew.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

INTERNATIONAL CLINICS. By Leading Members of the Medical Profession Throughout the World. Edited by HENRY W. CATTLE, A.M., M.D. Vol. III. Twenty-third Series. 1913. Cloth; price $2.00; illustrated; 303 pages. J. P. Lippincott Company, Philadelphia and London.

TRANSACTIONS OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. Vol. XXV. Twenty-fifth Session, held at Old Point Comfort, Va., December 17, 18, and 19, 1912. Edited by W. D. HAGGARD, M.D. Cloth; illustrated; 615 pages. Published by the Association.

LEHRBUCH DER HAUT UND GESCHLECHTSLEIDEN. By Dr. S. JESSNER. Vol. II, part 2. Paper; price 2 marks; illustrated. Curt Kabitzsch, Würzburg.

OUTLINES FOR CASE TAKING. By GEORGE DOCK, A.M., M.D. Cloth; price 25 cents; 44 pages. George Wahr, Ann Arbor, Mich.

PROTEIN SPLIT PRODUCTS. By VICTOR C. VAUGHAN, M.D., LL.D.; VICTOR C. VAUGHAN, Jr., M.D., A.B., and J. WALTER VAUGHAN, M.D., A.B. Cloth; illustrated; 476 pages. Lea & Febiger, Philadelphia and New York.

ESSENTIALS OF PATHOLOGICAL CHEMISTRY. By VICTOR C. MYERS, M.A., Ph.D., and MORRIS S. FINE, Ph.D. Cloth; price $1.25; illustrated; 137 pages. *The Post-Graduate Medical Journal*, New York.

DIGEST OF COMMENTS ON THE PHARMACOPOEIA OF THE UNITED STATES OF AMERICA and on the NATIONAL FORMULARY for the Calendar Year Ending December 31, 1911. By MURRAY GALT MOTTER and MARTIN I. WILBERT. Paper; 683 pages. Government Printing Office, Washington.

YEAR BOOK OF THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK. P. Brynberg Porter, A.M., M.D., Editor, June, 1913. Cloth; 176 pages.

THE MICROTOMIST'S VADE-MECUM. By ARTHUR BOLLES LEE. Seventh Edition. Price $4.00; cloth; 526 pages. P. Blakiston's Son & Company, Philadelphia.

DIE UNTERSUCHUNG DER LUFTWEGE. By Dr. P. H. GERBER. Paper; price 2 marks; illustrated; 45 pages. Curt Kabitzsch, Würzburg.

BELLEVUE AND ALLIED HOSPITALS, CITY OF NEW YORK. Eleventh Annual Report, January 1, 1912, to December 31, 1912. Paper; illustrated; 154 pages. Compliments of the Board of Trustees.

REPORT OF THE TRUSTEES OF BELLEVUE AND ALLIED HOSPITALS for Three Months Ending March 31, 1913. Paper; 22 pages.

THE PRACTICAL MEDICINE SERIES. Vol. VI. General Medicine. Edited by FRANK BILLINGS, M.S., M.D., and J. H. SALISBURY, A.M., M.D. Series 1913. Cloth; price $1.50; illustrated; 356 pages. The Year Book Publishers, Chicago.

PRINCIPES D'ANACOUSIE. By Professeur M. C. GARIEL. Paper; price 6 fr. 50; 267 pages; illustrated. A. Maloine, Paris.

OBSTETRICS. A Manual for Students and Practitioners. By W. P. MANTON, M.D. Second Edition, Revised and Enlarged. 292 pages; illustrated; cloth; price $1.00 net. Lea & Febiger, Philadelphia and New York, 1913.

NERVENKRANKHEITEN. By Dr. LEO JACOBSOHN. Paper; illustrated; 488 pages; price 19 marks. August Hirschwald, Berlin.

CLINICAL ELECTROCARDIOGRAPHY. By THOMAS LEWIS, M.D., D.Sc., F.R.C.P. Cloth; Illustrated; 120 pages. Shaw and Sons, London; Taylor Instrument Companies, Rochester, N. Y.

MORTALITY STATISTICS, 1910. Eleventh Annual Report. Prepared Under the Supervision of CRESSY L. WILBUR, M.D. Cloth, 611 pages. Government Printing Office, Washington.

SURGERY OF THE VASCULAR SYSTEM. By BERTRAM M. BERNHEIM, A.B., M.D. Illustrated; cloth; price $3.00; 104 pages. J. B. Lippincott Company, Philadelphia and London.

TREATMENT OF INTERNAL DISEASES. By Prof. NORBERT ORTNER. Second Edition in English. Price $5.00; cloth, 643 pages. J. B. Lippincott Company, Philadelphia and London.

GOULD AND PYLE'S POCKET CYCLOPEDIA OF MEDICINE AND SURGERY. Second Edition; revised, enlarged, and edited by R. J. E. SCOTT, M.A., B.C.L., M.D. Leath.; price $1.00 net. P. Blakiston's Son and Company, Philadelphia.

Miscellany.

The Egg as an Emblem of Heredity.—In an entertaining article on proverbs and eggs (it must be admitted that sometimes the age of the latter strongly suggests the antiquity of the former) a writer in the *British Medical Journal*, September 27, 1913, discourses on the egg as the emblem of heredity. A little-known proverb bridges over the gulf between the egg in embryology and the egg in diet: "An egg will be in three bellies in twenty-four hours." The hen's is one and the eater's is another, but, the author asks, who will guess the third? There is a Greek proverb, "A bad crow lays a bad egg," which represents the popular idea of morbid heredity, but neither eugenics nor Mendelism bears it out altogether, for an apparently good crow sometimes lays a bad egg, and an undoubtedly bad crow occasionally lays a good one. There is, however, here as in so many other cases, a proverb which seems to offer only a qualified approval of the statement that a bad crow lays a bad egg. It is this: "Many a good cow hath but a bad calf." So it often is with proverbs, and the reason is not far to seek, the proverb-maker wishing to give the proverb-user something to suit all contingencies. The Latin equivalent is *heroum filii noxae*, and Ray says "Aelius Spartanus in the life of Severus shows, by many examples, that men famous for learning, virtue, valor, or success, have, for the most part, either left behind them no children or such as that it had been more for their honor and the interest of human affairs that they had died childless." One might add many more instances out of modern history. Edward the first, a wise and valiant prince, left Edward the second; Edward the black prince, Richard the second; Henry the fifth, a valiant and successful king, Henry the sixth, a very unfortunate prince, though otherwise a good man. And yet there are not lacking in history instances to the contrary, as, among the French, Charles Martel, Pipin, and Charlemain in continual succession. Joseph Scaliger the son was, in point of scholarship, no whit inferior to Julius the father. There are, however, many contradictions in the matter of heredity, and some of the greatest men would never have been in the world at all if their parents had been successfully segregated or skilfully asexualized on modern principles. It is a tangle of tangles, and one is tempted to put Mendelian results into a new and up-to-date proverb to the effect that "it is hard to tell who a man's father was till you see what his son is going to be," or, perhaps, "you know not the hen till you have the chick's egg."

The Diagnosis of a Monstrosity.—W. T. Bertrand tells the story of a young man who started to practise medicine in a village of Indiana in the days when medical practice acts were not as stringent as they are at the present time. It could not be ascertained that any institution had conferred upon him the degree of M.D. He was soon called in to attend an obstetrical case. He made his examination, called the husband to one side, and said: "I hate to convey this information to you, but your wife is giving birth to a monstrosity. There are no bones in the head; it has but one eye, and its nose is where the other eye should be." It is needless to state that a genuine practitioner, who was then summoned, found a breech presentation and soon delivered a healthy boy.—"Stories of Doctors, etc."

NEUROVASCULAR GANGRENE.*

By M. D. BLOOMFIELD, M.D.,

PHILADELPHIA, PA.

Classified under the head of vasomotor trophic neuroses is a group of ailments presenting a symptom-complex indicating disturbed vasomotility and trophic alterations, so closely resembling each other, if not identical, that to differentiate specifically is well-nigh impossible. The more I consider these ailments the more am I inclined to believe that they are simply manifestations of the various stages of one specific malady. For instance, a careful review of the histories and the clinical picture of the cases I exhibit this evening will, I doubt not, convey an impression of the identity of this disease. It forcibly occurs to me that what so often is considered a distinct disease entity is in reality only a "stage," a manifestation of the phenomenon first thoroughly elaborated by Raynaud. It is claimed, for instance, that erythromelalgia should be considered a specific affection, and truly it seems so to me, likewise intermittent claudication, thromboangeitis obliterans, endarteritis obliterans; but upon a closer inspection and consideration of the symptomatology in each separate classification you will observe that they in no way differ from Raynaud's phenomenon, the clinical and pathological picture being identical. The only distinction I can make is that these "specific affections" are simply the undeveloped stages of Raynaud's phenomenon. They no more run their full course than any other malady does. During the past five years I have personally observed and studied thirty cases of this phenomenon, and what at first in some cases appeared to be purely erythromelalgia after the lapse of five years presented the typical symptoms of Raynaud's phenomenon, eventually terminating in the characteristic gangrene of the member, and finally in amputation with fatality in most cases.

"Everything concerning spontaneous gangrene is in a state of distressing uncertainty," says M. Victor Francois of Mons, in 1832, in a work[1] which has justly become classical. To this classical monograph, in this spacious gap of years, little has been added to advance our knowledge in this particular direction. To M. Francois we must assign honorable rank in bringing to light his theory well supported by facts and statistics that vascular obstruction is the cause of spontaneous gangrene, though this fact was advanced prior to his time.

Quesnay[2] in 1739 advanced the theory that it was the extinction of the organic action of the arteries, to which his confrères soon added venereal and scorbutic toxins.

*Read before the North Branch of the Philadelphia County Medical Society.

Hebreard[3] in 1817 and Avissard[4] in 1819 advanced the idea very convincingly that ossification of the arteries and concretions in the vessels were responsible for the occurrence of the gangrene.

Dupuytren and M. Roche subsequently developed a new train of thought, assigning arteritis as its cause, even advancing this as responsible for the inflammatory fever of P. Frank and the angioneurotic fever of Pinel.

M. Lagroux[5] laid particular stress on arterial concretions. Soon Virchow expounded his theory of solid bodies being transported to a distance by the blood current—the theory of embolism and thrombosis—which today, without contradiction, stands preeminent in the pathology of the affection.

To Virchow must be given the credit of being the original and correct interpreter of the pathogenesis, the true mechanism of obstruction and its resultant gangrene.

M. Godin[6] in 1836 advanced his theory that obliteration of the venous circulation was responsible for gangrene.

M. Bourgeois[7] of Etamps sought to establish typhoid fever as a cause of dry gangrene.

Virchow,[8] who has had a wealth of pathological material, admits that even in the most pronounced cases of gangrene he has been unable to find a true assignable pathology.

Zambaco and Charles Racle[9] established beyond doubt the capital point that gangrene, such as observed in Raynaud's phenomenon, can occur without alterations of the vessels.

Raynaud's phenomenon was first reported in 1862,[10] under the heading, "local asphyxia and symmetrical gangrene of the extremities." The earliest age at which this malady has appeared was in a patient who suffered his first attack at three months; the oldest was in a woman of 77. I have observed it in a man of 85 years.

The disease on this continent is most prevalent amongst Hebrews. Of my thirty patients twenty-eight were Hebrews. The average age at which this disease occurs is about thirty years. Males, in my experience, are more frequently affected. A history pointing to a neuropathic proclivity was elicited in all my cases, as well as exposure to severe weather: all but one recalled having suffered from some infectious disease; rheumatic family ancestry was common in most; lues was denied by all. All were married and had procreated large families except two ages, 12 and 19; they were all of hard working and industrious temperament and abstemious in habits.

The occupation seems to deserve some consideration. Most patients pursued an occupation which necessitated long hours of standing, or work requiring pressure by the feet, or were exposed to the severities of all weathers. Naturally such industries interfere with the venous circulation. An

addiction to ergot or any drug was conspicuously absent; all had smoked tobacco, but not excessively.

Before I detail the findings in this disease, in order that we may appreciate the mechanism of this pernicious malady, let us briefly consider a few anatomical-physiological factors. The nerves which innervate the arteries and to a lesser extent the veins, penetrate their outer coats in order to reach the media. These nerves have their origin in the sympathetic system. The muscular tissue of the walls of the finer arterioles are controlled by vasoconstrictor and vasodilator fibers. The dilating quality predominates in the vasomotor nerves which are found in the muscular coat. The constrictor type of nerves are found in the skin. The dilator nerves exert their influence locally and are of reflex origin; the constrictors may act either locally or over an extensive area.

Buerger, who has most recently exhaustively studied the pathological findings in the limbs amputated by him, has given us an excellent description of what he feels is a distinct clinical disease, but unfortunately his same findings were present in cases of symmetrical gangrene, the true Raynaud's disease. Throughout all the diseased vessels there is seen a strong effort on the part of nature to heal and produce compensatory collateral circulation. The vessels naturally show the changes incident to the severity and duration of the disease. In the very early stages there is occasionally seen small foci adherent to the inner coat. These are composed of giant cells.

At times I wonder whether microbic infection does not enter strongly as a causative agent. Considering the widespread distribution of this affection through the system, the fact that it may set in abruptly, especially as is seen in Cases III and IV, in a lad of 14 and a middle-aged man of 45, after cutting the nail of the large toe, agonizing pains, with elevation of temperature ensuing several hours after, followed by gangrene of the toe, with slow involvement of the remaining digits of the same foot, accompanied by a lymphangitis. Case XIV, operated on at Jefferson Hospital by Dr. Nassau, more than fully substantiates and warrants the opinion of microbic infection. Occupations which necessitate exposure to cold or damp and the industrial, that is those concerned in the manufacture of articles where poisons enter into its manufacture as lead (Cassirer[11]) predispose to the disease. Brasch cites the case of a boy who developed this disease after receiving an injury (circular saw). Hess has seen this malady in several bricklayers, whose occupation led to frequent injury to the fingers. Dehio (Cassirer) cites the case of a patient who developed this affection after being frightened by an attempt at rape. Cassirer states that this disease has often been observed after an attack of malaria. It has also occurred as a complication in typhus, enteric fever, grippe, erysipelas, and some observers have closely linked this disease with lues. A neuropathic proclivity no doubt strongly predisposes a patient to this affection.

This disease may manifest itself in three forms, viz., as (1) regional ischemia (Weiss[12]), (2) regional cyanosis, and (3) regional hyperemia.

The attack may be so slight as to pass off without the slightest cognizance by the patient. Occasionally, as in Case IV, it exhibits as its initial manifestations, severe cramps and stiffness. The history is usually typical. Beginning with a neuropathic family history, the description of an unhealthy occupation, the occurrence of some infectious disease in the recent past, it usually continues with the complaint of insomnia, a peculiar pain, a burning sensation in the toe or toes, occasionally the heels; not infrequently in the malleolus is a deep smarting, stinging sensation, deeply underneath, which is not painful to the touch. The foot is as cold as ice and usually you will see the patient on the warmest day having a thick flannel wrapped around the painful limb. To outward appearances he looks well nourished; his manner seldom betrays the state of discomfort he is in, for it is almost singular to mention that all my patients were in a sort of jolly state of mind. Occasionally when changing his physician he attempts to side track the next physician by telling him he thinks he stubbed his toe some time ago and merely wants a salve to heal the small sore. When you see the patient in his own home he usually is found reclining in bed fully dressed, except collarless, most of the time unshaven, for here a peculiar mental state of carelessness comes over the patient, who until a short time ago was perhaps a little overparticular in his appearance. Most of the patients are seen to smoke excessively, and when you caution them as to the danger of continuing this habit, they do not accept the advice kindly, reasoning to themselves the apparent foolishness of this correction, for as they have often expressed themselves, "how can smoking ever go down far enough to hurt my toe?" On examining the toes you will observe they are as white as a dead member. When the foot is hanging down you soon observe the pale color disappears and is replaced by a deep purplish blue. When local asphyxia is fully established a bluish black color replaces the pale color. I have often observed an actual play of colors occurring over the entire affected limb, especially when the patient changed position of leg. There is also observed a decrease in temperature (Cassirer having noted the temperature fall as low as 20° C. (68° F.).) At times I have been almost forced to believe that microbic infection should be considered as a causative agent. Considering the widespread distribution of this disease through the whole body, the fact that it may set in abruptly, as in three patients who had been in excellent health, until an injury was accidentally inflicted while cutting a toe nail, from which moment agonizing pains, temperature elevation, and slowly developing gangrene of the toe and remaining digits extending through the lymphatics of the affected extremity, showed that there must have been some infection.

Morrow, Raymond, Porter, White, and West cite numerous cases reported by themselves and others, where, after exposure and injury or some infectious disease, this malady had abruptly set it, in some cases with the physical and constitutional signs of a severe infection. All of my patients showed a high percentage of indican.

Whether this gangrene is preceded by a neuritis or whether the lumen of the veins and arteries becomes occluded by thrombi is extremely difficult to determine. Indeed, we have reports of cases where the entire lower limb was mummified, yet the lumen of the veins and arteries remained unobstructed. The only pathology observed was a peripheral neuritis, though distant to the point affected. Postmortem reports are extremely rare, because of the reluctance of the family to permit an autopsy and because the mortality is so low—at least that traceable directly to this disease. Recent thrombi may

involve extensive portions of arteries and veins, but Buerger does not feel that this condition is necessarily secondary to gangrene, for he has found this condition even when no gangrene was demonstrable. The affected area is usually swollen. This swelling occasionally disappears and not infrequently the patient will inform you that the previous day actually was "his own," he felt so well. There will be times when you will leave the patient in a most joyful state of mind, for he is temporarily free from discomfort, but when you see him the following day he is tired, haggard looking, has not slept except for occasional minute naps. In advanced cases the patients seldom sleep in bed. They usually remain in a chair by the window and sit for hours and days without ever going to bed. Sometimes the pain comes in attacks which may last for a few minutes; but I have seen these painful crises last several weeks, no medicinal or mechanical measure exhibited being able to relieve the suffering. On examining the toe carefully you may see a small vesicle or ulcer, or simply what looks like a little serum exuding from the margin of the nail. When an ulcer is present you can make up your mind it will be months before that will heal, if it ever does. This ulcer gradually develops a gangrenous character, which is almost characteristic of the disease. It is limited to a small area around the affected phalanx. The opposite extremity at the same time may show the same signs of beginning trouble, but this is not frequent during the first few weeks of this disease. At times, besides the gangrenous spot on the phalanx, the tip of the nose, the lobe of the ear, the head of the penis, as seen in Case V, the tip of the tongue, or even the nipple may become affected. The pain in this affection is characteristic. Raynaud says, "I have known persons otherwise quiet and patient, to howl with pain, their bodies bent and contracted as they sit in bed. These unfortunate subjects appear to pass their entire time in seeking a position which will afford some relief." Most cases have secretory disturbances, usually of the hyperhidrosis type. Cassirer has observed atrophy of the muscles affecting the gangrenous digits or limb. Symptoms referrable to the visual apparatus are of no import except for the tired look, the sleepy eyes. Raynaud observed some ophthalmoscopic changes in the eye grounds, but these I have never been able to confirm. Weiss also observed a peculiar contraction of the central artery, but this has not been confirmed by any other observers so far as I can ascertain. The urine of all my patients showed a plus indoxyl-potassium sulphate content. Raynaud frequently observed a paroxysmal hemoglobinuria. Some observers have reported a paroxysmal albuminuria and milituria. Uric acid is always in excess. Regarding the other viscera, I could find no change clinically as in two post-mortem examinations, the only evidence of a pathological nature being the arteriosclerosis. The symptoms herein enumerated are of an intermittent character. They may last for several weeks, the intensity of the symptoms gradually disappearing, leaving the moistened sloughtened digits dry occasionally hanging as if ready to drop off. Hirschfeld has seen the symptoms with all their intensity persist until death closed the scene of suffering. You will not infrequently observe cases in which only the vasomotor phenomena persist, where gangrene never manifests itself. Occasionally this affection complicates tabes or syringomyelia, as observed by Schlesinger. I have seen several patients suffering from embolism or thrombosis of the internal capsule who had associated with their hemiplegia a typical Raynaud's phenomenon. Most patients usually become hysterical or neurasthenic in a short time.

Solis Cohen[13] has seen changes in the mucous membranes in which the vascular supply manifested the changes of hyperemia, ischemia, etc. Gangrene may occur with or without vasomotor disturbances. Cassirer, it appears to me, has felt that infection, intoxication, and exposure to cold play a great rôle in the pathogenesis of this affection. Leprosy and beriberi have at times been mistaken for Raynaud's phenomenon.

The diagnosis is not difficult. Acroparesthesia, erythromelalgia, scleroderma (very rarely), intermittent claudication, thromboangeitis obliterans seem to me to be only the illy defined transitional stages of this phenomenon. Senile gangrene and the gangrene of diabetes mellitus occasionally will worry one, but the clinical history and course of the disease, the urine, the condition of the other viscera will assist in clearing the case. I believe that this disease shortens life, but in itself is not fatal. The cases usually succumb to a pneumonia or to infective lymphangitis resulting from amputation.

Treatment.—In winter when these patients suffer most, a change of climate would be of great benefit. I have tried almost every known remedy, the injection of fibrolysin, the washing out of the affected vessels with normal saline solution, quinine, ergotin, strychnine, electricity, hydriatic measures, mechanical elevation, hot-air apparatus, galvanization, cauterization, high-frequency currents, ointments of every description, Bier's hyperemia, rest in bed, postural treatment, exercise, cocaine as advised by Herz, mineral salts, but I must confess that to no one remedy could I ascribe any curative powers. I believe that this is a surgical malady, though, of course, the patient should be given a fair opportunity to receive conservative medical treatment. I have particularly been impressed with the freedom from suffering which the patients enjoyed while discussing their case, and upon this observation I have tried to have the family and especially friends engage as much of the patient's time as possible, and this has proved a wonderful temporarily relieving measure. Most patients are free from pain only when their minds are engaged. This is no doubt the reason that suffering is greatest during the night. J. Booth Miller[14] emphatically states that it is useless to delay when gangrene is clearly defined. He advocates amputation well above the affected area. My observations have taught me that conservation of limb should be the secondary consideration, preservation of life the primary one. Every step should be taken to prevent involvement of the other extremities. Building up the system with tonics, milk, and eggs is beneficial. Erb has found that smoking not only aggravates this disease, but he goes so far as to state that this may be the exciting cause, in some of his cases. Narcotics and coal tar products should never be given for they never do any good and only diminish the resistance power.

Case I.—William Callanan, 35 years of age, Irish-American ancestry. Served in the United States Army during the Spanish-American War. Was exposed to the severest weathers and the trials of camp life. Contracted malaria and has never been well since then. He does not recall any previous diseases, excepting measles. Was honorably discharged from the army. Upon reaching his home town, Bryn Mawr, he found his gait was

somewhat impaired. He limped a little, but paid no particular attention to this, thinking it was merely due to exhaustion. Rested at home for several weeks, but limping grew worse, and soon patient noticed he had pain every time he attempted to walk. He also had shooting pains through his body, but thought this was also due perhaps to a rheumatic complication. When he came to see me he was most surprised when I asked him how long he had noticed a small dark ulcerating spot on his large right toe. He had never observed this, but further inquiry elicited the fact that ever since his return home he noticed that his both feet were as cold as ice. I applied soothing antiseptic ointments to this necrotic spot on his toe, but no attempt at healing took place. I advised him to report to me at the Nervous Clinic at the Jefferson Hospital, where his condition was more thoroughly studied, and all agreed to the diagnosis of endarteritis obliterans. He finally was transferred to the surgical ward under Prof. J. Chalmers DaCosta's care, where another attempt was made by rest and medicinal treatment to check the rapidly progressive gangrene. When I saw him one week after his admission to the wards he had been having a daily temperature ranging between 101° and 104 F., and was very profoundly septic. Amputation was advised. Patient refused and returned home, and when seen at his home later by Dr. Righter he had a temperature of 104.8 . In a few days, by stimulation, etc., we were able to reduce the temperature, and had him transferred to Delancey Hospital, where Dr. Righter, together with Dr. Morrison, amputated both extremities—first the right and two weeks later the left leg. The patient is at present in excellent health and feels better than ever before. It will interest you, I am certain, when I tell you that various diagnoses had been advanced by several physicians who had treated him in the early stages of his disease. Rheumatism, intermittent claudication, malarial osteomyelitis were some of the diagnoses advanced prior to his coming under our care. I am sorry that the plasmodia of malaria were not looked for during his stay at the hospital, for I am very much inclined to believe from his history of having had cold, fever, and sweat sometimes coming on every other day that he had had the typical estivoautumnal type of malarial fever. I am also very much inclined to believe that exposure to cold and malaria were the exciting causative agents in producing his disease.

Case II.—M. Mogulefsky, Russian Hebrew, grocer, previously was a newspaper carrier. He also was exposed to the severest weathers. Had to carry heavy bundles of papers on his back, through the thick snows over rough country roads. His trouble began with pain over the mid-ankle joint. I saw patient four months after the onset of his disease when he came to me after having been treated at St. Joseph's Hospital. He presented a small discolored area, over the midankle joint, in the center of which could be seen a small vesicle, from which oozed a yellowish colored fluid. His right knee joint also pained him. He was of nervous temperament, good habits. On examining the right leg a cord-like structure, extending from the popliteal space to the middle of the leg, could be felt. His inguinal glands were swollen, he had burning stabbing pains over the internal malleolus, and tenderness over the femoral vessels. On putting his foot on the ground, it became red, swollen, and extremely painful. His pains were greatest at night and nothing would relieve him. The opposite leg was not involved in any way. Six months after onset the right leg was operated on by Dr. LaPlace, who removed it as far as six inches below the popliteal space. The stump refused to heal and two months later a second operation was done and amputation completed above knee joint. One year later his left leg began to give him the same trouble as had the right, and sixteen months after amputation of right leg, left was removed. He now looks a picture of health.

Case III.—Kollscher, young man, age 22, contracted Neisserian infection at 19. Two weeks later began to experience pain in his left ankle joint, which was treated for gonorrheal rheumatism. Improvement was soon experienced, but he never felt quite well in that joint following his acute attack of pain and fever. One year after exposure he came under the care of Dr. Horwitz and Dr. Loux, complaining of pain in both ankle joints, followed by a burning and stabbing sensation shooting through the inner side of both feet. This pain was intense. His feet would swell two or three times during the day. When in a reclining posture they were of a reddish blotched color, but on placing his feet on the floor they became purplish blue and the pain was agonizing. He has remained in this state of torture for the last three years and has traveled from physician to physician seeking relief.

Case IV.—Friedman, age 54, always enjoyed good health. Had what was diagnosed as typhoid fever when 24. His occupation is that of a canvasser which exposes him to all sort of conditions of weather. Last year, for the first time he experienced pain in his popliteal space, right leg; the pain extended down back of the calf muscles, and on attempting to walk he would limp quite perceptibly and would tire after walking one half square. One month after onset of this pain he could not walk at all, for the pain became intense. The left ankle joint now began to become swollen, red and painful. He increased his daily smoking to twelve packages of cigarettes daily, but surprisingly he felt no other effect except what he termed his only relief. There were hyperesthetic areas all over the posterior surface of right leg and over both malleoli of left. The pulsations in all vessels exposed could be elicited. He received constant medical care for three months, at the end of which time he was sufficiently improved to leave the house, and he insisted on resuming his occupation of canvassing. This he continued for nine months, when the old trouble occurred with greater severity, and now, though there is no visible gangrene, I am certain it is only a question of a short time before this will set in, for there is now beginning to exude from the margin of the right large toe a yellowish straw colored serum.

Case V.—Glassman, sewing machine manufacturer, consulted his family physician for ingrown toenail which he claimed was annoying him considerably. It interfered with his walking and pained so much at night that he insisted on having it removed. Five hours after Dr. Weinburg removed this, and as I understand, under the strictest of antiseptic precautions, the entire foot became blue, the toe grew about five times its original size, fever and prostration were present. I saw the patient during the height of this attack, and after several weeks of hard work I finally was able to get him some comfort. The inner margin of toe shows an ulceration which thus far has resisted all attempts at healing and the large toe of the opposite foot is now giving him considerable pain, is swollen, reddish blue in color, and causes him to have a distinct limp when walking. He tires easily, sleeps little through the night, although he claims that the pain is not great enough to keep him awake. However he is not free from it for a moment even.

Case VI.—Wolf, boy 12 years of age, developed the same condition as the above case and had to have his right toe amputated for gangrene following two weeks after extraction of what he thought was an ingrown toenail. Now the toe of the left leg presents the same condition as that described in case above.

Case VII.—Friedman was exposed to severe winters in Russia and remembers having frozen both feet. Ten years later began to experience pain in his middle toe of right foot, which he thinks he struck against a stone. Has a small ulcerated area at the inner margin. This has resisted all attempts to heal. His foot is red and the inguinal glands are enlarged. He suffers excruciating pains at intervals. Has taken considerable medication to relieve his pain but to no avail. Seen by Dr. Bachrach about two months after onset. Was placed at rest and heat applied. Is feeling considerably improved at present writing.

Case VIII.—Katz, ladies' tailor, age 32. This is the third summer in which he has experienced pain and swelling over right ankle joint. Now the popliteal space of right leg is very tender. He cannot put his leg down, for the whole extremity swells up, becomes fire red. Over the outer margin of nail, second toe, right foot, is seen a small spot which is blackish in color, the other toes are glassy looking. When he puts his foot to the floor these pale deadlooking toes become purplish red in color, accompanied by severe pain. He smokes considerably and tells me that his left leg was frozen in Russia about twelve years ago. Every winter, however, since having frozen his left leg, he has experienced difficulty in walking for several weeks. He has always complained of cold feet since his exposure. Dr. Stembler's case.

Case IX.—Sosslofsky, under care of Dr. Miller, at Polyclinic. Consulted me November 8, 1912. Both feet had all their toes amputated except for the third and first toe of left foot. These are now becoming gangrenous. First the left foot became affected, swollen, bluish, and painful. Soon followed by small bleb over middle phalanx of right foot. This soon ulcerated, resisted all treatment. Other toes of foot became involved. Had pain all over course of femoral vessels and distribution. Amputation was done, removing all the toes. Two years later right foot became involved. Condition at present: remaining terminal and middle phalanges soon will be removed.

Case X.—Gershuny, 81, architect. As a carpenter, many years ago, remembers having frozen his right leg. Two

years ago noticed a small black spot on the mid outer surface of second right toe. This did not pain him, but to heal it some one advised him to apply moist tobacco leaves. After applying this for several days the skin of this toe came off, leaving a weeping, painful ulcerated area which seemed to be deep down to the bone. This toe refused to heal. The ulcer extended, involving the entire phalanx. He accidentally hurt the inner margin of foot, making a slight abrasion. This never healed. Thirteen months after onset the entire right foot and popliteal space of right leg began to hurt him considerably. The foot became swollen at times. Felt hot as fire. Suffered agonizing pains over entire right leg and foot; gangrene extended around previous ulcerated phalanx, and the remaining digits of left foot became swollen and reddish blue. Sleepless nights and exhaustion weakened him considerably. Dr. Deaver advised amputation of left foot. Patient refused and died from septic thrombosis affecting his right lung.

Case XI.—Malamut, restaurateur. Remembers having had his toes of left foot frozen, about ten years ago. Consulted Dr. Babcock and later Dr. Hammond for a small ulcer on the outer margin of his right large toe, which he states he had already had for several months and which refused to heal despite everything he applied. When I saw him his left leg was swollen. Lymph glands along leg were likewise enlarged and tender. I lost sight of him for a year, after which time he consulted me again. This small ulcer on the outer margin of the left toe was still present, without any appreciable difference in size, etc., except now that his toe pained him considerably. Pulsations over both tibials were absent. He continued under my care for several weeks, but noticing no improvement he drifted from me and up to this time I have not seen him.

Case XII.—Cohen, operator, age 55. Like all the others was the father of a family of six. Seen by Dr. Deaver and later by Dr. Babcock, both agreeing that amputation should be done high above the knee-joint. History runs like that of the previous case. He remembers having had what from his description I believe was malarial fever (a fever which lasted two years, coming on every four or five weeks and lasting five days). His right leg was amputated at the Jefferson Hospital by Dr. Gibbon. I saw him one year later, when the left leg became similarly affected. I advised his readmission to the hospital. He died three days after amputation of left leg, from pneumonia and pyemia.

Case XIII.—Bainbridge, grocer. Operated on at the Jefferson by Dr. Gibbon. He gave a history of having had both feet frozen when a child. Three years before his admission to Jefferson he had experienced pains along entire left leg, and in fact the entire left side of body when walking. Deep breathing would cause him sticking pains over left side of chest. Had a small ulcerated discharging area over inner and outer surface of the second left toe. He applied tobacco leaves on the advice of a good friend. Ever since applying these leaves he has suffered excruciating pains in both feet. The toes of both feet are glassy looking. He does not walk, for the pain is too intense as soon as he places his feet upon the ground; both feet become swollen and deep reddish blue as soon as they are placed on the floor. The left foot was operated on by Dr. Gibbon. The last I heard of this patient was that he had died from sores over his entire right foot.

Case XIV.—Rubinson, brush maker, age 18. Has sore throat every year which requires opening up of tonsils. Also recalls having had his legs almost frozen off when a small boy in Russia. Seen by Dr. Franklin, at which time he had pain over the internal malleolus of left tibia, pain over all the toes of the right foot. Is extremely neurasthenic. Thus far all measures to relieve his pains have been of no avail. He received a slight wound over tibia, about center of leg, which took about three months to heal, though this was not painful. The vasomotor phenomenon in this case was typically that of other cases herein described.

Case XV.—Treeberg, shoemaker. Had a fever which lasted six weeks, when he was 18 years old, about 25 years ago. About three years ago the heel of his right foot ached him so badly that he could not stand upon it. Occasionally the toes of his right foot would become pale, as if dead, and when placing his hand on his right foot it appeared as if the foot were frozen. The toes of the left foot were swollen at times and occasionally appeared bluish black. When he would attempt to walk a few yards his knees would sink in as if he had walked miles. The pain in the right heel continued for about six months, when one morning he woke up feeling as if nothing ever troubled him and since then he has been fortunately free from pain, but the toes of both feet are cold as ice and frequently exhibit a display of colors.

Case XVI.—Rosenfield, 54, Hebrew teacher. Had a fever which lasted several weeks when he was about 19 years of age. Felt in good health ever since, but has always suffered from cold feet. When he came under my observation he was bed-ridden. Right foot was swollen and a small gangrenous patch appeared over inner surface of third toe. This was extremely painful, and seldom has the patient been free from pain since the onset of this gangrenous patch. He thinks this ulcer came on suddenly. I advised amputation of both feet in this case. Patient refused and three months later both legs were operated on at the Medico-Chirurgical Hospital, the patient succumbing two weeks after amputation.

Conclusions.—This, I believe, is a surgical disease. From the history of the various cases discussed and exhibited you will observe that at first they assumed the character of the various stages of this phenomenon, which some observers would diagnose as intermittent claudication, thrombo angeitis obliterans, endarteritis obliterans, etc., but as time elapsed, they eventually developed their true termination into gangrene and in 90 per cent. of the cases ended fatally. I believe if amputation were done early suffering would diminish appreciably, exhaustion be prevented and a greater degree of safety to the life of the patient and a better chance of recovery. Never wait for lines of demarcation. When they come it is too late to amputate. Do not give coal tar products to relieve pain. Mental diversion and heat, with plenty of nourishment, are the best means thus far at our command from a medical standpoint. Lastly, to quote from Raynaud (in this paragraph my colleagues will have gained the whole truth advanced long before any of us here this evening were born): "To moderate the pains, to prevent the use of unsuitable measures and doubtful remedies, such ought to be in the majority of cases the part played by the physician. Nature will do the rest. We shall be sufficiently satisfied, although we cannot immediately relieve our patients, if we can still encourage them with the hope of a probable and approaching recovery and should this point be the only one which clearly results from the work just completed, I should not regret the pains which I have bestowed upon it."

The case of Callanan is extremely interesting. It typifies in more than one respect the psychological makeup of these patients. He, like all the others, possessed a splendid degree of intelligence. Fully conscious of the severity of his disease and its probable consequence and fully realizing the uncertainty of cure from medical measures, he, most singular to state, like most of the others sought to find a cause and its probable elimination. He felt that to find the true exciting cause would be the only hope. However, in this connection, I must freely admit that he unfortunately possessed the fullest requirements for the development of this disease. Any one of the three causes mentioned in his history, viz., exposure to severe weather, sleeping on damp ground, the infection with the plasmodia of malaria, any one of these agents might have been sufficient in themselves to produce this terrible affliction. In reviewing his early and recent history, the history elicited prior to his development of gangrene, we learn that he was a graceful dancer, possessed of perfect features and bodily grace, admired for his military carriage in all sorts of exercise, his friends and family were shocked when upon his return from the army, he limped, looked pale and haggard, and soon after began to develop this malignant disease. The am-

putated limbs showed the typical pathological picture of obstruction of smaller veins and arteries, several large and deep holes in both feet, toes sloughing off. He is at present striving to earn a livelihood for his family of three children by selling cigars from a little stand and this has given to him quite some mental cheer. Up to the present time he has not fully learned how to use his artificial legs.

My views as to the etiological factors, viz., exposure to cold, trauma, and malaria are well supported by the observations made by different observers in various parts at home and abroad. The literature contains numerous cases where after slight trauma to a digit or phalanx this malady soon set in.

THE NEUROSES AND PSYCHONEUROSES OF CHILDREN: THEIR MODE OF DEVELOPMENT AND TREATMENT.*

By B. ROSENBLUTH, M.D.,

NEW YORK.

ADJUNCT NEUROLOGIST, BETH ISRAEL HOSPITAL AND THE HOSPITAL OF THE CITY HOME ON BLACKWELL'S ISLAND; CHIEF OF CLINIC ISRAEL HOSPITAL DISPENSARIES.

The matters and affections to be treated in this paper are those that have no other than a mental disturbance for their pathological basis. In these the pathologist, bacteriologist, and chemist cannot show anything but immaturity of the child's brain. Therefore among the many subjects to be omitted in this paper will be chorea and epilepsy, which are frequently described as neuroses.

The most frequent manifestation of juvenile mental disturbance is a motor expression of a spasmodic character. The most common of these will be described, and they will serve as a model as to how the various neuroses and psychoneuroses are developed.

A large number of the motor neuroses of children are those of facial grimace. It may occur among those that are well cared for, as well as those that are neglected. The children as a rule are bright and well thought of. They have no nightmares, and there is no history of fright.

Thus, two cases in the Mt. Sinai Hospital Dispensary Service (Nos. 105 and 846), aged six and a half years and nine years respectively, were above the other children of their age in school, and were quite precocious in their mental development. These children, on account of their cleverness and aptitude, are allowed a greater amount of leeway than their less well endowed comrades, and are allowed to manage themselves to a great extent. So they are left to their own devices on the street, where they run wild, and requiring less time for study, they remain in the street for a longer time. Being brighter, they take the lead in street play, and try to outdo everyone with whom they come in contact. So it is readily seen that they become excessively active in their bodies, as well as being mentally active from natural endowment. On the other hand, at home the parents take great pride in the erudition of the youngsters, and speak to them as to an older person, take them into the family councils, and, in short, treat them as adults. The gravity of the home atmosphere intuitively compels the child to assume a superior attitude, to deserve all of this consideration, and give thought to the weighty problems of the adult. The little personage sits up, is quiet as befits an older individual, and, in short, the child is compelled to assume the unnatural position of a person of mature years in conformity with the atmosphere with which he is being surrounded.

But the child remains a child. Its accustomed activity in the street, as well as the motor preponderance of the child's nervous system, assert themselves, so that the constrained attitude at home is too great for the immature mentality to balance, and the motor inhibition is unconsciously overcome and is exhibited in the most prominent part of the body, the face. The efforts at mental concentration are shown by facial twitch, and even as the child is conversing he is showing repression of his wonted motor activity. Thus the mouth is drawn to one side of the face or the other, or it is alternately pursed up or relaxed, and at times the motions are even transmitted to the trunk.

The management of these cases is very trying. The parents do not realize that the children are so wild on the street, and do not realize how harmful it is to tax their minds to too great an extent at home. They always feel that it is no effort for the particular boy or girl, because, as they say, they are so clever. The problem is so to arrange the daily life of the child that it will not preponderate too greatly in one direction. In the street the company of an older person will curb its overactivity by mere propinquity, and at the same time that person can direct its play to more quiet and even more utilitarian paths. In this way the child's confidence is gained, and instead of the unrestrained riotous play, quiet walks are in order and the body is spared the exertion of the overactivity. At home the conditions are made normal as for a child, the parents being told that the little patient will have time enough to be old, so let it be young now. Treat the child as any other Jack or Jill, and leave out the seductive sugary "my boy" or "my girl" with which the parents ensnare these children. Another great fault is that these children read too much; most of the literature is not at all necessary for their mental development, and often unsuitable for their age and powers of appreciation. So they get distorted views of things they read or hear discussed, and consequently use up energy trying to grasp all they read. Besides, the parents are continually exhibiting the wonderful studiousness of the children, so that they try even

*Read before the Eastern Medical Society, March 14, 1913.

harder to read more and more, with inroads on sleep and rest, thus again taxing their already overtaxed bodies and nervous systems. The loss of sleep is serious, for that is one thing that a child needs in large amounts, so that the nervous system can recuperate from the day's work. So, from all viewpoints, the child-wonder is the greatest menace to himself on account of the liberties which are taken with him.

Of course, any poor state of bodily health should be guarded against. A daily tepid bath of long duration is very beneficial. The method of treating them by disagreeable drugs and cold baths to shock is absolutely barbarous, besides being harmful.

This very well demonstrates a disturbance, the manifestations of which are due to faulty environment. This environment being created by family and friends, they have to be trained so that the environment is changed, and in this way the child's condition will be cured by itself in short order. But until the parents and friends realize that the mistake is theirs and that they are the cause of the child's illness, until then will the child remain sick.

An annoying neurosis in the child is a bilateral tic of the eyes. It is not a blepharospasm, but a rapid closing and opening of the eyes, as if the child were peeping at something. It usually occurs in children between the ages of five and twelve, who, as a rule, are well nourished and in good health otherwise. They very rarely show any degree of refractive error. The child just blinks as if it were in a strong light, but there is not any of the retraction as when one is exposed to great glare. The child is worse when it is being looked at, and the condition can very often be brought about by the child being made conscious that it is being examined for that particular symptom, and thus a simple request by the examiner will very often bring it out. But all the time the closure of the eyes impresses one that they are being closed in a slightly volitional manner, as if the patient were seeing something. On investigation the only thing that can be found as a basis for this condition is some dream trauma. Thus in the case of a little girl nine and a half years of age (Mt. Sinai, case No. 502) who had been suffering with this affection for about three months the only thing which could be found as a cause was an oft-repeated dream (dreams are repeated with great sameness in children). She saw thieves in her bedroom who were doing most unmentionable things—things that could not be spoken of or looked at. So in the dream she fearfully looked at these apparitions of thieves and their doings, but as she did this she realized their impropriety besides their fearfulness, and quickly closed her eyes to shut out the sight. But her curiosity overcame her fear, and again she opened her eyes, to be followed by the closing from the same causes. During the day there was a rehashing of this dream and a realization that it was improper for general discussion, so she withheld her dream experiences from her mother and playmates, but still she enjoyed those dreams and surreptitiously looked at them in her day imaginings, and repeated the sleeping performance of shutting them out when realizing their horrible nature. But the act of closing her eyes attracted attention from the family and playmates, and thus she became a distinctive personage who was closing and blinking her eyes, and therefore she automatically kept on closing and blinking them from this atavistic posing that was thrust upon her by this attention. The cause of the blinking soon was forgotten, but the blinking remained, due to an entirely new cause, without any remembrance of the dream, and it was only by a complete analysis of the dream-state that that etiological factor was brought out, and as soon as this was taken as a therapeutic basis the cure was complete.

In these particular cases the correction is moral to a degree. The child is reminded that she has seen this dream quite often, and is no doubt well acquainted with it, and by this time she should realize that it was only a dream and not real. Also that she should tell her mother about her dream and ask any information about it; for if she had, her mother no doubt would have told her that thieves come to the house to steal and not to do the various things that other little girls say that thieves do.

For the material therapeutic measures, daily cold baths are very good These cases recur, and the cause is the same—that is, recurrence of the dream—but the examiner can very quickly overcome this by directing the child's attention to the old dream.

This illustrates the mildest grade of neurosis from mental causes due to environments which have not been supervised by older people, for children, with their unlimited and untrained imaginations, interchange the most bizarre talks on the most unrelated subjects, which soon become very real to them.

There is also a form of unilateral tic of the eyes in children that is due to imitation of some teacher's or older person's tic convulsif. This has to be explained to the patient: that the cause that is present in the teacher is not present in them; that they are merely imitating.

All of these analyses have to be given with the aid of the patient, even where the examiner is positive of the cause of some particular complex, but cannot suggest it to the patient, as the patient may have forgotten how he or she came to do this particular thing and deny any such connection. So the patient is questioned, and tells of her own accord whom she imitates, and thus she reasons how the affection was caused, and the physician can reason backwards with her for re-educational purposes. In all of these cases it is very important to educate the parents, as nowhere else is it so patent that parents have suffered from lack of training for their particular rôle. One is impressed with the conviction that, though Spencer was not married, he very well knew how few people had a right to marry, considered from the viewpoint of how they had been trained for the upbringing of children.

Of the more complex psychoneuroses, the one that is most frequently encountered is a motor expression of mental disturbance that is characterized by general spasmodic movements of the entire body. These have been described as "habit spasm" or "habit," or "convulsive tic," as a peculiar form of paramyoclonus multiplex, and as pseudoparamyoclonus multiplex.

The chief symptom of this affection is an irregular jerking of various parts of the body, either all at once or one after the other; the intensity varies according to the states of excitement. At home and in the company of other people the patient is busy with the most useless movements of associated groups of muscles. There is none of the progression in the motions as is seen in chorea, but they are of a sudden and of a spasmodic character. There are frequently also movements of the face

and eyelids. Many of the cases make audible and inspiratory noises, either of the nature of a low-sounding sniffle or a loud laryngeal groan. Some hiccough very loudly. In some of the cases the spasms may be so violent that the child is thrown from the bed, and is unable to walk, though a few minutes afterward the patient may be walking about as if nothing were the matter with it. One of my Beth Israel Dispensary cases was of the most aggravated form—the mother had to sit on it to keep it in bed. I wished to demonstrate her before this society, and on the way to the place of meeting the girl had to be carried in the arms of the father, and often she was thrown from his arms by the spasms, and they were followed by hundreds of people in the streets who were attracted by this convulsive burden. But as soon as she came into the rooms of the society every sign of her malady vanished, so that my colleagues were doubtful of the child's having any sickness at all, and they had to take my word for it. It was two years before I cured the girl permanently. This distinguishes this affection from chorea, where, no matter what the influence, we can always obtain typical choreiform movements.

In the Mt. Sinai Hospital Dispensary I had fifteen such cases in the past four years; in the Beth Israel there were two. Their ages ranged from 5 to 12 years; thus, there were five of 9 years of age, ten of 6 years of age, and three of 11 years of age, and three of 12 years of age. From their histories it would seem that the greater number began at the age of 8 and 9 years, but every year of childhood is represented in the series. Seven were males and ten were females. The onset, as a rule, is sudden, and generally accompanied with a varied amount of excitement.

The above cited case followed promotion of several classes in school at one time. When the girl came home from school she had some malaise and stiffness, shouted that she could not breathe, and threw herself around in bed at such a rate that she had to be held down. Psychiatrically, she showed fear of being in the dark; she thought she saw strange men in her room, and imagined men and thieves in various parts of the apartment. She had to absent herself from school for about two years, until she was completely analyzed and re-educated. All the time the girl was made to realize that she was put ahead in school because she deserved it, and not because anyone wanted to get rid of her, and the reason she came home and felt the way she did was because of the excitement of going from one classroom to another and not because she ran up the dark stairs, and that thieves and men are quite omnipresent, and that it was none of the business of a little girl to try and fathom the purposes of thieves who came for material profit, and not to pay attention to the nonsense of children. All of this has to be carefully worked out with the aid of the child. Nothing is told to the child unless it tells the facts by itself. Any suggestion may become a new fact in the psychosis of the patient, and there is quite enough to treat without engendering any further mental disturbance.

Another patient in the Beth Israel Hospital was sent in from a neighboring school, with her whole body going through the most violent spasmodic evolutions, which had come on after the teacher had spoken sternly to the patient and perhaps had threatened her with punishment. In this case I did what I do not approve of—that is, I gave the girl a few strong shocks with the faradic current, so that the physical pain should overshadow the mental distress. This, with a few doses of bromide, was sufficient to prevent further display of these corporeal pyrotechnics. I doubt that she was really cured of the condition that allowed of any such reaction, but the case has not returned, and apparently has remained cured.

Another case came on after excision of the tonsils, which had been followed by a fright at home during the night. All of the cases give dream complexes resulting in child fear. Most of the cases are results of encounters with the dream actuality in the waking state, which is reproduced in dreams. Some of these dreams are also caused by tales, either by older people or among the young people themselves. These patients also become run down, anemic, irritable, are sleepless, and are great cares for the mother, as well as the physician. They do not play with other children, inasmuch as they are accounted ill. They are fearful of the dark, and so will not go down into the street where the hallways or stairways are not sufficiently lighted. The parents in these cases are either too kind to the children, or, becoming tired and disgusted, are too rough—one extreme or the other being naturally very bad. What the children need is kindly interest and investigation of what is causing their bodily manifestation of mental fear. Misinformation of punishment, things occurring in the dark, the actions of thieves, who thieves actually are, ghosts, and all the other conglomerate terrors of darkness and sleep have to be investigated *for each particular patient*, and corrected. Anemia has to be corrected, the patient must be made to go out into the fresh air, and environmental influence must be overcome as far as possible. If possible, the child should be taken from home, but in public practice this is not easy, for hospitals do not care for these cases, the country homes less so, and we have but poor co-operation from the various eleemosynary activities for the treatment of these unfortunates. Thus again we have an affection due to poor environment combined with faulty guidance.

Enuresis in children is of two varieties—one occurring at any time during the twenty-four hours, and found mostly in the very young and in defectives. When it occurs in the child it is usually in one that is from three to five years of age, and if the child is of normal make-up it is due to neglect and also to repression, from the fear of letting its wants be known. The caretaker allows the child's bladder to be filled to the point of overdistention until the child cannot hold its urine any longer and has to void it. If this is kept up for a sufficient length of time the child becomes habituated to wetting itself, and keeps on doing so. Then it is punished for its supposed carelessness, and thus its attention is directed to its urinary organs, over the control of which it becomes apprehensive at first and careless later, so that it loses the necessary confidence in itself for the full control of the bladder and behaves like a neglected child. The child becomes depressed, soon runs down in health, and becomes anemic. The cure requires close attention to the regular emptying of the bladder, and thorough cleanliness of the parts, with plenty of bland powdering. Change of the caretaker will in most cases be sufficient for the cure. It is important to impress on the little patient that all parts of the body are made for some particular use, and it should be put to such proper use in the proper time.

That proper use for one part of the body is as good for that part as proper use of any other part of the body is good for that part; as, for example, eating is good for the stomach. All this to overcome the shame which has been attached to the urogenital attention.

The other form of enuresis is that which occurs in older children, and is characterized in that the urination takes place only when the patient goes to bed and after he has fallen asleep. Most of these cases occur in boys. In the Mt. Sinai series there are four such cases, and one case in my statistics is from Dr. M. Schulman. In the Beth Israel Hospital, which has a larger service, there are a still greater number of cases, but with a very small percentage of girls. These patients are well able to hold the urine during their waking hours, and from fear they are most scrupulous in emptying the bladder before retiring; but no matter how soon they are awakened the bed is found wet. As a rule these patients are very healthy and good specimens of children, and all of my cases happened to be very bright ones.

Here, then, we have a condition where in the conscious state there is complete and excellent control of the bladder, but as soon as consciousness is removed, *no matter with what apparent emptiness of that organ,* there is voiding of its contents, showing that this must be from the smallest amount of urine, and cannot be from overflow, but from forcible detrusion. So we must look for some mechanism that is effective during sleep, which is held in abeyance while the patient is awake. This can only be from some psychic disturbance which is repressed during the conscious state, but which comes into play during sleep, due to the removal of the conscious censor, and this stimulates the lower spinal centers with forcible expulsion of bladder contents. It would seem as if the bladder is continually being contracted as soon as sleep ensues, because the bed is being wet continuously during the entire sleeping state. All these cases as a rule have had enuresis from earliest childhood, so that the emptying of the bladder has become automatic; when the child grows older it controls it by main force while awake, but during sleep this control being removed, the bladder automatically reverts to its old habits. When we realize that the emptying of the bladder is accomplished by impulse from the higher centers to the sympathetic and pelvic autonomic centers, it is patent that the quoted mechanism must be the one at work. The newer teaching of the causation of the neuroses from a sexual basis makes it attractive to try and connect this form of enuresis with something sexual, especially considering the close proximity of the ejaculatory center to the bladder centers. But I have not been able to establish this, either by dream analyses or by direct psychoanalysis. So all the cases represent a habituated hyperirritability and overstimulation of the vegetative centers, as there is no relaxation of the sphincters, as has always been supposed, but a steady contracture of the smooth musculature of the body of the bladder. Of course it is possible that a dream state of a satisfying nature (these do not disturb the sleeper) might be responsible for the bladder discharge, but as noted, this was not established. Also the persistent contracture of the bladder might be the result of a summation of stimuli carried over from the conscious state, but confirmation of this was not feasible.

Remembering the various points made in the study of these cases, we have figured our treatment accordingly. We give large doses of bromides before retiring, both for allaying the subconscious dream states which may give the stimulation of the lower spinal centers, and also for the same effect on the lower spinal centers themselves. Besides, daily tepid baths are very useful in lowering nervous irritability. Some patients take more kindly to a cold pack in which the patient is allowed to remain for about half an hour and thus it becomes tepid from the warmth of the body. Sometimes we have to reinforce the bromides with antipyrine. The treatment has to be kept up for a long time—three or four months and even five months is necessary for permanently overcoming the annoyance.

Allied to the last neurosis, is pavor nocturnus; the child either crying out in its sleep, or wakes up in fear and cries out in terror. In both forms there may be a complete amnesia of the night's occurrences when the child wakes up in the morning. In those cases that do wake up and also in the ones that speak when they cry out, it is at once seen that a dream is at the basis of the trouble. These conditions have been considered as being secondary to nasal or pharyngeal obstructions, especially the class of patients that only cry out in their sleep. That nasal and pharyngeal obstruction may cause a deep stuporous sleep from carbon dioxide poisoning is not denied; but that it will cause a psychic disturbance is not quite so reasonable, especially since many of my cases have had the attention of nose and throat surgeons with no amelioration. So we must look for other causes for the production of this malady. Thus a little lad of seven (Mt. Sinai No. 123, 1908 series) began to get his sleep terrors during the night after he had seen a man meet with a bad accident during the preceding day. Another boy, 8½ (Mt. Sinai, No. 1419), had been frightened during the day by being left alone in the house and he reenacted his fear in his sleep. A girl of 9 (Mt. Sinai, 794) dreams that a man is harming her, the individual being pictured as forcing his way into her bed and with all the other concomitants of such an occurrence that an imaginative child of that sex will bring out. Of course this dream is added to by the imagination of the child during the waking state and re-enacted in the following night's dreams. So in all the cases there is a psychic disturbance which is responsible for the dream gratification or dream fear—that is, the child sees or experiences while dreaming the things she might want to see, or fear to see while awake. The natural curiosity of the child is such that it gets great gratification even from things it fears, and the greater the fear the greater the resulting pleasure, even as it brings on terror. No doubt nasopharyngeal obstructions keep the child from awakening, but it is not responsible for its dreams nor for the fear induced by these dreams.

For this we must turn for the cause of all mental action, the reaction to environment by the psyche as far as it is developed. Many adults have as much obstruction, but no one would blame the condition of any dream disturbance or mental perturbation to insufficient pulmonary aeration. The older person when he dreams of these things may wake up, but only in unbalanced individuals will they attract attention. In the child the terror is easily shown because it has not become habituated to repressing superficial emotions. These children as a rule are irritable, neurotic, and present as many

fears and aberrations during the day as they do in sleep during the night. And even if adenoids, etc., do modify the symptoms, we must not think that they can be cured by storming the nasopharynx. Investigation of the psychic contents of the child-mind and analysis of its abnormal parts will allow of its resynthesis into normality by one who has larger experience than the child. Until the mental re-education is completed it is well to give a dose of bromide before retiring, or several doses, and of course the physician must remember that the body must be attended to as well as the mind. Here again we have a condition due in a great measure to poor environment and faulty guidance.

One of the most confused conditions seen in early childhood is the appearance of a flaccid condition in the presence of an injury to a limb or a joint, or an inflammation of the same. The cause of this seemed obscure to me since the history as a rule was that of pain and a rigidity of the parts involved, before the apparent palsy occurred. The next day, however, the same parts hung limp and flaccid as if the child had anterior poliomyelitis; in fact, it has to be differentiated from this in every case. The absence from fever cannot be taken into account, as fever may occur in the most simple condition of childhood. The electrical reactions are normal, showing none of the hyperirritability to the galvanic current. (Many clinicians say that they are unable to get electrical reactions in children; this is for want of patience only; they are as reliable in early childhood as in later life.) And in a day or two and often after only a good hot mustard bath the condition passes away. This no doubt represents many of the cases of abortive poliomyelitis. I have seen two such cases recently, one from Dr. W. Pincus and the other from Dr. M. Rosenbluth, and in both crepitation was ascertainable in the knee-joint, which also was tender to touch and passive motion. How this occurs is easily explained; when one considers the undeveloped state of the association systems in the child's central nervous system, it can be readily seen that continual irritation of the centripetal neuron gives the necessary neuron stimulation shown by the reflex rigidity. This in the well developed has more than the merely primary neurons for elaboration and distribution of this inflow of irritations. That is, there are more neurons to do the work in older individuals than in children, but in the child the motor neuron having to bear the brunt of continued stimulation becomes exhausted and gives way.

An analogous condition is the strabismus of early childhood, which demonstrates that this is the mode of the production of these pseudopalsies; these are well known to be due to refractive errors. In older persons, asthenopic symptoms are seldom if ever manifested by muscle palsy, though by careful examination, muscular insufficiency is frequently demonstrated in the eye musculature.

In the child the constant reflex irritation of the eye muscles, which have not their association systems fully developed, give the neurons constant stimulation, resulting in their exhaustion, so that they are unable to receive or send out nerve impulses with resulting palsy of the muscle that these nerves supply and the eye rotates in or out, according to whether there is hypermetropia or myopia. That this is an association neuron defect is shown by the fact that, as soon as the good eye is closed, the supposed bad eye rotates in all directions in following an object, so that it must be the commissural systems between two sets of ocular nuclei which are at fault and not the neurons whose axons immediately supply the muscles. So it is the immature state of the juvenile nervous system which is responsible for this inability to overcome stress from peripheral conditions, and the palsies, temporary in the passing trouma of inflammation of bone or joint, are more or less permanent in the conditions where the error remains. That the eye condition is of the association neuron, is shown by the fact that the rotating eye assumes a correct position when the good eye is taken from the field of vision, and also the cure of the condition when refraction is corrected by the proper glasses, if the condition has not lasted too long.

The most fixed and common neurosis of childhood is that of defective speech, represented by stammering and stuttering. The usual description of this affection is that of a local nervous disturbance of the musculature of the various parts concerned in the formation of correct speech. This affection is universal in its distribution, and occurs in all social levels, and in all races. Heredity and being in the environment of other stammerers has frequently been taken as a cause for stammering and stuttering. Indeed, R. Denhardt* emphasizes heredity as a factor in its causation.

This same author also insists upon the psychic factor in the causation of speech defect. The history given by the patients or their parents is that the trouble was first noticed when the child began to go to school. Since I have become interested in the history of the onset of this particular trouble I am convinced that many if not most of the children faltered in their speech before school age, but it was not observed until the demands of the school made it noticeable as a genuine defect. So it seemed to me that if I could get at the cause of stammering in the three or four year old child it might throw light on the eitology of stammering in older individuals. Lately I have been fortunate to get a clearer history in these very early cases.

In the very young child halting speech comes on suddenly. In some cases it is not continuous during the whole day; in some cases it is. Investigation of the children who stammered intermittently showed that every period of stammering was associated with an act of masturbation. For example, No. 977, Mt. Sinai, age 2½ years, does not speak well for periods during the day. This follows an episode where the child sits in the chair from which it refuses to be taken, and where it is noticed that it rubs its thighs together and then it falls backwards, becomes pale, and seems as if in a faint; after which she allows herself to be moved; but as soon as she is removed she runs from the mother and hides in a corner as if in shame or fear, and when she attempts to speak she stammers for about a half hour after such occurrence. More or less similar histories are to be elicited in more than half of this kind of cases. Of course the cases are not as common as those of older children, but this I think is due to the neglect of the parents in bringing them to notice. The treatment of these cases is universally successful, being cleanliness and good powdering of the genitals and a week of dosing with bromides. Watchfulness is essential, so that the habit with its concomitant speech defect shall not become permanent. And no matter whether the history is obtainable or not, every child who stam-

*Denhardt, Rudolph: "Was ist Stottern," Leipzig, Ernest Keils.

mers between the ages of 2 and 5, yields to this form of treatment.

So here we have a distinct form of typical stammering, the development of which is open and before our eyes, and may we not reason that a similar cause may be at the root of the trouble in older cases? In one-third of the Mt. Sinai cases for the last four years the trouble came on suddenly. Some nervous strain of an acute nature must have been the cause. Thus one came on after a narrow escape from an accident; two others came on suddenly at school; so, as in the masturbating child, acute nervous tension is induced and the breaking point comes when the apprehension is greatest; that is, when or with their being spoken to at some critical moment. The momentary stammer, with its accompanying blush and arrest of attention when the patient stammers on attempting to speak, makes the subject stop and take notice. The stammerer becomes aware that something is wrong with his or her speech, and feels different from those who do not stammer. This feeling of difference from the normal causes the apprehension and gives the halting in the speech when addressed. That this is so is demonstrated by the fact that the stammerer can declaim to himself or herself solus, when the same effort would bring out the defect if the subject were aware that some one were listening; thus we have an acuteness of onset and apprehension as the two great factors in stammering. The third symptom of the stammerer is the mental state induced by the fact that one is a stammerer.

In the child there is retiring from playmates and an introspective feeling of being different from other individuals; not of superiority, but the wish to be like every one else. Not having the larger outer world to occupy its attention as the child who has the normal amount of play and friends, it draws on its limited imagination and creates a little world of its own, into which no outside influences enter. The little patient loses interest in various things that should interest it. It becomes more shy and retiring than ever and has no confidence in itself when it is drawn out from its shell, because it has not had an opportunity to gain such confidence, having kept away from playmates and people who ordinarily would form its world and cause its development by interchange of various amenities. And when attempts are made to bring it out, or give it amusement, there is the expression of apprehension —faltering speech. In other words, we have a defect due to some acute stress or strain, and secondarily an apprehension psychosis.

So, with this in mind, we can face the treatment of stammering from a rational viewpoint: (1) If an acute case, find the cause and correct it by re-education or hygiene. (2) If a fully established case, treat with any well-tried method, the easiest being one of the melody cures. (3) At the same time treat the mental state of the patient so that there should be a more speedy cure and, what is more important, a permanent one.

The excellence of the melody method is that instantaneously the child is shown that it can speak as well as any of its comrades. One does not need any elaborate system of notes or apparatus. The patient is made to speak sentences in a singsong manner, each syllable having the value of a note; the odd syllable being pronounced as a low note and the even syllable as a higher note.

If the patient had enough confidence in himself he would not need the services of a physician with this method at hand, but the patient has not the confidence, from the fact of being a stammerer, and so the training has to be done for him by the physician who at the same time hammers the cure home permanently by analysis and reeducation. Of course, many technical details present themselves, but in the main this form of treatment has given me the most excellent results for the last eight years.

Conclusions.—A child with a psychoneurosis is an anomaly. And when we consider the limited sphere of the child, we wonder how it can develop psychic disturbance. But no matter how circumscribed the view, it is patent that there is a continual inflow of impressions from the smallest of surroundings. And this being continual it no doubt tires the cerebrum whose elaborative functions are as yet but in an indifferent and early state of development. Hence, some impressions are lost, and necessarily are missing in making up various psychic complexes in their entirety, and so the child receives its impressions which go to form its ideas in a broken-up state.

This being so, the ideas must be incomplete, incoordinate, and therefore often unreasonable. So it is no wonder that the child shows aberrations, as it is reacting to the incomplete perceptions and apperceptions—just as in an older person who forms an opinion on incomplete facts. So, if the child shows a departure from the normal in its mentality it must be ascertained whether there is no departure from the normal in the central nervous system, no matter what the cause. Secondly, the nature of its surroundings; and thirdly, the efficiency of its training. We have ruled the first item from the limits of this paper and the conditions that we have treated are, with one exception, due to some ill-balance in the surroundings or training.

It is conceivable that there is dissatisfaction with surroundings, or that there is a desire for better environment, or that there is an inability for adaptation to the particular place in which the person has been placed by birth or accident. Since this cannot as a rule be changed, it becomes necessary to train the individual for better adjustment to whatever position he finds himself, both for comfort and material advantage. This has been what the human has always done, trained himself and his offspring to meet certain conditions, and by taking advantage of past experiences of himself and ancestors he has assumed his kingly position as the head of the animal kingdom. So it all peters down to the state of the psyche in its reaction to surroundings. And how greatly surroundings affect individuals can in a degree be seen from a comparative standpoint from the animal experiments of Thorndike.* He shows that, according to environment, or some modification in the character of the environment, the habits of the animal can be predetermined, so that by simple means of dressure the most complicated habits become a part of the animal.

So, in children, training or education, call it whatever you please, can be so applied that they will become habituated, as in the animal, to the greatest amount of good to self in the particular environment in which it finds itself, and, if there is a malreaction, by tracing the modes of its production and retraining the child from a normal viewpoint will place it in proper accord with its surroundings.

In the adult the phenomena of maladjustment to

*Thorndike, E. L.: "Animal Intelligence," *Psychological Review Monographs*, 1898, Vol. II, No. 4.

surroundings are so varied by the magnitude of his experiences that it requires the most exact psychiatric studies to bring them to the surface. But in the child, whose sphere of action is limited, it is easy to lay bare the psychological content of any given experiences, and by the early training of minds, that from one cause or another have not been trained to adjust themselves to their proper environment, or to rise above it, we can prevent more grave maladjustment in later life, thus bringing in prophylaxis, which should be the main aim of the psychiatrist, as it is of the physician.

NOTES ON LARYNGEAL CASES.*

By WALTER F. CHAPPELL, M.D.,

NEW YORK.

In all parts of the body the diseases which possess the greatest interest are those presenting some difficulty in diagnosis, and this seems to be especially true in diseases of the larynx. The neoplasms, swellings, thickenings, and ulceration occurring in this vicinity present so many confusing manifestations that a definite diagnosis can usually be made only after the patient has been under observation for some time. Butlin, writing on this subject, said that there were three classes of cases. Those on which any one can make a diagnosis; those on which only the better instructed and more experienced make it and others do not; and the third class in which the conditions are so obscure that no one can make the diagnosis unless the larynx is opened, and even then it may be difficult to make sure of the nature of the disease.

Early thickenings and swellings in the interior of the larynx have caused me the most perplexity, and I sometimes think that the more cases I see the more difficulty I experience. Believing that my confrères may have had similar experiences, I venture to present these mingled notes of the interesting parts of many cases. It has been my privilege to watch, from their incipient stage, the course of two neoplasms on the vocal cords, whose appearance, growth, and subsequent history have been so entirely different that they have done a great deal toward helping me to an early diagnosis and the course to be followed in such difficult cases.

A man forty years of age, while suffering from a serious cold, spent about four weeks cooking peanut oil. The fumes were very irritating to his upper respiratory tract and he soon became hoarse. He gave up his employment, but as the hoarseness persisted, he sought medical advice. On examination the right cord appeared quite normal. The superior surface of the left presented three small, separate, flat papules on its anterior third. They had a dull red appearance and looked as though they were a part of the cord pushed up. The anterior papule was the largest and occupied the superior margin of the cord. The other two occupied the center of the upper surface of the cord, one placed behind the other. The color of the tissue between these papules and the rest of the cord had a natural white appearance. There were no other local appearances or symptoms to aid in a diagnosis. The father had died of carcinoma of the stomach and a brother and sister of tuberculosis. The family history did not render any further aid to a definite conclusion; a Wassermann test proved negative. The condition on the cord was fully recognized as being unusual, but the uncertainty of the nature of the papules was so great that I explained the situation fully to the patient and advised him that he should use astringents in the larynx and carefully watch the case. This was agreed to and no change was noted for about a month. The anterior papule at this time became larger and was removed for microscopic examination. The piece examined was very small, but two pathologists independently reported it to be an epithelioma. Having in mind some previous experience when the diagnosis of the microscope did not coincide with the clinical appearance and history of the case, I recommended that the case should be more carefully watched for the development of confirmatory clinical appearances. Several of my associates agreed to this course and also to see the case from time to time. For two months no change was noticeable, but during the third month the anterior papule began to reappear and extend posteriorly, soon coalescing with the other two papules. This seemed sufficient confirmatory evidence of the microscope diagnosis and an immediate thyrotomy and removal of the vocal cord was urged. The patient, however, was in such splendid health and his throat giving him so little trouble that it was impossible to make him view his condition seriously and submit to an operation. He wandered from doctor to doctor for the next six weeks, getting various opinions, which were in the majority against his laryngeal condition being malignant.

When I saw him again the mass on the cord was considerably larger, the surface had a fine granular gray appearance and the hoarseness was more pronounced. After a great effort I succeeded in getting his consent to an operation, which was successfully performed, and there has been no recurrence up to the present, four months after the operation.

The second case was in a man of sixty-three years of age, with a good personal and family history. The laryngeal growth when first seen was about the size of a small French pea, sitting on the superior surface of the anterior third of the cord, but did not seem part of it, there being no thickening at the base and all surrounding tissue being white and normal in appearance. The growth was removed and submitted to microscopic examination. Two competent pathologists were consulted and one pronounced it a papilloma and the other was doubtful, but favored its being malignant. Again I decided to watch the case further, as no clinical appearances led me to think it an epithelioma. During the following eight years the case was constantly under my observation and four times I removed the growth by the introlaryngeal method. The average time of a recurrence was eighteen months, and after its reappearance it grew slowly and always in the same location, and at no time was there any extension of the growth at the base.

Numerous pathologists examined the tumor after each removal and were about equally divided in their reports on its being innocent or malignant. In view of this and the excellent condition of the vocal cords and larynx, I held to the course of noninterference externally. This happy state of affairs continued until the latter part of the ninth year, when an accident occurred which changed the whole aspect of the case. To wash down a capsule, the patient swallowed, as he supposed, about an ounce of water; it was, however, ninety-five per cent. alcohol.

The following morning the laryngeal growth

*Read before the American Laryng. Rhin. & Otol. Society, May, 1913.

was a cherry red, also the mucous membrane of the larynx and trachea, as far as could be seen. Bronchopneumonia followed, which nearly ended the patient's life. The cherry red color of the growth continued for a month, with no increase in size. A week later the color became a deeper red, the growth being slightly larger and edematous in appearance. Two weeks later the base of the growth began to extend anteriorly and soon reached the commissure and blossomed on top, almost over night, like a cauliflower. The clinical appearance was that of a rapidly growing epithelioma, and although a microscopic examination seemed unnecessary, a piece was removed and submitted to a number of pathologists, who unanimously pronounced it a malignant growth. This was removed by an external operation through the thyroid cartilage, and the patient is alive and with no recurrence up to the present time, one year and seven months since the operation.

The change in the clinical appearance and history after the irritation of the alcohol brings up the old question as to the possibility of an innocent growth changing to a malignant one. This case would provide plenty of material for argument on this question. The early appearance and history of the neoplasms in these two cases and in others more advanced, have impressed me with the belief that a competent observer can distinguish at an early stage between the malignant and innocent growth. The former appears as part of the tissue of the region in which it occurs and may seem to grow from under and push up the tissue above, or grow into the surrounding tissue. A papilloma, on the contrary, sits on the surface of the tissue and does not seem to form part of it.

Malignant growths when removed in whole or part return quickly and almost at once begin to extend at their base; even when not disturbed their first change is usually at the base. Innocent tumors do not return quickly when removed, neither do they spread from the original base as long as their innocent character is maintained. Furthermore, I have found that it is quite safe to defer a major external operation until the clinical appearances and history confirm the microscopic diagnosis of malignancy.

Thyrotomy for early cases of laryngeal epithelioma is yearly increasing in popularity, and any advance in technique or better prognosis is anxiously awaited by all. No intention is here made of giving in detail my cases of thyrotomy, but only a brief expression of some of my views, especially those on the management of the tracheotomy. At another time I intend to present in detail all my cases of thyrotomy. The practice of using a tracheotomy tube during the operation for thyrotomy has been generally followed, but there has been quite a difference of opinion as to what should be done with the tube after the operation. A few have taken it out immediately and allowed the wound to granulate, while others have left the tube in from one to five days. Some operators introduce a tube a week or ten days before the operation and let it remain in the trachea two or three weeks after.

My belief for a long time has been that whatever danger or difficulty was attached to an operation for thyrotomy, was due to the presence and irritation of a tube. During the past winter I have performed thyrotomy in three cases, two for the removal of epithelioma of the vocal cord and a third for a more extensive involvement of the anterior part of the larynx. In one case a tube was used during the operation and removed the following day, in the other the ordinary tracheotomy tube was not used, but a long soft piece of rubber tubing was substituted, and removed as soon as the operation was completed.

Two cases have been treated after this method and their success was so satisfactory that some notes of it are related in this paper. When the trachea was exposed it was carefully pulled forward by a fine tenacium placed on either side. A small opening was made in the trachea and a long soft rubber tube introduced. The chloroform was administered through this and packing put in above the tube to catch the blood and mucus and prevent it running down the trachea, the same as we treat the ordinary tracheotomy tube. As soon as the operation was finished the tube was removed from the trachea and the wound was closed with stitches, excepting a small superficial drain at its lower part. In dealing with the larynx all tissues were treated gently and with as little traumatism as possible. The thyroid wings anteriorly were pared on either side with a sharp and heavy knife. These cartilages should never be crushed with heavy forceps as small bits of detached cartilage will remain and become necrossed, causing trouble for months afterward. Every small vessel should be tied or twisted so as to leave a perfectly dry surface. No adrenalin is necessary, and is apt to cause secondary hemorrhage. When the work on the larynx was concluded the entire external wound was closed and two small superficial gauze drains left in place, but no packing in the larynx. This patient raised a little blood for a few hours after the operation but had absolutely no cough at any time and no tracheal or bronchial discharge. The external wound healed almost by first intention and a rapid and wonderful recovery was made.

This is the second case in which I have operated without the usual tracheotomy tube and by closing the external wound completely. Tracheitis, bronchitis, and bronchopneumonia, which has so constantly followed this operation is, in my opinion, due to the use of a tracheal tube and its retention afterward, also to unnecessary traumatism and prolonged operation. In my future early and limited cases I do not expect any occasion to arise for the use of the usual tracheal tube and shall treat the operation as one wherein we may expect a primary union, with the usual satisfactory results. Granulations in the anterior part of the interior of the larynx always follow this operation and it takes from two to three months for them to become organized tissue. This new tissue helps to strengthen the larynx and should not be subjected to much cauterization.

A fourth case of thyrotomy for carcinoma of the cord occurred in my practice about two years ago. This case has proved very interesting as an entirely new cord of cicatricial tissue has replaced the one removed and is about an eighth of an inch wide, has its full length, and is white in color and placed exactly opposite the other cord. The voice is really excellent at times but as a good part of the thyroid cartilage was removed the vocal sounds cannot be sustained for any length of time.

When the posterior fourth of the cord is healthy, or even a small part of it, I leave a piece attached to the arytenoid cartilage as it gives an increased point of strength and makes the voice much stronger after recovery. One of my cases did not

come under observation until the entire anterior part of the larynx was infiltrated with malignant disease and although all of the larynx, excepting the arytenoid cartilages, was removed the patient spoke very well and could be heard ten feet away when the tracheal wound was closed.

Since the direct method of operation on the larynx has come into use, there is a great falling off in the number of men who are able to do skillful work by the indirect method. I do not believe that at any time every specialist was very adept in laryngeal operations and only a few could promise a removal with absolute certainty. The direct method has opened this field to a great number of men as it does not require the skill and patience necessary for the indirect method. In my experience after carefully trying the new method I unhesitatingly favor the indirect method. It is not only easier for the skillful operator but also easier for the patient, causing less traumatism and a much more exact operation can be done. The kind of instruments for use for the indirect method need a careful selection and in my opinion the MacKenzie laryngeal forceps should not be employed as they are too large, obstruct the view, and do not allow of exact manipulation. Fine snares and some of the new instruments are much better. Patients differ very much in the distance from the teeth to the larynx, also in the curve of the pharynx and larynx, all of which are factors to be considered. Specialists who do much of this work must be provided with instruments of various lengths and curves to accomplish a successful and skillful operation.

Two recent laryngeal cases have been selected as showing some of the difficulties which we may encounter. The first case on laryngeal examination showed a small triangular tag of red tissue below the left cord and well forward in the anterior commissure. It was only apparent on phonation, when it momentarily flashed into view to be lost immediately after. In addition to the difficult location, the patient had a long back and a large chest and abdomen which prevented the operator from getting a satisfactory position. He was easily nauseated and so nervous he could not hold his tongue long enough for an examination. This picture of difficulties did not look promising and he had already been treated by a specialist for five months and various attempts made to remove the growth. To produce anesthesia, 20 per cent. cocaine was employed, sprayed gently with a hand atomizer on the soft palate, pharyngeal wall, root of tongue, and epiglottis. With a laryngeal syringe the solution was dropped into the upper part of the esophagus, larynx, and upper part of the trachea. The mucous membrane in these sensitive cases should never be touched with the usual cotton on an applicator, as it disturbs the reflexes more readily than the method I have described.

A few drops of cocaine in the upper part of the esophagus is of great assistance when there is a tendency to gaging and nausea. Properly employed 20 per cent. cocaine solution will quiet any rebellious larynx for operative procedure. To meet the difficulties of a patient's nervousness, I have trained my operating nurse, so that standing behind the patient she can hold the tongue with complete success.

The instrument employed for removing the growth was one of Pfau's own models of his new universal laryngeal forceps, with a dull cutting bite, bent from the shank toward the growth. Its movements could constantly be watched and when the patient phonated and the growth momentarily came into view, it was seized and promptly removed. Any of the older laryngeal forceps would have obstructed the view of the operating field and could never have caught the growth without a great deal of unnecessary traumatism.

The examination of the second case showed a small triangular papilloma at the junction of the anterior and middle third of the cord but on its under surface, and bobbing into view only on phonation. An unsuccessful effort had already been made to remove it before consulting me. A long thick uvula and epiglottis tipping backward obstructed the laryngeal view. Partial removal of the uvula and a black silk thread passed through the base of the epiglottis, pulling it forward, solved our troubles.

The various shapes and sizes of the epiglottis are frequently a difficulty in laryngeal cases and can usually be treated as described. Snares are recommended for the removal of large and medium size growths. Dull cutting instruments for small growths. Never try to take a piece off a small growth, except for examination, but wait until you can seize the entire mass.

My concluding notes will be on an interesting condition which of late came under my notice and which for want of a better term I have called "laryngeal snoring." During the past winter a gentleman consulted me for peculiar attacks of breathing while asleep. His history was as follows: For about five years he had snored at night making the usual noises. Three years ago his wife noticed that while snoring his breathing would gradually become slow and shallow and continue so all night, with an occasional snort and blow which brought temporary relief. After about a year all these symptoms became exaggerated, the respirations more labored and shallow, and the face gradually became blue. After an hour of this breathing the patient became completely cyanosed, stopped breathing, threw up his hands like a drowning man, and had a general muscular convulsion. When this took place there was a loud violent expulsion of air from the larynx and trachea and respiration was reestablished. The patient was not wakened by this but continued as though asleep and soon began the noisy respiration again and continued until another attack, and so on until seven or eight occurred during the night. Latterly the attacks were so severe that his family feared he would die of suffocation, and his health began to fail from the carbonic acid poisoning from which he suffered every night. On examination the larynx was found high in the pharynx and the uvula and soft palate normal in size but hanging a little lower than usual. The mucous membrane of the uvula, soft palate, and larynx was edematous and covered with white creases, resembling the hands of a washwoman or one who had soaked the hands in hot water or had had them in a poultice. I concluded this wrinkling of the mucous membrane was due to smoking as it is not unusual in heavy smokers. This patient, however, did not smoke and some other cause had to be found to account for such a condition. Thinking over the case it occurred to me that while the patient slept the uvula dropped low in the pharynx and was sucked in and out of the larynx until complete occlusion was produced. A violent expiration then expelled the uvula from the larynx and temporarily reestablished respiration. Acting on this

theory the uvula was removed and no attacks have occurred since the day of the operation.

The possibility of laryngeal snoring was so forcibly brought to my attention by this case that I have since diagnosed several less severe but similar cases.

7 East Fifty-fifth Street.

METHODS IN JOINT DIAGNOSIS.*

By WILLIAM S. THOMAS, M.D.,

NEW YORK.

EXAMINING PHYSICIAN, ST. LUKE'S HOSPITAL.

The subject of this paper is methods in diagnosis rather than diagnosis itself. For the purposes of a short paper it has been necessary to limit the subject thus and I shall deal principally with lesions which are the results of injury.

Examinations of joints are made in two different ways; first without apparatus and second with apparatus. Another method must be briefly considered, namely, diagnosis by means of drugs, and I shall stop in this connection only to say that the principal instance of making a diagnosis in this manner is, as will doubtless occur to you at once, the use of salicylates in suspected cases of rheumatism. My impression is that it is a frequent practice to employ insufficient quantities of these drugs. Doses large enough to cause mild toxic effects are necessary to clear up the diagnosis or to effect a cure. "The true rheumatic can tolerate 150 to 350 grains of the sodium salt before toxic symptoms occur, whereas in other forms of arthritis the same occur with smaller doses." Thus in a series of experimental cases in gonococcic arthritis the average dose necessary to produce toxic symptoms was 131 grains. In true rheumatism the fever, pain, and swelling disappear after salicylates in two or three days, whereas in other forms of arthritis, while the temperature may fall to normal, there is no change in the swollen joints. True, the pain may be less, but this is due to poisoning of the sensorium, for when the effects of the drug wear off the pain is as acute as before.

The physical examination of joints should be made, as far as possible, when they are in a state of rest and when the neighboring muscles and tendons are thoroughly relaxed. For instance, a knee should be examined when the leg is lying in an extended position, if possible with the whole limb supported by bed or chairs. It may not be amiss for me to urge the importance of a thorough exposure of the joint before the examination is begun. How often do we see a physician examining a knee joint with the patient's trousers and drawers rolled up tightly so that but an incomplete exposure of the joint is permitted and at the same time the tight garments produce a deceptive change in the contour by pressure. A correct method—and no other can be justified—demands not only the exposure of the affected joint but in each and every case the exposure of its opposite fellow as well, for the sake of comparison. It is also worth while to remember to examine all aspects of the joint, not only that nearest the observer. Thus, much can be learned at times by passing the fingers into the popliteal space or into the axilla. It will not be harmful if we hark back to student days and recall how we learned that physical diagnosis employs inspection, palpation, percussion, and auscultation. These methods serve us in the examination of diseased joints as well as in diseases of the chest.

Inspection.—When inspecting a joint we look for change of contour, either swelling or atrophy, redness, ecchymosis, glazed tense skin, wounds, sweating, limitation of motion, and deformity. In nearly all of these conditions one is likely to be deceived if they are present in but slight degree if we do not take the trouble to compare the affected joint with its healthy fellow. The spindle-shaped *swelling* of a tuberculosis joint with its atrophy of the muscles above and below gives a very different picture of swelling from that of a simple chronic synovitis. The *redness* of acute articular rheumatism differs from the redness of a beginning purulent infection in remaining more circumscribed and practically always being accompanied by similar conditions in other joints. An interesting differential point in *ecchymosis* about a joint is the time of its appearance after injury. If the hemorrhage is entirely within the joint capsule as in dislocations it will require two days or longer before the skin is discolored; but if the ecchymosis is from a fracture in the neighborhood or contusion it will appear within a few hours. The profuse sweating of rheumatic joints is quite characteristic and is useful as a diagnostic point. The interesting question in the case of wounds near joints is whether or not the capsule is penetrated. The endothelium lining joint cavities is notoriously prone to become infected where other structures might escape and an infected joint is always a serious matter. The limitation of motion which is observed by inspection is of the active sort and the natural method of examining for it is to have the patient seek to use it for ordinary purposes — the lower extremity by walking, the upper by lifting or carrying, when possible. Passive motion is elicited by the hand of the examiner and brings us to the palpation of joints as a method of diagnosis.

Palpation.—Here the practised hand is necessary and should be assisted by frequent recourse to comparison with the healthy joint opposite, whenever this is possible. The sense of touch reveals the following conditions, viz., presence of an excess of fluid in the joint, spasm of the neighboring muscles, grating or crepitus on motion of the joint, tenderness, heat, pitting, the amount of mobility in all directions, both normal and abnormal. Palpation will determine also the presence or absence of fracture near the joint or separated epiphysis.

Muscular *spasm* in joint disease more or less completely fixes the joint in one position and is a symptom of extreme significance. While considering this symptom of spasm it will be well to remember the difference between the false and true varieties. On moving an affected joint a nervous patient may stiffen the surrounding muscles in his fear of pain, but when reassured and gently dealt with will be able to relax and permit the joint a degree of normal movement. On the other hand the immobilization of the joint by the rigid muscles may be quite beyond the patient's volition, disappearing only under general anesthesia. This is true spasm and as such is a valuable diagnostic aid and of grave significance. During sleep this true spasm may relax a little and allow enough motion in the joint to cause the eroded and tender cartilages to rub each other and thus cause pain which awakes

*Read before the West Side Clinical Society, March 12, 1913.

the patient with a cry. Thus are explained the so-called starting pains of certain forms of arthritis, particularly tuberculous. To elicit spasm the limb is grasped above and below the joint while gentle attempts are made to move it. In true spasm the joint will be apparently immovable, as though truly ankylosed. Spasm is usually the first symptom to appear in a tuberculous arthritis and is the last to disappear if recovery ensues. Accompanied by its partner, muscular atrophy, it goes far towards justifying a diagnosis of tuberculosis. In no case is accuracy more important than in the determination of wasting above and below the joint. It is necessary at this point to anticipate mention of the use of apparatus by calling your attention to the importance of the use of the tape-measure in eliciting the symptom of atrophy.

Fluctuation about a joint is one thing if due to fluid in the subcutaneous fascia and an entirely different matter if the fluid be confined within the joint capsule. Distended bursae in the neighborhood of joints are met with often and confuse the diagnostician at times. If the fluid be subcutaneous it will probably be either serous or purulent. If serous there will be pitting on pressure and probably no great amount of tenderness and no fluctuation; if purulent there will be redness and tenderness, besides the pitting and fluctuation if an abscess is present. In both of these cases the motion of the joint will not be markedly interfered with. If, however, the fluid be within the joint the symptoms will be seen to differ if their details are carefully worked out. In this case if there is considerable swelling and it is due to fluid in the joint, fluctuation may be elicited in the classical manner by feeling with the tips of the fingers of one hand while tapping at a distant point over the swelling with the fingers of the other hand. In attempting to elicit the symptom of fluctuation in this manner in any location where muscular tissue is present, it should not be forgotten that the space between the sending and receiving fingers should be along the muscle fibers and not across them. When percussing across a bunch of muscle fiber one is apt to be deceived by a false sense of fluctuation.

To elicit *grating* or *crepitus* of the joint surfaces upon each other when moved it is necessary to grasp the joint in the hand. A refinement of diagnosis has been attempted in this connection by use of the stethoscope but the sense of touch is apparently quite as satisfactory either in the case of an old syphilitic joint or in a badly disorganized Charcot joint when spasm is absent. Grating can seldom be elicited in tuberculous joints because, though the condition of the articular surfaces might well be such as to cause crepitation on motion, yet muscular spasm will have immobilized the joint, thus preventing the sensation. The symptom is often of no apparent significance.

Tenderness is an interesting symptom when present about a joint. In acute articular rheumatism it is greatest at the area of redness and here it is extreme. In the case of a beginning tuberculous invasion it can often be elicited at some special point in the bone, for in about sixty per cent. of tuberculous joints the process begins in a focus in the bone near the joint, while the remaining forty per cent. commence in the synovial membrane. Here the tenderness is more general. In the case of joint effusions following injuries, careful palpation with one finger tip will often find a tender spot over a torn ligament. In the majority of cases of traumatic synovitis there is a starting point of ruptured ligament or capsule. From this point the synovitis spreads all over the capsular surface and so long as such a spot of local tenderness reveals the unhealed tear in the torn ligament the joint must be considered diseased and the treatment continued even though effusion and other symptoms have disappeared.

It is not always necessary to touch the joint to elicit the symptom of tenderness. Which one of us is there who has not seen a patient with acute gouty or rheumatic arthritis wince or cry out when a finger is pointed at his inflamed joint?

Local *heat* about the inflamed joints as elsewhere is of great diagnostic importance and to determine its presence the back of the fingers are found to be more sensitive in determining slight changes than are the palmar surfaces. The palpating fingers are shifted gently from the surface of the joint to other places on the limb in order to compare their respective temperatures.

Passive mobility is a symptom the determination of whose character is not to be omitted in the examination of any diseased joint. The limb is grasped below the joint and steadied above while movements are made as far as conditions will permit. These passive motions are made gently and slowly first in the normal directions of flexion extension and rotation. Spasm may check the slightest attempt at motion or may be so slight as to permit it to a very extreme degree. A dislocated joint always suffers great limitation of motion and in fact all of the important diseases to which joints are subject are causes of restricted movement with one striking exception, namely, swollen, flabby, disorganized joints of tabetic patients—the so-called Charcot joint, which has also been called the caricature of an arthritis. If the joint be fixed or if passive mobility be limited, the attempt must be made to ascertain to what this is due. If caused by a disturbed position of the bones from fracture or dislocation or by bony outgrowths the movement of the joint may be suddenly checked at some point in its range. When the fixation is due to changes in the soft parts, joint motion may cease less abruptly, and when it has reached its apparent limit may be carried yet a little farther by added force on the part of the examiner. The diagnosis between these two forms of ankylosis, viz., that due to misplaced bone and that due to abnormal soft parts, will at times require the use of a general anesthetic, preferably nitrous oxid.

Abnormal mobility, that is to say, mobility of a joint in directions which should be checked by the surrounding ligaments, must be tested for. Charcot joints as well as the ricketty joints of children or adolescents or the flail joints following anterior poliomyelitis, or again a fracture of the humerus at its lower end, all may present the symptom of abnormal mobility. That is, instead of motion being limited to flexion and extension, for instance, a greater or less degree of lateral motion is permitted.

In the diagnosis of joint diseases without apparatus there remains one method closely allied to palpation, of occasional service, and that is

Percussion, not of the affected joint, but striking the end of the extended extremity with the hand of the examiner. The principal use of this procedure is in the case of a suspected fracture near a joint. For instance, in the case of a fractured phalanx, a percussing tap against the tip end of the extended

digit will elicit sharp pain at the site of fracture and help to differentiate it from a sprain or contusion, and this method is of use in the case of an injury at the hip joint, knee, elbow or shoulder.

Auscultation.—One does not usually think of auscultation as a method to be applied in the diagnosis of joint diseases, although Garrod in the *Lancet* of last year maintains that he is able to detect significant sounds with the stethoscope in cases of arthritis before other signs are manifest upon physical examination. The coarse or grating noises, which may sometimes even be heard at a distance, are due to the grating of rough articular surfaces which may be more delicately examined by the sense of touch. There is an interesting use for auscultation, however, which should be mentioned here. A fractured clavicle is often confused with shoulder joint injuries. When it is suspected the stethoscope is placed over its outer end and pressed firmly against it. If now the inner end of the bone be tapped with the end of the examiner's finger, or with a percussing hammer, the sound will be distinctly borne along the clavicle if the bone be intact. If it be fractured, however, the sound of the blows will be almost inaudible. Comparison with the sound side will be of much assistance. This is a very useful sign.

Those methods of diagnosis in joint diseases which require the use of apparatus will include procedures at the bedside and those in the laboratory. Time does not permit us to dwell upon laboratory methods at any length, but it is proper to remember at this time the value to the examiner of a differential *blood count* where the question is one of the presence of suppuration in a joint; of bacterial *cultures* of aspirated fluid for the determination of varieties of infection; of the examination of a *urethral smear* or complement fixation test where a gonorrheal arthritis is suspected; of a Wassermann test for syphilis of the joints, and of the *tuberculin* test. The preferable method in the latter case is that of von Pirquet as applied to the skin. This test is applicable only in the case of young children for, as you are aware, a positive reaction to tuberculin in adults may mean nothing more than the presence of a tubercular focus anywhere in the body which may have been long since cured. For lack of time I must omit mention of details of *x*-ray examination.

Tape Measure.—The most generally useful artificial aid to the diagnostician is perhaps the tape measure. In the case of injuries to joints it is not only proper to test for slight degrees of enlargement of the joint by measuring its circumference as compared with that of the unaffected side but also for comparative measurement of the enlargement at different times. The tape feasure will also determine accurately as will nothing else changes in length of a limb in fracture or dislocation. When thus used for longitudinal measurements a pencil mark is made over the bony prominences on both sides above and below the site of injury as points of departure.

In the lower extremity the anterior-superior iliac spines and the malleoli; in the upper extremity the acromion processes and the knuckles are made use of as landmarks. The conical shape of portions of the limbs cause a difference in circumference at points but a little distance apart, hence it is important to select precisely corresponding parts on both well and affected sides for measuring their circumferences.

Calipers.—At times measurement with a pair of calipers is the only way in which we can determine spreading of the ankle joint or undue distance apart of the condyles of the humerus or femur. Now and then circumstances will demand an exploratory incision into a joint to determine the presence of foreign bodies, etc., but this subject is one for a paper by itself.

Aspirating needle.—Of more frequent necessity is the aspirating needle. With proper surgical cleanliness there need seldom be hesitation in using a rather coarse hypodermic needle such as is used in intramuscular injections in order to determine the nature of the fluid where effusion into joints is present. If a gonorrheal infection of a joint is among the possibilities the patient should be required to pass some urine into a tumbler and the presence of shreds or pus in the specimen will assist in clearing up the diagnosis.

Anesthetics.—Where the examination of a diseased joint is painful and doubt exists as to the nature of the affection the patient is entitled to the aid of a general anesthetic. In such cases the judgment of the examiner must decide which one to use. I have come to depend more and more upon nitrous oxide gas as a means to relax spasm and prevent pain, especially in injuries about joints. Often a great light is thus suddenly shed upon the problem.

Methods in the Case of Special Joints.—Each class of joints has its special clinical aspects. For instance, in diseases of the shoulder the formation of adhesions and stiffness are especially frequent. In affections of the knee effusion is often the noticeable feature, while in diseases of wrist or ankle pain seems to stand out prominently.

In examining the *knee* for effusion one is apt to be deceived by the usual test for floating of the patella unless he is careful to press upon it directly in the center. I have seen cases where an unusually long patellar ligament allowed the lower edge of the patella to ride up so that when tapped or pressed it would give a deceptive sense of floating although there was no excess of fluid in the joint. The frequency of a dislocated semilunar cartilage in knee cases makes it necessary to examine intelligently for the existence of such a lesion. Often the upper end of the tibia is difficult to find though this is the landmark for the disks and its edge should be carefully palpated in order to determine whether the coronary ligaments which hold the disks in place have been torn. In order to find the upper surface of the tibia and thus locate the coronary ligaments and semilunar cartilages of the knee I have devised the following method: the patient sits quite relaxed with the foot of the affected side resting upon the opposite knee. The weight of the limb causes rotation of the knee and a marked depression appears at its inner anterior aspect. This pit can usually be both seen and felt and its location is marked upon the skin with a pencil. When the knee is again extended the pencil mark may be carried transversely around the knee and will show the site of the edges of the disks.

If effusion into the knee joint is apparent and fever, redness, tenderness, pain or other circumstances make it proper to determine its character, aspiration is performed preferably by puncturing with the needle at right angles to the surface just outside the outer edge of the patella at its middle when the leg is extended. Examination for joint mice seldom succeeds in demonstrating their pres-

ence to the diagnostician. Mice hide from the cat. By grasping the leg and flexing and extending often with the leg rotated, the body may at times be felt about the patella or along the edge of the disks, or the joint be made to lock, but as a rule the diagnosis is presumed from the history of sudden and painful locking and verified by operation. If a tender line along either coronary ligament coexist with inability to extend the leg fully as a result of injury, one is pretty sure to find a dislocated semilunar cartilage—usually the internal one.

When pain is complained of in the knee with no physical signs of a lesion there, one should examine the region about the hip for the cause. Not only is the pain of a hip inflammation often referred to the knee but I have seen a patient who, as a result of a trolley accident, had torn his thigh adductors at their origin, suffered long-continued pain in his knee and was treated for weeks for synovitis of that joint when it was sound.

In the case of the *shoulder,* if the head of the humerus is in its socket, then, and only then, can the hand of that side grasp the opposite shoulder. This fact justifies the common test when luxation of the humerus is suspected.

Many of the stiff, lame or painful shoulders are caused by a subacromial bursitis and the tender spot just beneath the acromion process reveals its presence even though the sac be not enough distended, as it sometimes is, to cause a noticeable swelling under the deltoid. Abduction of the arm pushes the bursa under the process so that tenderness disappears in this position of the arm.

The movement of the scapula upon the chest wall is so great that even when the humerus is firmly ankylosed to it, there is a surprising amount of movement of the arm. When examining movements of the shoulder, one hand should remain in touch with the lower angle of the scapula as the arm is raised and lowered from the side.

The head of the humerus can be felt to rotate by the finger tips, palm uppermost, in the axilla, and in suspected cases of fracture of the neck of the bone this is a method of examination of the first importance.

IS STERILIZATION DESTINED TO BE A SOCIAL MENACE?

By G. FRANK LYDSTON, M.D.,

CHICAGO, ILL.

It is hardly necessary to state that I am thoroughly in sympathy with the employment of sterilization in social therapeutics. I was one of the pioneers in promulgating the theory and practice of sterilization of the socially unfit, and have had no occasion to change my views as to its value. It is a truism, however, that any therapeutic resource which is beneficially potent is also capable of harm. This is quite as true in social therapeutics as in the ordinary kind. It is the purpose of this brief paper to discuss some of the possible evils of sterilization.

Sterilization a Possible Menace to the State.—The laity is already becoming familiar with the technique, safety, and effects of sterilizaton upon the sexual function, and is aware that infertility, not impotency, results from it. The consequence is that, more often than the profession at large is aware, laymen are appealing to the surgeon for sterilization as a means of evading the responsibility of the procreation of children. That the surgeon will in future be still oftener appealed to is inevitable. The assumption of the responsibility of procreating and rearing children demands a certain degree of self-abnegation and self-sacrifice which many of both sexes gladly avoid. The fact that sterilization in either sex does not impair sexual power is likely to appeal very strongly to the average man.

The desire to avoid the physiological results of the sexual act is necessarily stronger out of wedlock than within it. Not only will sterilization appeal to the male sex but also to the female, perhaps in some instances more strongly, because of the fact that the burden of responsibility and care of bearing and rearing children falls most heavily on the female.. Especially will it appeal to the female because she herself need not submit to the knife in order to accomplish the desired result.

The Economic Phase of Sterilization.—The foregoing considerations are inextricably commingled with economic conditions. The increased cost of living, which means increased obstacles to matrimony, bears particularly on the expense of rearing a family. Economic conditions are likely to grow worse instead of better. The proportion of marriages will necessarily decrease. Sterilization obviously is an answer to some of the problems which confront society in reference to the expense incidental to rearing a family.

A very important phase of the economic problem that confronts people of marriageable age is necessarily the probability of children. Under present conditions the average wage earner is compelled to remain a celibate on account of the disproportion between wages and the amount necessary to maintain a family. It is possible that sterilization may increase the proportion of marriages among wage earners.

The Moral Aspect of Sterilization.—While it may be an open question whether sterilization will increase the proportion of marriages, there can hardly be any doubt as to its demoralizing effect, according to present ethical and moral standards of sex relations. Under present conditions a rapidly increasing class of wage earners is commanded by society to remain sex neuters. This is especially true of the female wage earner.

The sex function alone of all the functions of the body is commanded by ethical considerations and moral law to remain dormant. As a matter of fact, however, it does not and will not remain dormant.

Society has not yet arrived at the stage of development which would enable it to openly face this issue. Society merely shuts its eyes and goes on mouthing impractical and hypocritic ethical and moral inhibitions of biological law.

If the practice of sterilization ever becomes at all general, society eventually may be compelled to admit that inhibition of sexual immorality has depended more upon the danger of paying the physiological penalty, especially on the part of the female, than upon any moral or ethical influence *per se.* Remove the danger of pregnancy and we take the lid off.

Sterilization as a Substitute for the Abortionist.—However much the fact may be deplored; however strenuously we may legislate and preach against abortion, the practitioner of this illegal operation is, under present moral and economic con-

ditions, a popular and unavoidable social institution.

The substitution of the term "curettement" for the term "criminal abortion" has merely served to conceal the fire and to make the custom more widespread among supposedly decent physicians. Sterilization may prove to be a social factor which will greatly limit the practice of abortion.

Sterilization and the Church.—The church, which has always exercised a supervision over the right of the human being to procreate or not to procreate, will soon, in my opinion, have a very important problem on its hands, and will have to join with the State in the endeavor to regulate the practice of sterilization.

Whatever religious views one may hold upon the subject, and whatever social theories one may entertain, it must be admitted that the individual right to determine whether or not he or she shall have children, and when, and how many shall be procreated, is at least an open question.

The large family is an ideal proposition in the abstract, but in the concrete, in the light of present economic conditions, there are those who believe that not to be born at all is better than a life of misery and degradation, and that a few children, properly reared, should be the ideal of the family rather than a large number of children who can by no possibility be brought up as healthy and useful citizens. That woman should be sacrificed, as she often is, to the "Rooseveltian" idea of a large family has never been quite so clear to me as it seems to be to some.

Church and State unite in condemning all methods of prevention of conception. Will not both, if consistent, be compelled to "sit up and take notice" when sterilization of "the fit" becomes popularized?

Relation of Sterilization to Illegitimacy.—Should sterilization supplant the abortionist as a social institution, it will be a saving factor for certain of the unborn.

Society's attitude toward the abortionist is about as inconsistent as any social folly that could be mentioned. The woman who bears an illegitimate child becomes a social pariah. She is downtrodden by man and despised of woman. Her child is branded as a bastard before it is born, and again branded directly afterward. The State practically does nothing to save the life of the illegitimate child, or to preserve its health and morality and develop it into a useful citizen.

If the bastard child were the arbiter of its own destiny, it never would be born.

A demand for the abortionist is created by society itself, and then society penalizes the operation of abortion, rubbing its hands in hypocritic and savage glee whenever a poor starveling who is caught in the act is convicted and sent to the penitentiary as a sop to the Cerberus of ethics and morality. The fact that where one abortionist is punished thousands go unscathed does not weigh in the balance.

Individual Rights versus State Rights.—I will concede, for the sake of argument, the right in general of the individual, male or female, to be sterilized, especially in view of the fact that in the case of the male sterilization need be only temporary.

I will concede, also, that sterilization is a valuable therapeutic resource in certain diseases, and a valuable preventive of the transmission of disease and degeneracy to the unborn.

I will further concede that under proper regulation it will be of immense advantage to the State.

I nevertheless hold the opinion that the laws to protect society against the criminal and other unfit classes *by* sterilization must soon logically be followed by laws to protect society *against* sterilization, said laws being in the way of regulation of the operation on "the fit."

As to where the individual right to be sterilized ends and the State's right to prohibit sterilization begins, that is a subject which will require very careful study, wide experience, and considerable time for its elucidation.

The regulation by the State of the surgeon's practice of sterilizing the unfit is a corollary of the foregoing, and probably will be the most practicable way of handling the problem by the State.

The foregoing possibly will be considered by some as a prophecy by a social alarmist. I believe, however, that what I have said comprehends merely the logical results that may be expected to accrue from the inevitable familiarity of the public with sterilization and its results. Possibly it may come with better grace from myself, who always have been a strenuous advocate of sterilization as a factor in social therapeutics, than from others who have not been quite so friendly to this particular method of social self-defense.

32 North State Street.

ANATOMY OF THE UTERINE-PELVIC SUPPORT.*

By JOHN W. WINSTON,

NORFOLK, VA.

The uterus, which is not a fixed organ, lies within the pelvic cavity, and is held in position by folds of peritoneum and certain bands of unstriated muscle. The uterus is divided into an upper portion called the body and a lower called the cervix. These two portions are divided by a constriction known as the isthmus, and it is also known to be the weak portion of the uterus for it is here that pathological flexions take place. In the virgin this point is midway between the two extremities, but in the woman who has borne a child it lies near the junction of the middle and lower thirds. This gives one important reason for the greater frequency of flexions in those who have borne children. The upper portion is not only longer but is heavier and its support is relaxed. The direction of the uterine axis is not fixed but varies with fullness of the bladder and rectum. Its long axis is the same as that of the body, but when the bladder is empty it may incline forward to the extent of 15° or 20°.

The position of the internal os is at the level of the isthmus, and, as stated, in the virgin is at the middle of the uterus. Attention may be called to the fact that in labor it is only the cervical portion of the uterus that undergoes dilatation and stretching. Above this point there is only contraction and below only dilatation. It is, therefore, very evident how important is the subinvolution of the lower half of the uterus, especially when one remembers that the attachment of the uterosacral ligaments is at the upper and back portion of the cervix. The lengthening of the extravaginal cervix takes place from below upward and the longer it becomes the more relaxation it allows of the uterosacral ligaments. A tear of the intravaginal cervix has little effect upon the uterine support, but as soon as a tear extends to the extravaginal portion of the posterior wall it allows a relaxation of the uterosacral ligaments. The vaginal walls constitute one of the

*Read before the Norfolk County Medical Society.

main factors in holding the uterus down in the pelvic cavity and any relaxation or stretching of these walls, especially the posterior, allows the cervical portion to move upward and is most important in causing relaxation of the uterosacral ligaments. It is very evident, then, that shortening of the uterosacrals alone cannot restore to a normal condition unless the whole fault comes from stretching of these ligaments alone. At first sight it appears that shortening the posterior vaginal wall would pull the uterus backward as the posterior attachment is higher than the anterior, but what it does is to put tension on the uterosacrals and tension of these ligaments pulls the lower back half of the uterus its way and the fundus must go forward.

The uterus is held in its position by so-called ligaments, peritoneal and muscular. The peritoneal are six in number, two anterior, two posterior, and two lateral. The two anterior are the uterovesical ligaments, and while they are only very slightly supporting, their attachment at the front of the isthmus affords a point on which the axis of the uterus hinges.

The posterior ligaments are still less supporting, as they sweep over the cul-de-sac of Douglas and reach the uterus at the inferior edge of the extravaginal portion of the cervix. Together with the uterosacrals, they assist in pulling the lower pole of the uterus upwards and backwards. The lateral ligaments are generally classed as two, but there are really four, two being peritoneal and two of unstriped muscle fibers. The lateral peritoneal or broad ligaments are attached to the sides of the uterus enclosing the uterine vessels between them and pass outward, spreading out like a bat's wing to become attached to the pelvic walls, the upper portion enfolds the fallopian tubes and passes out to the pelvic wall to be attached to the obturator fascia, that part from the end of the tube to pelvic wall is called the infundibulopelvic ligaments and it is here that one can best take up the slack in the broad ligaments.

The lower part of the broad ligament is adherent to the levator ani and rectovesical fascia. The external part lies against the obturator fascia and between the divergence of this ligament there is fat-bearing cellular tissue. The upper and lateral portions of the broad ligaments are direct continuations of the peritoneum covering the lateral walls of the false pelvis and lateral abdominal walls. Any relaxation of the above peritoneum will cause relaxation here and this shows how relaxed abdominal walls and general visceroptosis lead to displacement of the uterus. Any tear of the levator ani, its fascia, or the obturator fascia relaxes the points of fixation and therefore the broad ligament. The broad ligaments together with the uteroplevic ligaments constitute the main support of the uterus. The uteropelvic ligaments are bands of unstriped muscle fibers stretching from the side of the uterus and vagina, where they ensheath the uterovaginal vessels and nerves, to the side of the pelvis, narrowing to a band that is inserted into the obturator fascia. The importance of these ligaments together with the fat-bearing cellular tissue beneath the broad ligament are often overlooked as they bear much of the uterine strain and support the broad ligaments. In shortening the infundibulopelvic ligaments the broad ligaments should always be opened and the uteropelvic ligament strengthened, as failure to do this may spoil the operation. The uterosacral ligaments are two flat bands of unstriped muscle tissue, extending from the highest and posterior portion of the cervix uteri, where they are more or less continuous with the uterine fibers of the uterorectal peritoneal folds, to the side of the sacrum opposite the lower border of the sacroiliac synchondrosis; they run one on each side of the rectum, where they are connected with its muscular coat. They serve to hold the uterus up and tilt it forward; when stretched they allow posterior displacements and procidentia. They also serve to hold the posterior vagina wall tense.

The round or uteroinguinal ligament is a cord of unstriped muscle fibers attached to the side of the uterus just below the opening of the fallopian tubes. It is about five inches in length and passes downwards, outwards, and forwards just beneath the anterior layer of the broad ligament, entering the inguinal canal at the internal ring. In the canal it derives from the abdominal wall striated muscle fibers, and gets other fibers independently. It gives off some fibers that become attached to the external ring and some to the pubic spine; finally it breaks up into a number of fasciculi, which become lost among the interlobular connective tissue of the labial margin. The round ligament serves in normal cases to hold the uterine fundus forward, but as it is on a lower level than its origin from the uterus, it cannot pull the uterus upward. This fact shows that in backward displacements of the uterus, with some procidentia, the shortening of these ligaments alone is not the ideal operation, and will not give entire success. These ligaments hug the bladder and have a tendency to prevent overdistension. The fact that they derive many fibers within the inguinal canal suggests that shortening of the ligaments extraperitoneally is not as well as when done from within the abdominal cavity. We should do the operation for shortening the round ligaments only, when there is a posterior flexion and absolutely no procidentia. A post-displacement is almost an impossibility without some procidentia.

The transversalis fascia, which lies between the transversalis muscle and the peritoneum, passes down into the pelvis covering the internal iliac muscle as the iliac fascia, and as it passes over the brim of the pelvis it becomes the pelvic fascia. At the edge of the obturator foramen it divides into two layers, the outer layer covering the obturator internus muscle and being known as the obturator fascia, while the other passes to base of bladder and side of rectum as the rectovesical fascia. Just in the internal left, by the splitting of the pelvic fascia, arises the levator ani muscle, which also arises from the spine of the ischium and the back of the pubes. The point of origin from the fascia is known as the white line. This muscle separates the pelvis from the ischiorectal fossa and forms the floor of the pelvis.

The fibers of this muscle form a flat plane of considerable strength and pass downwards, backwards, and inwards to their insertion—the most posterior into the tip of the coccyx, those next in order joining the opposite muscles in a median raphe extending from the coccyx to the tendinous center of the perineum—the rest becoming lost upon the side of the rectum, a few fibres running in front of the pre-anal raphe. The outer side of this muscle is covered by the ischiorectal fascia. The anterior and posterior borders of the muscle are free and the fasciæ here become continuous with each other.

The anterior border of the muscle becomes continuous with the side of the vagina as it sweeps around it. While this fascia and muscle do not directly support the uterus, they help to steady the vaginal wall and their continuation, the pelvic fascia, in turn holds fast the fixation of the broad and uteropelvic ligaments. A tear through the levator ani and its covering fascia or through the perineal body allows a relaxation of this fascia and muscle and through them of the broad ligament and uteropelvic ligament. It also causes a relaxation of the vaginal wall and through it a relaxation of the uterosacrals. Thus it is plain what part it may play in uterine displacements. A tear involving this muscle or fascia should be repaired at once or if delayed it should be carefully dug out and its torn ends approximated. Pressure directed against it during labor often tears it, when there is no superficial tear visible and it requires much judgment and skill to detect it. It may be stretched without being torn; in such cases, the slack must be taken up. Any tear to the pelvic floor requires a close study, as the parts must be restored to as near normal as possible.

Until the child's head strikes the pelvic floor its expulsion is carried on without strain to the uterine ligaments, and after it hits the floor the abdominal muscles should be used to their full strength, as this pressure from above takes much strain from the ligaments. A little anesthesia helps to this end, but complete anesthesia does harm. Tears above the intravaginal cervix should always be sutured, as they weaken the uterine support, while those within the intravaginal portion cannot produce this effect. In repairing the levator ani, it must be remembered that its fibers run antero-posteriorly, and bringing them together, as is often done, across the mid-line, alone does not repair the muscle.

On reviewing the anatomy of the pelvis, it appears that the ideal operation for posterior displacement accompanied by procidentia would be a modification of what is known as the Baldy operation—that is, instead of taking the round ligaments directly through the broad ligaments and attaching them to the upper back part of the uterus, they should be carried through at a lower point and attached to the back of the uterus at a point low enough to overcome both the slack in the ligaments and the amount of procidentia present. When the round ligaments are carried through the broad ligaments high up, they pull outwards, forwards, and downwards, but when put through at level lower than that at which they enter the inguinal canal, they are made to pull outwards, forwards, and upwards.

3303 Colonial Avenue.

HIGH EOSINOPHILE PERCENTAGE OF UNEXPLAINED ORIGIN.

By EMIL AMBERG, M.D.

DETROIT, MICHIGAN.

Mr. J. B., policeman, 35 years old, was referred to me November 9, 1912, by Dr. Gorenflo. He had some ear trouble three or four months previously and complained that the air came out of his right ear when he blew his nose. A good sized perforation was found in the anterior lower quadrant. On the following day he complained that he had not slept well in the night and that he had a thumping pain in his ear. Temperature 98.8°. On the 11th he said that he had had a bloody discharge during the night. Temperature was 98.8°. On the 12th, at 3 P.M., his temperature was 98.6° (mouth). There was no discharge visible. He said that he was nervous during the night, but that he had no pain. There was tenderness on pressure over the mastoid antrum. On the 13th the tenderness still existed and he complained of a sickening numb pain in the right temple. On the 16th the tenderness persisted and the head still felt bad. On the 17th he was admitted to Harper Hospital. He complained of pain in his right ear.

Blood examination showed:

	On the 18th:	On the 19th:	On the 25th.
Polymorphonuclears	48.0	49.7	52
Large lymphocytes	5.5	4.3	3.5
Small lymphocytes	35.0	32.0	34.5
Eosinophiles	10.5	14.0	10.0
Hemoglobin	85	...	...
No increase.	Signed, Carstens.	Signed, Sill.	Signed, D.

The *x*-ray examination revealed cloudiness in the right mastoid. The bacteriological report of the discharge, November 20, 1913, showed *Staphylococcus albus*. The laboratory report of November 21, 1912, says that no parasitic eggs could be found in the stool. Castor oil had been given previously. The urine examination (22d) gives specific gravity 10, acid, no albumin, no sugar, occasional leucocytes and epithelial cells.

The mastoid was opened on the 22d at noon. (Bacteriological report from the mastoid says: The cultures show no growths.) The patient complained of dizziness when he lifted his head after the operation. At 4:30 he had a chill lasting 15 minutes. The temperature revealed nothing unusual, except that it was mostly subnormal, rarely reaching 99.8°—once, the highest, on the 24th at noon, 100.4°.

A second report on the stool on Nov. 27 says: "No parasitic ova found."

The result of a blood examination on November 25 is shown in the chart.

December 2 patient was discharged from the hospital for office treatment. On February 15 he reported as follows: He went to work again February 1. February 4, 1913, on a very cold night he was in the open air. When he returned in the morning the right ear seemed to be very sore. When he put a hot water bottle on the whole ear felt as if frostbitten. That night when he left his bed he felt dizzy. The next day he vomited, and was dizzy even when sitting quiet. Dizziness lasted until the first part of May.

Examination February 15, 1913.—Patient hears voice in right ear with noise apparatus in left ear. Vienna fork and A′ fork heard in right ear by air and bone conduct. After turning (in revolving chair for labyrinthine tests) to right, nystagmus to left for 25 seconds. After turning to left, nystagmus for about 24 seconds to right. There is small rotary nystagmus on looking to left, also to right. Now his appetite is bad; while he worked inside it was good. He feels light, "just as if getting out of a sick bed." He has a sensation "like buzzing in both fingers." Ear dry.

The attending physician notified me that there developed an inequality of the pupils. After receiving from Dr. Gorenflo iodide of potassium since the middle of April the condition cleared up.

Dr. Varney reported June 6 that the Wassermann test was negative.

Remarks.—An explanation for this high percentage of eosinophiles has so far not been found by us. The patient follows his occupation.

THE DEVELOPMENT OF NEW REFLEXES AND INHIBITIONS.

FEW physiologists of the past fifty years have opened up richer territories of investigation than has Pavlov, of St. Petersburg. His studies of the mechanism of the secretion of the digestive juices, which have formed the foundation for later work on the hormones, constitute one of the most important chapters in modern physiology. But he has not confined his attention solely to the problems of digestion. The psychic aspects of this process naturally led to the investigation of some of the most fundamental functions of the central nervous system. The results of these studies were communicated at the recent International Congress of Physiologists held at Groningen, and are published in the *British Medical Journal*, October 18, 1913.

At the outset the point is emphasized that all real advances in the study of the higher cerebral functions must come not from psychology, but from physiology. All previous studies of the localization of these functions represented merely the pioneer explorations of a region of which vast areas were yet to be discovered. Certain chance observations made during the course of experiments on the secretion of saliva in dogs, led Pavlov to pursue a new line of investigation. He found that in addition to evoking certain established reflexes governing the secretion of saliva, it is possible to cause the development and organization of new reflexes. Thus the introduction into the dog's mouth of food, or of a few drops of dilute acid excites reflexly a flow of saliva. If coincident with each application of the mouth stimulus there is also applied a cutaneous stimulus, such as heat, pain, or electricity at some definite part of the body, and if the experiment is repeated a number of times, there is reached a stage when the cutaneous stimulus alone is sufficient to evoke the secretion of saliva. This new reflex is termed a "conditional" reflex in contradistinction to the "unconditional" or customary reflex. The strongest electrical stimuli applied to the skin may thus be made to give rise to a feeding reaction instead of to the usual reaction of pain or of fright. Pinching, burning, or cutting the skin will evoke the symptoms of the keenest appetite. It is possible in a similar manner to cause the organization of a large number of new or "conditional" reflexes. This is a discovery of unique and vast importance in physiology. It shows that a reflex is not necessarily a stereotyped and inborn characteristic of the nervous system, but may be developed as an adaptation to changing phases of the environment.

Whereas painful stimuli applied to the skin may set up a conditional salivary reflex, it has been found that noxious stimuli applied to bone cannot be made to arouse such a reflex. This phenomenon is explained on the supposition that the cerebral center concerned with the stimulation of bone is physiologically stronger than the center connected with the feeding reflex. There are a number of conditions that tend to inhibit the conditional reflexes. Spontaneous inhibition occurs when the animal becomes drowsy and falls asleep. External inhibition may be the result of stimuli arising from without or from other parts of the nervous system. Internal inhibition occurs when, in a fully formed reflex, the conditional stimulus is occasionally not followed by the particular unconditional stimulus, as feeding or the administration of an acid, in which case the conditional stimulus is converted into an inhibition.

Certain unexpected phenomena which may eventually throw considerably light upon the physiology of sleep and hypnosis were unearthed in the course of these experiments. It was found that if the conditional stimulus preceded the unconditional stimulus by half a minute or one or more minutes the response was retarded. By varying the time relations between the conditional and unconditional stimuli a stage was reached when the animal entered into a cataleptic condition, and finally fell into a deep sleep from which it could be aroused with difficulty. This phenomenon indicates a widespread internal inhibition that may be closely analogous to the manifestations of sleep and hypnosis.

A conception of broader significance, however, than the formation of new reflexes is that of the organization of the central nervous system in the elaboration and control of all reflexes. Pavlov adopts the term "analyzers" to connote specialized parts of the central nervous system, each of which includes the peripheral endorgan, the nerve fiber belonging to it, and its termination in the cerebral cells. A separate analyzer is apparently developed for every specific stimulus in the outer world. The significance of the analyzers resides in the fact, that, as so well expressed by Pavlov, "a living animal responds by activity to only particular phenomena of the external world, so that it must analyze these and pick out from them certain special components." Frequent repetition of a conditional reflex results in a specialization and restriction of the stimulus. This change corresponds to the development of a more delicate and sensitive analyzer. If a mechanical stimulus of a definite area of the skin be used as a means of developing a conditional feeding reflex, extirpation of a certain part of the cerebrum will abolish this reflex. But the latter may be obtained on stimulating other areas of the skin. If the inactive area of skin is stimulated simultaneously with one of the active areas, there results a stronger inhibition of the reflex than would be obtained by stimulating one of the active areas alone. Moreover, this stimulation of the inactive area leads quickly to drowsiness and sleep.

Without detailing all of the interesting results obtained by Pavlov in laying bare some of the most complicated and elusive mechanisms of the mental function, it may suffice to emphasize the extreme importance of his discovery of the feasibility of developing new reflexes and inhibitions. This work is of fundamental importance in both physiology and psychology. It bids fair to mark an epoch in the history of these sciences.

ENDEMIC TROPICAL DYSENTERY.

Since we have embarked upon a career of expansion which requires a considerable number of our public servants to pass the greater part of their time in the tropics, the subject of endemic dysentery has acquired a renewed interest. With the possible exception of malaria, entamebic dysentery is the most widespread tropical disease. It has been estimated that no later than 1904, 50 per cent. of the invalidism among our officials and soldiers in the Philippines was due to this cause. This high rate of morbidity has stimulated research until our knowledge concerning the essential nature of the disease has been very materially increased. It was formerly believed quite generally that tropical dysentery was due to *Amœba coli*, and under this generic term were rather indiscriminately grouped a large number of protozoan organisms which are now known to be practically harmless.

In order to clear up some of the still mooted points of this subject, Walker and Sellards* secured the consent of a number of convicts in the Bilibid prison at Manila to be used as subjects for experimentation. In all, 60 feedings were administered to these men with the different species of *Amœba* and *Entamœba* which have been supposedly implicated in the production of the disease. Aside from the fact that these experiments differed from those hitherto performed in that they were conducted upon men instead of upon animals, they also have especial value because the conditions were such that perfect control could be exercised. Furthermore in every instance the species of ameboid organisms fed to the subjects and recovered from them was accurately determined. As a result of this investigation they conclude that the ordinary cultivable amebas which are usually found in the water supplies of the tropics are nonpathogenic. Likewise the hitherto suspected *Entamœba coli*, although resembling the true cause of dysentery in so far as it is also a strict or obligatory parasite and refuses to grow on culture media, is nevertheless absolutely unconcerned in the production of tropical dysentery. The specific cause of the disease was found in every instance to be *Entamœba histolytica*. Although it has been so far impossible to cultivate this organism, its microscopical characteristics are so pronounced that by observation of a comparatively simple technique a differential diagnosis can be accurately made between it and all other forms of ameba. The actively motile forms encountered in the stools of persons suffering from the clinical symptoms of the disease are exceedingly non-resistant, dying and disintegrating within a few hours after being passed in the feces. The encysted form is highly resistant. It is this form of the organism which is the greatest source of danger, as it is found abundantly in the stools of persons who are not suffering from dysentery at all. Consequently it is the latent and chronic forms of the disease which are chiefly responsible for its spread.

The incubation period was found to be long. In four cases which Walker and Sellards produced experimentally by feeding, the organism was recovered from the feces 20, 95, 87, and 57 days respectively before the disease appeared. This fact holds the key to the prophylactic treatment. An examination of the stools of all persons residing in regions where amebic dysentery is endemic would, if made no more frequently than once a month, result in the finding of the parasite in ample time to initiate successfully the ipecac treatment and dispose of the organism before the disease itself had made any headway. Thus each individual has it within his power to institute a personal prophylaxis which is effective so far as he himself is concerned. These are in brief the conclusions of Walker and Sillards whose monograph on tropical dysentery is the most important contribution to our knowledge of the subject since the classic researches of Schaudinn.

*Ernest Linwood Walker and Andrew Watson Sellards: Experimental Entamœbic Dysentery, *The Philippine Journal of Science, B. Tropical Medicine*, August, 1913.

THE LIVER IN RELATION TO TUBERCULOSIS AND CIRRHOSIS.

In 1907 Stoerk reported that he had succeeded in producing cirrhosis of the liver in guinea-pigs, which he had inoculated with tuberculosis. He concluded from his investigation that in cirrhosis of the liver in human beings tuberculosis plays an etiological rôle. If this were the case the systematic examination of the liver in a large number of cases of individuals who had succumbed to tuberculosis would show, at any rate, the beginnings of a cirrhotic process. Vice versa, autopsies on individuals in whom a pronounced cirrhosis of the liver was present would show old tuberculous foci in other parts of the body. A careful investigation of this nature was conducted by F. H. Lorentz (*Zeitschrift für Tuberkulose*, June, 1913), who made detailed macroscopic and microscopic examinations of the liver in 100 persons dead of tuberculosis in the Westend Hospital in Charlottenburg.

Gross examination of the liver showed in the majority of cases a normal or friable consistency. A hardening or an occasional cirrhotic change in this organ is so uncommon as to suggest that there is no causal relationship between tuberculosis and hepatic cirrhosis. In only a small percentage of cases are tubercles seen in the liver. In the average case the liver in relation to the entire body is too large and too heavy to suggest any cirrhotic process. In the great majority of the author's cases the liver showed upon microscopic examination the results of tuberculous infection. There was an inflammatory infiltration of the interacinous tissue, and there were numerous small and minute tu-

berculous granulations. The observation is made by Lorentz that even in the least florid cases of tuberculosis, the bacilli reach the liver in large number but are rapidly destroyed in this organ. The liver is regarded therefore as an agent that exercises a powerful destructive influence upon the tubercle bacilli that gain access to the general circulation. In spite of the inflammatory process revealed in the interacinous tissue, and in spite of the distinct evidence of stasis in the liver, the acini themselves show no evidence of change or impairment.

According to statistical analysis, therefore, the association of cirrhosis of the liver with tuberculosis is quite infrequent. When these conditions do occur together the relation is one of coincidence, both conditions separately being rather of common occurrence. Moreover, tuberculosis may arise as a manifestation secondary or terminal to cirrhosis of the liver.

Cures at Lourdes.

In recent years, according to the *Münchener medizinische Wochenschrift*, September 30, medical men have been taking an increasing interest in this subject. If we remember correctly, the late T. Gaillard Thomas reported a so-called Lourdes cure which he was quite unable to account for, to wit, the resolution of an intractable case of pelvic cellulitis in which the pelvic organs formed one continuous mass. Despite his authority, it is not likely that his remarks were taken seriously by his colleagues, because it is very simple to believe that mistakes in diagnosis must now and then occur. Recently a circular letter was sent to 1,000 physicians in respect to Lourdes cures. The answers varied notably. Despite a large degree of scepticism, conscientious practitioners have been found who admit frankly the cure of actual disease. A list of prominent practitioners is on record as upholding the existence of a superterrestrial agency in some of these cures. Several university professors have gone on record with attests to this effect—for example, Duret of Lille. "Suggestion" in the minds of men like himself may be quite left out of consideration in some severe cases. Among cases which yield to Lourdes treatment tuberculosis is well represented, including recoveries from lupus. Without going more deeply into the subject at present we may conclude by noting the expressed determination that in future the fullest degree of publicity will be given to all cases of apparent cure occurring at Lourdes.

News of the Week.

The Red Cross.—The American National Red Cross announces the receipt of gifts of $100,000 each from Mr. Jacob H. Schiff and Mr. James A. Scrymser, and of $2,000 from Mrs. Whitelaw Reid. The gift from Mr. Scrymser is to be added to the fund for the purchase of land in Washington on which the Government is to erect a building for the Red Cross as a memorial to the women of the Civil War. Congress has already appropriated the sum of $400,000 to cover the cost of constructing the building, and the Red Cross has offered to raise the $300,000 necessary for the purchase of the land. With the completion of this memorial building the Red Cross will have a permanent home and headquarters where the various departments of the service can be housed. The other two gifts are to be used as endowments for the fund for the town and country nursing service, which is practically new work for the Red Cross.

Convalescent Colony.—The United Hebrew Charities of New York at a recent meeting entertained a proposition to establish an industrial colony where persons who have recovered from tuberculosis may work and earn their living under proper hygienic conditions. It is to be hoped that some practical scheme for carrying out this proposition may soon be effected.

Low Death Rate.—For the week ending October 25, the death rate in New York City was 11.26 per thousand, which represented a total of 1,160 deaths, as compared with a rate of 12.48 and a total of 1,238 deaths for the same week of 1912. There was an increase in the number of deaths from pulmonary tuberculosis which totaled 138 as against 112 for the same period of last year. The Babies Welfare Association reports that during the last three weeks of October the number of deaths of infants under one year of age was 128 less than during the corresponding period of 1912, and estimates that the death rate for babies for this year will be considerably less than 100 per thousand. For the year 1907 the rate was 144.4, and for last year it had dropped to 105.3.

School Medical Inspection.—At a hearing before the Board of Estimate and Apportionment of New York City last week an appeal was made for the insertion in the budget for 1914 of an additional appropriation of $26,000 to provide eight additional nurses and four medical inspectors in the public schools. Dr. Haven Emerson, representing the Academy of Medicine; Dr. S. Josephine Baker, director of the division of child hygiene; Dr. E. H. Lewinski-Corwin, and Mr. Bailey B. Burritt, representing the Association for Improving the Condition of the Poor, appeared in support of the demand. It was stated also that the present staff of dentists in the public schools was inadequate, and the appointment of an additional eleven was urged.

Medical School Appointments.—The following promotions and new appointments in the medical faculty of the New York University and Bellevue Hospital Medical College have been announced: William B. Trimble, professor of dermatology and syphilology; Lewis K. Neff, clinical professor of medicine; William H. Luckett, clinical professor of surgery; George H. Kirby, assistant professor of mental diseases; Ephraim M. Ewing, assistant professor of physiology; Charles Krumwiede, lecturer on bacteriology; Edward S. McSweene, lecturer on the management of tuberculosis institutions; Arthur G. Keane, clinical lecturer on surgery; Robert P. Wadhams, John F. Nelson, Walter W. Griffin, and George A. Koenig, instructors in surgery; John H. Carroll, John H. Wyckoff, Jr., Mills Sturtevant. Emanuel D. Friedman, and William H. Boese, instructors in medicine; Frederick W. Rice, William E. Bailey, Filip J. Wettervik, Richard T. Atkins, and Alfred Kahn, instructors in otology; and John J. Rothwell and Clement J. Hailperin, instructors in dermatology.

Cornell University Medical College opened on Wednesday, October 1, 1913, with an enrollment as follows: For the degree of M.D., first year,

36; second year, 32; third year, 20; fourth year, 20; special students (work not leading to the degree of M.D.), 5; for the degree of Ph.D., 2; for the degree of M.A., 2; making a total of 117. All students now registered, with the exception of those pursuing the combined seven years' course leading to the degrees of A.B., and M.D., are graduates of Arts or Science, or Doctors of Medicine doing advanced work.

Civil Service Examinations.—The United States Civil Service Commission announces an open competitive examination, for men only, for the purpose of filling a vacancy in the position of chief mine surgeon in the Bureau of Mines, Pittsburgh, Penn., at a salary ranging from $2,400 to $3,600 per annum. The duties of the position are to investigate and report upon health conditions in mines and at mining towns, to outline and direct methods of first aid instructions to miners, to attend mine disasters, and to direct and make pathological and physiological studies concerning the effect upon the human system of poisonous gases, death by shock at mines, and similar subjects. Application for the details of this examination, which will close on December 8, 1913, should be made to the United States Civil Service Commission, Washington, D. C.

The New York State Civil Service Commission announces that the positions of nurse, head nurse, and matron in county tuberculosis hospitals have been included in the competitive class, and that applications will be received by the Commission at any time, and appointments made as necessary. The positions are open to both men and women, over twenty years of age, who have been residents of the State for at least three months. The salaries vary from $40 per month and maintenance to $75 per month and maintenance. No written examinations will be held, but candidates will be rated on their age, education, preliminary training, and experience. Further details may be obtained by addressing the State Civil Service Commission, Albany, N. Y.

Otisville Sanatorium.—Because of the large number of patients applying for treatment at the Otisville Sanatorium for early cases of tuberculosis, the capacity of which is now 600, many have been compelled to wait for a number of weeks before admission, and to remedy this undesirable condition the Department of Health has arranged to receive such waiting patients at the Riverside Sanatorium on North Brothers Island. Two new pavilions on the island have been set aside as reception pavilions for subsequent Otisville patients, who are thus enabled to receive the benefits of treatment as soon as possible after diagnosis of the disease. Vacancies at Otisville will be filled first from patients already under observation at the Riverside Sanatorium.

Diagnosis Clinics for Venereal Disease.—Commissioner Lederle of the New York Department of Health, has recently issued a circular letter stating that the Department of Health of New York City has for some months conducted two diagnosis clinics for venereal diseases, where physicians may send patients for Wassermann tests for syphilis, for the complement deviation test for gonoccocus infection, microscopical examination for *Treponoma pallidum* in fresh specimens and for gonococci. Under no circumstances are the results of these examinations communicated to any one but the physicians sending the case. All the examinations are made free of charge. In order to extend the usefulness of these clinics in combating the spread of venereal diseases, a specially trained physician has been appointed to act as "Medical Adviser" to the patients attending the clinics. Under no circumstances will he treat cases. His duties consist in advising patients as to the nature of the disease, the necessity of proper medical care, the dangers of self-treatment, and the importance of obeying the directions of their physicians. Upon request, the "Medical Adviser" will also instruct the patients regarding the nature of venereal infections, their mode of spread, ordinary course, complications and far-reaching effects and in various questions of sexual hygiene. The establishment of these venereal clinics has been disapproved by some physicians, on the ground that ample facilities for the free treatment of venereal diseases now exist. It is apparent, Commissioner Lederle says, that this objection is based on a complete misunderstanding of the diagnostic functions of the clinic, and the duties of the "Medical Adviser," for the medical advice given will in no way interfere with the legitimate work of private physicians and dispensaries.

Brady Clinic.—Contracts have been awarded for the erection of the James Buchanan Brady, Urological Clinic of the Johns Hopkins Hospital, Baltimore, and work has been begun on the new building, which will, it is estimated, cost $250,000. It will be of brick with marble trimmings, and six stories high, and will be placed on the Monument Street side of the hospital grounds. It is expected that the clinic will be completed by October, 1914, at which time opening exercises with Sir William Osler as the chief speaker will be held.

Missionary Physician Needed.—The Presbyterian Hospital and Dispensary at Tsinanfu, North China, a city of about 100,000, lying 300 miles south of Peking, is in need of the services of a woman physician. Details may be obtained by applying to Mr. Wilbert B. Smith, 600 Lexington avenue, New York.

Nobel Prize.—Prof. Charles Richet of the Faculté de Médecine, Paris, a Member of the Académie de Médecine, and director of the Institut Marey, Paris, has been selected as the recipient of the Nobel Prize in Medicine for 1913. This is a recognition of Prof. Richet's recent work on anaphylaxis.

Hodgkins Prize.—The committee on award of the Hodgkins Prize which was offered by the Smithsonian Institute in connection with the International Congress on Tuberculosis held in Washington in 1908, have finally reported that they agree in recommending that the prize be equally divided between Dr. Guy Hinsdale of Hot Springs, Va., and Dr. S. Adolphus Knopf of New York, for their respective essays on the relation of atmospheric air and tuberculosis. The prize committee consisted of Dr. William H. Welch, chairman; Dr. Simon Flexner, Surgeon-General George Sternberg, and Dr. John F. Fulton. The total amount of the prize is $1,500.

Personals.—Dr. W. P. Cunningham of New York announces his removal to 323 West 14th Street.

Dr. Edward S. Peck of New York has removed to 57 West 58th Street.

Dr. Winfield Scott Hall, dean of the Northwest-

ern University Medical School, Chicago, spoke before the students of the University of Washington, Seattle, on October 20, on social hygiene.

Gifts to Charities.—The United Hospital of Port Chester, N. Y., receives a bequest of $50,000 by the will of the late Mr. William Henry Macy of Harrison, N. Y.

By the will of the late Mr. Frank G. Keeney of New York the Brooklyn City Dispensary, the Brooklyn Home for Consumptives, and the Home for the Blind receive bequests of $2,000 each.

The American Association of Immunologists.—This society was organized on June 15 at Minneapolis, Minn., with forty-one charter members, all of whom have been pupils of Sir Almroth E. Wright of London. The objects of the society are: "To unite the physicians of the United States and Canada who are engaged in the scientific study of immunology and bacterial therapy. To study the problems of immunology, and to promote by its concerted efforts, scientific research in this department. To spread a correct knowledge of vaccine therapy and immunology among general practitioners." The officers temporarily chosen are: *President,* Gerald B. Webb, Colorado Springs, Colo.; *Vice-Prersident,* George W. Ross, Toronto, Canada; *Treasurer,* Willard J. Stone, Toledo, Ohio; *Secretary,* Martin J. Synnott, 34 South Fullerton Avenue, Montclair, N. J.; *Council,* A. Parker Hitchens, Glenolden, Penn.; Oscar Berghausen, Cincinnati, O.; J. E. Robinson, Temple, Texas; Campbell Laidlaw, Ottawa, Canada; Henry L. Ulrich, Minneapolis. The first annual meeting of the Society will be held June 1, 1914, at Atlantic City, N. J.

The New York Society of Anesthetists.—Dr. Geo. W. Crile of Cleveland, Ohio, will address this Society at a meeting at the N. Y. Academy of Medicine, November 20, 1913, on "Anesthesia and Anoci-Association."

Obituary Notes.—Dr. Alexis Marcy Léon of this city died suddenly on November 2. He was born in New York March 25, 1857, and was graduated from the College of Physicians and Surgeons in 1878. He was a member of the County and State Societies and a Fellow of the American Medical Association, a member of the Alumni Association of the City Hospital, and visiting physician to St. Francis' Hospital.

Dr. Alfred J. Pedlar of Alameda, Cal., a graduate of the Cooper Medical College, San Francisco, in 1877, a former member of the California State Legislature and of the Medical Corps of the United States Army, died at his home on October 19, after a long illness, aged 60 years.

Dr. Arthur Fray Niedermeier of Trenton, N. J., a graduate of the Medical Department of the University of Pennsylvania, Philadelphia, in 1900, for many years chief medical examiner and surgeon in New York for the Pennsylvania Railroad, died at the Mercer Hospital, Trenton, on October 23.

Dr. Joseph Augustus Stites of Springfield, N. J., a graduate of the Bellevue Hospital Medical College, New York, in 1875, health officer and medical inspector of Springfield township, and a member of the New Jersey State and Union County Medical Societies, died at his home from apoplexy on October 22, aged 61 years.

Dr. John Kuestner of Philadelphia died of strangulation by food on October 20 at the Pennsylvania Hospital for the Insane. He was graduated from Hahnemann Medical College and Hospital in the class of 1887.

Dr. Samuel A. Martin of Clinton, Pa., died on October 23 as the result of injuries received by the overturning of his automobile. He was graduated from McGill University, Medical Faculty, in the class of 1892.

Dr. Henry A. Mettauer of Macon, Ga., died at the home of relatives in Farmville, Va., on October 22, aged 87 years.

Dr. T. W. Keys of Leroy, Ill., a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1879, and a member of the Central Illinois Medical Society, died at his home on October 21, aged 75 years.

Dr. Frederick A. Hall of Hoxie, Kan., a member of the Kansas State and Sheridan County Medical Societies, died at his home suddenly on October 21, aged 60 years.

Dr. Allen L. Wood of Brooklyn, N. Y., a graduate of the Hygeo-Therapeutic College, Bergen Heights, N. J., in 1863, died at the Paul Kimball Hospital, Lakewood, N. J., on October 25, aged 73 years.

Correspondence.

THE ETIOLOGY OF GASTRIC ULCER.

To the Editor of the Medical Record:

Sir:—An editorial comment under the above caption, in the Medical Record for October 25th, introduces a description of one factor in the development of gastric and duodenal ulcer, but it seems to me we may generalize and assume that vascular obstruction due to emboli proceeding from omental vessels would represent only one feature of a condition in which vascular obstruction practically comprehends the entire subject. Statement is made in the editorial article that "the source of such thrombosis or embolism is undetermined."

In 1893 I published a description of proliferative endarteritis occurring in the presence of toxic injury of the walls of terminal arteries. The appendix gives a very typical object lesson. In cases of intrinsic infective appendicitis proliferating endarteritis may occur in all branches of all the terminal arteries, and yet the round or restricted ulcer of the appendix may appear in the field of obstruction of only one of these arteries. In such cases a local hyperleucocytosis seems to take charge of the tissues in the vicinity of other terminal arterial filaments which are involved in the proliferative endarteritis.

In cases of ulcer of the stomach or duodenum we may have a similar process. Whenever any actively developing colony of the colon bacillus is at work, either in acute appendicitis, cholecystitis, or acute colitis, the patient may have hematemesis as a complication, and this represents the bleeding ulcer. There appears to be acute toxic destruction of cells of capillary walls at points at which excretion of colon bacillus toxin is being carried on rapidly from the walls of the stomach or duodenum. When toxic excretion irritates the walls of blood vessels larger than capillaries, belonging to the terminal arterial system, proliferating endarteritis may occur over a rather large area, and yet some one of these areas—which then become anemic—is selected for destruction by saprophytes or by digestive processes. When any one anemic area is attacked in this way in the stomach or duodenum, a phagocyte protection seems to be called out which guards against

destruction of tissues in neighboring areas, although they are being subjected to the same toxic process.

It is probable that different toxins which are being excreted by the mucosa of the stomach and duodenum make demonstration in different ways. For instance, in a case of burn of the skin of only the first degree, perforating ulcer of the stomach or duodenum may appear as a complication. Heat causes proteolytic change in some of the albuminoids of the skin, and the end-result toxins which are then excreted by the mucosa of the pylorus and duodenum may set up proliferating endarteritis at points of excretion. Direct toxic destruction of the protoplasm of capillary wall cells over the areas of excretion of anerobe toxins might at another time cause ulcerative erosion of the "bleeding sponge" type in the same patient.

Ulcers of the stomach and duodenum of all kinds, from the bleeding sponge ulceration, superficial in character, to round perforating ulcer, are to my mind similar to many of the skin diseases, i. e., selective action of the glands of the skin or of the mucous membranes results in toxic irritation of or destruction of cells at the points of excretion of these selected toxins.

The entire field of gastric and duodenal ulcer may not be covered by this theory of the vascular obstructive origin of such processes, but we may at least employ such a theory for a working hypothesis, basing our concept upon the proportion of cases in which microscopic examination demonstrates the presence of proliferating endarteritis or capillary thrombosis of small branches of terminal arteries belonging to any part of the enteron. My first contribution to this subject was made in 1893, and a photomicrograph of a terminal artery involved in toxic proliferating endarteritis may be found upon page 24 of the second edition of "Lectures on Appendicitis," published in 1896. Since that time I have published various notes in reference to the same process and its bearing in explanation for the toxic excretion symptom which is called "ulcer of the stomach and duodenum."

616 Madison Avenue.

MALARIA IN THE NEWBORN.

To the Editor of the Medical Record:

Sir:—In view of the desirability of collecting data which may aid in throwing light upon the question of maternal transmission of malaria, the following case is reported so that it may become of record.

A child, Filipino, born January 2, 1913, at the Iwahig Penal Colony in Palawan, on January 7 had a rise in temperature and symptoms which led to the suspicion that it might be infected with malaria. Examination of the blood made on January 9 showed distinct malarial crescents. The mother had suffered from estivoautumnal infection at intervals during her pregnancy. For a number of months prior to December 25 she had been actively treated with daily gram doses of quinine sulphate given in capsules by the mouth.

Victor G. Heiser,

Surgeon U. S. Public Health Service, Director of Health for the Philippine Islands.

Manila, P. I.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

NEW SESSION OF MEDICAL SOCIETIES—MALINGERING—LOCAL GOVERNMENT BOARD REPORTS—FLIES AS CARRIERS OF DISEASE—LECTURES ON TROPICAL DISEASES—OBITUARY.

London, October 17, 1913.

The new session of the Medical Societies has begun, and from the early proceedings and programs promises to be successful. The Royal Society of Medicine was to have had on Monday a demonstration by Dr. Hideyo Noguchi of the Rockefeller Institute, and this was looked forward to with great interest, but unfortunately it had to be postponed on account of indisposition, which prevented the demonstrator's appearance. We trust the hindrance is ephemeral, for it is said he will be able to come on Monday next. On Tuesday the section of surgery met to hear Mr. C. A. Pannett on the selection of the incision for celiotomy, and Mr. Frank Kidd on pyeloradiography.

The clinical section had previously opened with an exhibition in which were numerous cases of interest, *e.g.* a man who had benefitted from salvarsan who was admitted to hospital for diphtheria, but numerous Vincents' organisms found in throat cultures. He was treated by various local measures for a fortnight, the pain in throat increasing, extending to both ears and submaxilliary glands. A swab moistened with glycerine and dipped in salvarsan was then rubbed over the parts affected. It gave no pain and four hours later the throat felt easier. Three more applications were made with the effect of clearing the fauces, abating the adenitis and banishing the organisms. There was no history or evidence of syphilis and Wassermann's reaction was negative. Among other cases were actinomycosis of the cheek benefited by injections of formalin; osteomyelitis in a boy of eight years; osteogenesis imperfecta with multiple fractures in a boy of eleven and one-half years; skiagrams revealed the fractures and an abnormal translucency of the bones; splenic enlargement with oval sepsis and anemia in a man of fifty years, and another in a woman of fifty-five years with arteritis obliterans; Bazin's disease in a woman of thirty-one years; arthritis of the wrist following a wound attended at first by great pain and swelling reaching half way up the arm, but quickly subsiding and leaving the joint swollen, but painless and insensitive to heat or cold. Tactile densation not much affected, though the joint is evidently disorganized, as rough grating shows.

The Medical Society of London held its first meeting of the session on the 13th, when the audited accounts and treasurer's report was presented and approved, the retiring officers vacated their positions and the newly elected ones assumed them. The first ordinary meeting followed when the incoming president, Sir David Ferrier, delivered an address and Dr. E. F. Buzzard read a paper on "Varieties of Facial Spasm and Their Treatment."

The West London Medico-Chi. met on the 3d inst., when Dr. Palmer, the new president, was inducted, and, according to custom, presented the "Keetley" medal to his predecessor, Dr. Shutel, and then delivered an address on the subject of "Malingering," which he considered had of late years increased, especially among the industrial class. For this he held the trend of modern legislation was to no small extent responsible. The Insurance Act had opened the floodgates to the risk on a scale hereto-

fore unknown. The sickness claims of women were amazing; the logical sequence to compulsion was resistance, and it was certain to show itself, in some cases, in malingering, the psychology of which was interesting if complex. Gain was not the only motive; idleness and others might be at work. No doctor was a detective, though he would discourage any fraud he noticed. He would not make an accusation unless he had positive evidence. Cases which might be termed subconscious or unconscious malingering might occur and valetudinarianism was important to remember, for it included genuine invalids and others. True neurasthenics were often great sufferers, and to brand them as malingerers would be cruel. As to prevention Dr. Palmer suggested: (1) The appointment of independent, experienced medical referees. (2) Medical assessors with arbitrators to interpret evidence in courts. (3) Organized lay visitation. (4) Retention in hospital of doubtful cases. (5) Time limit to functional illness. (6) Periodical examinations of suspected cases by independent practitioners. (7) Registration of the benefits of claimants from all sources.

The local government board last week issued its half-yearly return of pauperism. From the mass of figures it appears that there is a further decline in the total number receiving Poor Law relief, but a continuance of the disquieting increase noted for several years in the number of pauper lunatics and idiots. In London unions the decrease of paupers was 0.1 per cent.; in the provinces 1.1 per cent. The number of the insane (paupers) has increased year by year since the numbers of this class were recorded. Since 1872 the increase has mounted to 148 per cent., mostly determined by the increase in the number maintained in the county and borough asylums.

The number of insane and idiot persons in relation to the population has increased from 2.2 per 1,000 in 1872 to 3.4 per 1,000 in the present year.

The board has also issued further reports concerning the carriage of infective material by flies. They comprise papers by Dr. Gussow on "*Empusa Musca* and the Extermination of House Flies"; by Dr. Hindle on "Color Preference of Flies" and the "Range of Flight of *Musca Domestica*," and by Dr. Graham Smith on "Nonlactose Fermenting Bacilli in Flies." The chief medical officer of the board comments on these papers, considering them to have important practical bearings. He admits that the number of flies in summer may be some index of the probability of contamination by microbes where decomposing agents are permitted, but draws attention to the other sources of danger. There is also a paper by Dr. Copeman on the "Hibernation of House Flies." In a search he instituted it is surprising that among a number of hibernating flies caught in likely situations, as generally supposed, he found not a single specimen of *musca domestica*. He thinks it may possibly be because that fly was very slightly prevalent last summer, but further investigation is needed as to the circumstances in which survivors pass the winter and serve to perpetuate the species.

A course of lectures on "Diseases of the Tropics" is being delivered at the Young Men's Christian Association for the benefit of missionaries, students and persons likely to travel in tropical regions. Sir Ronald Ross took the chair at the first lecture, which was given by Dr. D. E. Anderson, who formerly was a worker in Mauritius and is now a lecturer in Mansfield College, Oxford. Sir Ronald congratulated the audience and the people of London that these lectures had been inaugurated and told them that Dr. Anderson had traveled widely and made important observations, and when working in connection with malaria had been one of the first to discover the parasite.

Dr. Fielding Ould said that fifteen years ago he was associated with Sir Ronald Ross in West Africa when there was no systematic study of tropical medicine and they were subject to jeers for urging it. At that time no microscope was used from Sierra Leone to Nigeria, but since then hundreds of lives had been saved by the knowledge acquired.

Dr. Anderson then gave his lecture, which comprised an account of the morbitic organisms which have been shown to be responsible for various diseases.

Sir John Batty Tuke has died in his seventy-eighth year. He graduated M.D., Edin., in 1856, and went to New Zealand, where he had medical charge of Imperial troops and later of Colonial forces. After some six years in the colony he returned to England and obtained the appointment of medical superintendent of the Fife and Kinross Asylum. He had then been engaged in some research work on the brain with Professor Rutherford, and from this time he steadily rose until he became recognized as one of our leading psychologists and a practical physician and specialist on insanity. He was Morisonian lecturer on this subject at the University of Edinburgh in the early seventies. He was in due course a member of the General Medical Council, and from 1900 to 1910 he was M.P. for the joint university seat of Edinburgh and St. Andrews. He received a number of honors, among them D.D. Ed., D.Sc., T.C.D. and F.R.S.Ed.

The death took place last week of Dr. J. H. Fergusson, M.O.H. for London Ferry, Port Medical Officer (Lough Hoyle), late examiner R.C.S.I. and on the conjoint board was F.R.C.S.I. and D.P.H., 1894-6. Also L.R.C.P.Ed. and F.P.S. Glas. He was author of "The Sanitary Service in Rural Districts."

Department Surgeon-General Nathaniel Norris, who died in Sept. 29, in his eighty-third year, qualified in 1854 and entered the army the next year, served in India, Afghanistan, Egypt, etc., retiring in 1885 with three medals and clasps as well as the Khedive's Star.

Dr. Henry John Thorp, whose death occurred on Oct. 3, at eighty-one years, was surgeon on the *Perseverance* during the Crimean war and afterwards at the Royal Dispensary, London, and at one time was V.P. of the Hunterian Society.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

CHOLERA—INCUBATION PERIOD OF LEPROSY—PERSONAL.

MANILA, P. I., September 13, 1913

AFTER an absence of several years two cases of cholera again suddenly made their appearance in the city of Manila during the latter part of August. So far there have been no additional cases reported. The first case occurred in the person of a Filipino who worked as a carpenter in one of the local hotels but lived on Calle San Sebastian and was said invariably to have taken his meals and slept at his residence. On Saturday evening, August 23, he left his place of employment, apparently in good health. About noon the next day he was seized

with violent pains in the stomach, which later in the afternoon increased in severity and in addition, marked pains began in the muscles of the calves and forearms. There was no diarrhea. A physician was called, who reported that by evening the case presented many of the clinical symptoms of cholera and the patient was ordered transferred to the San Lazaro cholera hospital. The man was in a moribund condition when he arrived, at about 10 P.M., and died a few minutes later. At the autopsy, which was held on the morning of August 25, the typical pathological lesions of cholera sicca were present. The lower bowel contained a large amount of hard, formed, feces. A liquid rice-water-like fluid was found in the ileum, cultures from which, examined in accordance with the procedure recommended by the Internationale d'Hygiene Publique Conference, resulted in the isolation of the true cholera vibrio.

The next case came under observation on August 25, and occurred in the person of a Filipino who was employed as a cook in a British family in Caloocan, which is a suburb of Manila and a number of miles removed from the first case, and so far as could be ascertained there was no connection between the two cases. This person gave a history of having been ill with diarrhea and cramps in the muscles of the extremities for a period of about a week. He claimed that he was too ill to work and was requested to leave by his employer. It was at this time that he came under the observation of the sanitary authorities and was transferred to San Lazaro Hospital, where a clinical examination showed him to have the typical symptoms of cholera; that is, rice-water stools, cramps in the muscles of the legs, suppression of urine, husky voice, subnormal temperature, and other well-recognized symptoms. Cultures made from his stools, examined in the same manner as mentioned above, resulted positively for the cholera vibrio. This case is recovering and is still under observation in the San Lazaro cholera hospital.

The stools of twenty persons who lived in the same house, who were considered contacts of the first case, were examined. Of these, one proved to be a vibrio carrier and the organism in the laboratory corresponded with the vibrio of Koch in all essential details with the exception that no agglutination took place with cholera serum. Seventeen persons were examined who were considered contacts of the second case, and one vibrio carrier was found among these, the organisms from which acted the same as those from the vibrio carrier of the first contact group.

The nearest known focus of cholera is at Hongkong. Careful inquiry showed that neither of these cases had been out of the city or had come in contact with persons recently from Hongkong.

Since the appearance of these cases a complete house to house inspection has been made many times in all sections of Manila, but so far no additional cases have been found. Laboratory stool examinations for vibrio are made of the bodies of all persons that die in the city, but so far this has resulted negatively. The death rate for the city is decidedly lower than it was last year during the corresponding period, from which it is assumed that few, if any cases of cholera are being overlooked.

On account of the fact that so very little is known of the incubation period of leprosy, the following case of a child aged two years and sixteen days at the time that a positive diagnosis was made may be of interest. This child was born at the Culion leper colony on May 15, 1911. The mother was admitted to the colony on February 10, 1910, aged 34, with the positive diagnosis of leprosy both clinically and microscopically. The father was admitted on August 10, 1908, aged 26, with a clinical diagnosis of tubercular leprosy and microscopically positive. At the time of examination, on June 30, the only clinical symptoms exhibited by the child were a slight reddened area of the cheeks and of the lobes of the ear which to experienced eyes gave the appearance of a mild leprous dermatitis. Microscopical specimens made of scrapings from the cheek and from the septum of the nose resulted positively for the leprosy bacillus.

As the police system in the Philippines gradually improves, it is becoming more and more apparent that there are still a considerable number of cases of leprosy of long standing at large, so that the rapid reduction in the number of new cases of leprosy which had been hoped for after the segregation of the lepers was supposed to have been almost completed can scarcely be expected as yet. During the fiscal year ended June 30, 1913, there were 848 cases admitted to the Culion leper colony. Of these 260 had physical signs and symptoms which showed that they must have been afflicted with the disease for a period of at least two years.

Dr. George G. Davis of Chicago has arrived in the Philippines to take up his duties as associate professor of surgery in the College of Medicine and Surgery of the University of the Philippines.

Dr. Louis Schapiro, who was formerly medical inspector of the Bureau of Health and later Chief of the Bontoc Hospital Division, has resigned and returned to his home in Milwaukee.

2. An Anatomical and Surgical Study of Pericecal Membranes. M. F. Fallon.
3. The Evolution of Mental Healing. C. F. Painter.

2. **Pericecal Membranes.**—M. F. Fallon emphasizes the fact that the so-called Jackson membrane is a congenital, normal, peritoneal membrane and not a membranous pericolitis. It may be confused with the pericolitis of Virchow. The ascending mesocolon is a less frequent form of attachment of the ascending colon and the accompanying *cecum mobile* in itself is not pathological. Digestion in man requires the retarding of the food current in the first half of the large intestine—the physiological stasis. When this stasis is pathological the causes frequently are faulty habits; and hygienic and dietary, rather than surgical measures, as a rule, are indicated. Pericecal membranes frequently predispose to appendicitis, and afford one explanation for family appendicitis.

3. **The Evolution of Mental Healing.**—C. F. Painter points out that present-day tendencies in psychotherapy are simply the revival in new form of principles and practices which are very ancient. The amulet represents the earliest recorded attempt of primitive man to satisfy his psychic self in the treatment of disease. Closely allied to the use of the amulet was that of talismans. Their virtue was acquired through the observance of certain religious rites and ceremonies at the time that the talismanic characters were imparted to the parchment, bit of wood, or other material employed for the purpose of conveying the talismanic influence. The chief distinction between

the amulet and the talisman seems to have been that the former was provided to meet a particular emergency or exigency, generally to ward off evil, whereas the talisman was something that was carried all the time and exerted a more all-pervading influence both of a positive as well as of a negative character. The belief in demons influenced the treatment of disease, which now became the special function of the exorcists. The period of the Crusades gave rise to the traffic in relics. Pilgrimages were yearly made to the shrines of the saints. The "royal touch" became a special insignia of the divine right of kings. In the sixteenth century magnetism was invoked as a method of healing. The revival movement of the eighteenth and nineteenth centuries signalized the development of psychic influences in the treatment of the sick which reached their culmination in the genesis of Christian Science and the more rational Emmanuel Movement.

10. A Note on the Treatment of Fractures near the Wrist Joint, with Especial Reference to Colles' Fracture. A. O. Wilensky.

1. **Legal Responsibility and the X-Rays.**—Ellsworth Eliot, Jr., questions whether the function of the *x*-ray specialist is to be extended to those cases of fracture in which the attending surgeon by methods of diagnosis and reduction, evolved through centuries of observation and investigation, can be reasonably certain that the fragments are in such apposition that satisfactory union may be expected. He believes that this is no more essential than it is to call a special consultant in every case of pneumonia, appendicitis, or strangulated hernia. It is in the spirit of self-protection that, in cases of fracture or dislocation, an *x*-ray is suggested when the surgeon is morally certain that the fragments are in apposition or that the dislocation has been successfully reduced. The fear of litigation in the event of nonunion or other unfortunate result, in no way the fault of the surgeon, is a very strong incentive for generally advising an *x*-ray irrespective of the location of the fracture. The writer believes that these questions must be answered affirmatively and that it is time to establish the principle that the use of the *x*-ray, although in many instances most desirable, yet in many cases is not indispensable to the proper treatment of a fracture. That such a principle should be established is all the more essential in view of the fact that, having become a specialty, the use of the *x*-ray is frequently inaccessible in many cases of fracture. It is a well known fact that on exploration a condition may be found essentially different from that which the *x*-ray seemed to indicate and, similarly, deformities may be either exaggerated or minimized by the manner in which the photograph is secured. Although in many instances a most important and valuable aid in the diagnosis and treatment of fractures, the use of the *x*-ray must not be judged indispensable, and the neglect to advise its use should in no instance constitute a basis for the recovery of damages. Should such a principle prevail the time is not far distant when the prospect of litigation will prevent those most competent from undertaking the care and treatment of cases of this character.

2. **Percussion of the Pulmonary Apices.**—M. Fishberg states that light percussion is sufficient in most cases, especially at the apices. The contrast between the resonance of the air containing tissue and the deadness of the airless spot is striking when light percussion is practised. The sound becomes entirely inaudible when areas of defective resonance are reached. Small disseminated foci of airless tissue can only be found with light percussion; an increase in the force of the stroke in such cases may evoke a normal, or overresonant note If on increasing the force of the stroke the dulness remains one may safely conclude that we deal with an extensive area of airless tissue. In most cases of tuberculosis shrinkage of the apex occurs quite early, and the determination of a narrowing of the resonant area in the supraclavicular and supraspinous fossæ on one side is of eminent value in the diagnosis of early tuberculosis. By mapping out the resonant areas on both sides anteriorly and posteriorly, any disparity appears quite vividly at a glance when the two sides are compared. For practical purposes it is sufficient to percuss the apex in its true anatomical position, which is anteriorly between the heads of the sternocleidomastoid, reaching about 3 or 4 cm. above the clavicle; and posteriorly, close to the spinal column to the height of the vertebra prominens. A shorter apex on one side is of immense significance. The resonance also must be of about the same intensity on both sides; the outline of the mesial borders of the apices can be easily ascertained by careful percussion, and it is expected that both sides should have the same course. Percussion of the supraspinous fossæ proper, over the scapulæ, and anteriorly between the trapezius and the sternocleidomastoid is a vain effort—no pulmonary tissue is located there. During extreme and held inspiration, in the normal lung, the resonance is increased, while during forced expiration the resonance is duller. In infiltrated apices a long and held inspiration gives a duller note on percussion than is found over the opposite, healthy side, and this is often of great value in doubtful cases.

6. **Intravenous Injections of Theobromine Sodium Salicylate.**—S. Neuhof has demonstrated the practicability of intravenous injections of theobromine sodium salicylate. The solution is readily prepared and sterilized, and when properly given produces no reaction. While 20 c.c. of a 5 per cent. solution have been found a convenient standard, this may be modified to suit individual requirements. It seems particularly indicated in uremia, in the anuria of cardiovascular renal diseases, and in some types of primary renal disease when internal administration is impracticable or impossible and quick diuretic action is necessary. It is further suggested that these injections may be of benefit in some types of uremia accompanying eclampsia; in conjunction with other forms of treatment, it may help in starting diuresis.

1. **Reducing Mortality of Pelvic Operations.**—By G. W. Crile. (See MEDICAL RECORD, July 5, 1913, page 44.)

2. **Syphilitic Infection from the Blood of Paretics.**—W. W. Graves alludes to his former theory of relative tolerance as opposed to that of latency of syphilis and holds that this theory is supported by the results of the modern aids of the laboratory and clinical refinements in the treatment of the disease. Since Schaudinn's discovery the demand has become more and more insistent for the recognition of the luetic virus in every stage of the disease, and he gives an account of his experiments on rabbits with blood inoculations from syphilitics and paretics. From the blood of two paretics the author was able to procure the syphilitic infection in rabbits and reproduce the spirochetes. He concludes that one is justified in affirming that, until confirmatory and additional work can be done, clinical observations and laboratory methods will continue to support the idea that in paretics, tabetics and so-called latent syphilitics the living virus of syphilis is ever present.

3. **Cultivation of the Rabies Virus.**—Anna W. Williams claims priority in the recognition of the developmental cycle of the Negri bodies for which as early as 1906 she had suggested the name "*Neuroryctes hydrophobiæ*." No one has since brought forward clear evidence against her findings and conclusions as to their protozoan nature and some investigators have confirmed these findings. Recently Noguchi's announcement of the cultivation of the parasite of rabies has been made, but the writer notes that unfortunately it leaves one with no more exact knowledge of the cultivation of the rabies organism than one had before. With the idea of the protozoan nature of the Negri bodies in mind, she had herself attempted to cultivate them, but the results have been too unsatisfactory and incomplete for publication. Some suggestions, however, have been obtained, which may be published now. There has been no change of mind needed as to the varieties and arrangements of the Negri bodies as shown in her former paper. The changes are seen more clearly in brains left in the skull of the animal in which the air has been excluded by some method before examination. Some of the larger forms appear in from twenty-four to seventy-two days, according to temperature, with more definite groups of smaller forms, some of which seem to be surrounded with a form of membrane. In street and passage virus brains, many of the large forms seem to become distinctly separated into smaller forms, some within the membrane and some without. By animal inoculations with dilutions, material with these segmental-like forms appears to increase in virulence, but it has not been decided if this is a real gain or not. Experiments were made with the passage of virus from culture to culture by methods similar to that used by the author in making cultures of the dysentery ameba. After each transplant guinea pigs were inoculated and all of them had typical rabies after the inoculation with the fourth culture. By the fifth transplant the material was contaminated and the animals did not become rabic. The author criticises Noguchi as not giving anything new in his announcement of the appearance of coarse pleomorphic chromatoids which can be carried through many generations. All investigators, from Pasteur down, have stated at one time or another that minute and coarse pleomorphic bodies are the cause of rabies and they can be seen by any observer arising in uninoculated mediums, after the tissue has undergone a certain amount of degeneration. The author also criticises Noguchi for indefiniteness of statement as regards the culture generations and questions whether the positive results asserted may not have been due to dilution of the original material rather than to continued growth and division of a specific organism.

5. **Ivory Plates in the Treatment of Fractures.**—P. B. Magnuson describes the use of ivory plates and screws in the open treatment of fractures. He has found by experiments that ivory is gradually absorbed, does not cause softening of surrounding bone, or become loose, as may metal plates, since the bone grows in as the ivory is absorbed. It has also the property of being strong enough to stand any muscular strain affecting the fragments. The author also uses ivory screws and mortises the ivory plates into the surface of the bones in applying them.

9. **Routes of Bacterial Invasion.**—E. E. Southard and M. M. Canavan have studied the routes of bacterial invasion of the body by way of the pelvic lymph-nodes. The cerebrospinal fluid still leads the heart's blood in percentage of positive cultures. Pelvic lymph-nodes lead both blood and cerebrospinal fluid. This is possibly due to the great percentage of pelvic lesions in the author's present series. It is still uncertain whether these findings indicate ante-mortem or post-mortem invasion. An acute or chronic lesion may conceivably help the penetration of organisms from without. If, as seems likely, the invasions are intravital or agonal, then it would appear that the pelvic lymph-nodes are accustomed to harboring many bacteria. Whether this habit of receiving more organisms than other nodes induces any superiority on the part of these nodes in respect to their power of digestion the authors cannot say. If so, a rationale for Fowler's drainage position might be imagined. Such a rationale would be superior to saying that the pelvic peritoneum is a better filter than others or is differently constructed from peritoneum elsewhere. The pelvis, often subject to acute and chronic disease in the insane, appears to supply its lymph-nodes with very numerous bacteria. Some of these are saphrophytes, some doubtless pathogens; they are often found in the cerebrospinal fluid post-mortem, even when absent in the blood. The pelvis compares, under the random conditions studied, with the intestinal tract in its habit of supplying bacteria to regionary lymph-nodes, and perhaps the pelvis surpasses the intestinal tract, since the latter's lymph-nodes happened to be studied during an epidemic of intestinal disease which provided an excess of secondary invaders. The hypothesis of a route of meningeal invasion by way of the blood receives added support from this work, although the possibility of more direct invasion must be considered.

2. **Cerebrospinal Fluid in Health and Disease.**—Sir David Ferrier discusses the various aspects of this subject. He notes that hitherto the benefits of lumbar puncture from a therapeutic point of view have been overshadowed by their diagnostic value. Beneficial results as regards the reduction of intracranial pressure have been reported in cases of hydrocephalus, serous meningitis, and cerebral tumors, but these results have not been so marked as to lead to any very general adoption of the method; and in some forms of cerebral tumor the procedure is not free from risk. In many cases of infectious meningitis, other than tuberculous, improvement has re-

sulted from lumbar puncture, and the headaches of chlorosis, migraine, syphillis, and uremia have been relieved, as well as the symptoms of Ménière's disease. The injection of cocaine into the spinal subarachnoid for the purposes of producing paraplegic anesthesia, and the injection of magnesium sulphate in order to allay tetanic spasms, and similar procedures, are well known.

3. **Relief of Pain of Laryngeal Tuberculosis.**—E. D. Davis during a period of a few months injected a solution of two grains of eucaine in one ounce of 80 per cent. alcohol into the internal laryngeal nerves of twelve selected cases to relieve the dysphagia. The method of injection adopted was that described by J. Dundas Grant and is briefly as follows: The patient is in the prone position with the head and neck slightly extended and the chin turned away from the point of injection. To avoid sepsis the skin in the region of the nerve is painted with iodine. The larnyx is pressed out of the mid-line by the thumb and made to project on the side about to be injected. The nerve is marked out by the nail of the index finger, which is placed between the hyoid bone and the thyroid cartilage and immdiately above the superior thyroid tubercle where a tender spot is found. The blunt needle of Schlosser's syringe is now pushed in with a jerk at right angles to the surface and at the middle of the finger nail to a depth of 1½ cm., *i.e.* to the mark on the needle. The needle is carefully moved so as to seek the spot at which the patient complains of pain in the ear. A few drops of the solution of alcohol are injected, and if there is a violent fit of coughing it indicates that the needle has possibly entered the pharynx and is too deep, but this very rarely happens. Finally, the slightly warmed alcoholic solution is injected until the pain in the ear has ceased. About 1 to 2 c.c. is generally sufficient. Of the twelve cases in which this procedure was resorted to not one showed any signs of hemorrhage, injury to the surrounding structures, or other disturbing results—in fact, the proceeding is not much more difficult than the usual hypodermic injection. With the laryngoscope the side of the larynx injected was found to be slightly paler and appeared to be less sensitive when touched with a laryngeal probe. This local anesthesia is probably the cause of the immediate relief experienced in most cases. In two cases both nerves were injected at the same sitting without any untoward symptoms and without the regurgitation of fluid into the larynx during swallowing, but as a general rule it is wiser to allow a few days to elapse before the injection of the second nerve. Of the twelve cases two were unsuccessful, owing to ulceration of the pharynx in one and extensive disease in the other. One patient obtained complete freedom of pain for one month and put on 3½ pounds in weight in a week. This patient died a few months later from diffuse pulmonary tuberculosis, and microscopic sections were made of the internal laryngeal nerves and compared with a section of the same nerves of a healthy subject who had been killed by an accident. The nerve which had been injected twice showed increased fibrous tissue and numerous spaces within the bundles of the nerve fiber. Ulceration of the free upper portion of the epiglottis is treated by amputation with punch forceps. This is not a serious or difficult operation. The effect of the insufflation of powders such as orthoform and anesthesin or morphine is transitory, and depends on the skill of the patient in getting the powder well into the larynx.

4. **Hereditary Optic Neuritis.**—A. S. Worton states that this affection, frequently known as Leber's disease and also by the synonym hereditary optic atrophy, was first clearly described by Theodore Leber in 1871. It is characterized by rapid loss of central vision, usually lasting some considerable time, and followed in a certain proportion of the cases by more or less spontaneous recovery of visual function. Both eyes are affected, as a rule, either simultaneously or within a few days of each other. The loss of central vision is evidenced by a central scotoma usually absolute in character, the peripheral limits of the visual fields remaining normal in extent. Many of the cases regain full normal visual acuity after the attack, but even in these cases some deficiency of the light sense can usually be demonstrated by a comparison of the results obtained from the black and gray (Bjerrum) test types. A few cases, on the other hand, go from bad to worse, and vision may be permanently reduced to hand movements or the merest perception of light. Between these extremes a varying amount of useful vision may be regained by the sufferers, and this amount is probably influenced to some extent by the mode of life both before and during the course of the attack. The condition is essentially one of inheritance and follows the type of a sex-limited disease in so far as males are very much more liable, transmission occurring usually through unaffected females. The diagnosis would depend chiefly on the discovery of similar cases in other members of the family or on tracing backwards through the female side of the genealogical tree. From retrobulbar neuritis it is distinguished by the absence of pain on pressure over the eyeball or on movements of the eyeball. Retrobulbar neuritis is frequently unilateral and runs its course towards recovery in a very much shorter time. The scotoma associated with it is also frequently relative throughout. Tobacco amblyopia is infrequent before the fourth decade of life, the scotoma is usually relative in character, and recovery, as a rule, rapidly occurs when the tobacco is stopped. The ophthalmoscopic appearances during the attack are those simply of a mild neuritis, hyperemia of the discs, fluffiness of the disc margins, and slight perivasculitis. The author reports eleven cases of this condition occurring in three generations of a family.

1. **The Higher Nervous Functions.**—By I. Pavlov.

(See page 850.)

3. **The Rigidity of Calcified Arteries.**—A. H. MacCordick lays down as a general rule that so-called calcified arteries are not of a stony rigidity during life. The calcareous matter in the arterial wall is not present during life in the form of rigid plates. It is there, but in the state that may be compared with unset mortar. The author employs the simile of unset mortar, but apparently this is more than a simile—it is, in fact, an identity. On making inquiries, the author finds that it is generally accepted by chemists that the process of setting of mortar is one of conversion of calcium hydroxide into calcium carbonate by the absorption of carbon dioxide from the air. The reaction of the tissues and body fluids during life is alkaline but becomes acid shortly after death. After death the gas which replaces the blood within the arteries is largely composed of carbon dioxide. When there are large areas of necrosis appearing in the tissues the production of acid is sufficiently abundant to bring about an *intra vitam* setting of the calcareous matter. For instance it is the experience of the gynecologist that a calcified fibroid of the uterus may be found of stony hardness even while in the body. It is the author's experience that in a case of senile gangrene the arteries of the necrosed or gangrenous area are of stony hardness whereas the same arteries higher in their course where the circulation is still maintained are soft and pliable and can be ligatured with ease. In short, the realization of this fact, that in arteries provided with an adequate circulation the calcareous matter, whether it be

in the intima or the media, remains unset, is calculated to fully explain why, after handling pipe-stem radials, there is no thrombosis and gangrene, and it is easy to understand why rigid and tortuous splenic and other mesenteric arteries in the aged arteriosclerotic do not undergo traumatic rupture. During life they are not rigid. It is easy also to understand the occurrence of extensive so-called atheromatous ulceration of the aorta without thrombosis commonly occurring during life. Those ulcers, in short, and the saucerlike plaques with surrounding rupture of the endothelium are post-mortem productions. The calcified areas become in the intima set and rigid before the muscular contraction of the aorta gives way and the tube undergoes dilatation. The result is that a tension upon the endothelium at the edges of the plaque induces rupture of this lining.

5. Fats as Ointment Bases.—R. B. Wild reports the results of his investigations on this subject. In the course of his experiments it became evident that the factors which go to make up the perfect ointment base are still not completely understood. Chemical composition seems to be chiefly of importance in that the glycerine esters of the higher fatty acids and the cholesterin fats are absorbed more readily than the hydrocarbons. It does not, however, follow that all drugs are more easily absorbed from these bases, since we still lack information as to the readiness with which they part from the drugs with which they may be combined; neither do we know what effect the volatility of certain drugs has upon the rate at which the base may give them up to the tissues, or whether a drug dissolved in the base behaves differently from one which is merely mechanically mixed with it. The physical properties alone of the bases do not seem to explain their relative values as ointment bases; the melting points are certainly of the first importance, but some substances which are too hard for ointments have melting points below those of comparatively soft bases. One essential point appears to be that an ointment is better for most purposes when it melts gradually, and this is apparently the reason why a mixture of fats or hydrocarbons (provided that the difference between their melting points is not too great) is better as an ointment base than a single pure fat or hydrocarbon with a sharply defined melting point.

Berliner klinische Wochenschrift.

October 6 and 13, 1913.

Pure Cultures of the Exciters of Smallpox.—According to Fornet the increasing demand for a stable vaccine has led to an official demand for a preservative which must be far more effective than glycerin in moderate and warm temperatures. Since glycerin tends to destroy the admixed germs it will in time attack the specific germ and weaken its virulence unless kept continually in cold storage. Of all other preservatives tested, and they are very numerous, chloroform and antiformin held out some promise but they have been superseded by ether, the idea having originated with Vincent in his work with typhoid vaccine. Very recently several makers of smallpox vaccine have tested ether with very favorable results. Crude lymph was kept alive and virulent. It could be propagated hours and even much longer, thereby sterilizing the lymph for ordinary germs without impairing its virulence, as shown abundantly in animal experiment. Next was asked is the ether lymph stable? The interval is somewhat short to permit a final answer but the outlook is good in this respect. Now is at once suggested the only true manner of keeping lymph stable and that is by repeated cultures. Ether lymph has therefore been tested on all sorts of nutrient media. The earlier attempts were not crowned with success. But when passed through a succession of ordinary media, while no cultures appeared, (only slight clouding at times) it was evident that the lymph was kept alive and virulent. It could be propogated in calves, both fully developed pocks and small so-called "culture pocks" appearing. Attempts were of course made to isolate the germ. The outlook here was naturally unfavorable. No real colonies appeared in the lymph, and all attempts to obtain such, including the most varied stains brought at first no results. The methods by which Flexner succeeded in cultivating the germ of acute poliomyelitis were closely parallel. Finally a combination of stains—hot carbol fuchsin, strong Giemsa, and Zoeffler's stain (Beize) rendered visible extremely minute rounded bodies, having a characteristic grouping. The bodies in themselves vary but slightly from numerous finds of predecessors, but the author claims priority in cultivating and staining the so-called *Microsoma variolæ* (vaccinæ). He thinks Weigert described the same bodies in 1874, Calmette in 1901, Prowazek in 1905, etc., to say nothing of numerous others. Even Koch seems to have described them in 1881. In this list we look in vain for the cytoryctes of Guarnieri, which is reckoned in some quarters as the proven cause of smallpox. The author's work stops short with his positive staining results, and his quasi-cultivation, and apparent elimination of all other germ life. The vast field opened up by such discoveries he leaves to the imagination.

Four Attacks of Puerperal Eclampsia in one Patient.—Holste states that there is but one case on record of three eclamptic labors in one woman, and that as far as he knows but a single four-time case has ever been reported. Even two cases in one subject form a great rarity. The first pregnancy in which eclampsia occurred was in 1910, and was her second gestation, the first having been normal throughout. In the eclamptic case gestation had been normal throughout and there was no evidence of neuropathy. Very near time she developed headache and nephritis, followed at once by three convulsions. Labor was at once induced, six more convulsions following. The case ended favorably for mother and child. The second eclamptic attack occurred in the third pregnancy, appearing in the seventh month as a series of severe convulsions and coma. Stroganoff's treatment met with great success, and there was no return of the symptoms, the urine becoming normal. She was delivered at term without any suggestion of toxemia. Singularly to relate, she had one mild attack in the puerperium. The third case occurred in the fourth pregnancy, the woman breeding very rapidly. It began in the fourth month, as typical eclampsia, with no other evidences of gestation toxemia. The kidneys appeared to be nonparticipating in the attack. The symptoms consisted of numerous severe convulsions and coma. Stroganoff's method was useless on this occasion. The sole resource was to induce abortion, which was done successfully, convulsions ceasing absolutely. When the woman again became pregnant, which was not long afterward, she was at once placed under observation. Albumin never appeared in the urine, nor was there any evidence of other sort to suggest pregnancy toxemia. Then (the author neglects to mention the month, but it should have been very near term) a fulminating attack appeared, which resisted all measures. Pneumonia also supervened and was the actual cause of death. The child, extracted by accouchement forcé, survived. The author regrets that he did not centrifugize the urine in search for former elements. Autopsy showed no hepatic necroses.

Mercurial Vaginitis.—Wolffenstein writes on the dangers of intensive mercurial cures, the use of which seems to have been modified by the introduction of salvarsan. The evil effects are usually seen in ointment and injection cures. The usual clinical expression, as is well known, is ulcero-gangrenosus stomatitis, and it is but little known that an analogous type of vaginitis may replace this or be associated therewith. The author cites two cases from

literature and reports in detail a third personal observation. The patient was a girl of 22, who had noticed a sore spot on the genitals. The physician consulted ordered a mercurial injection cure after he had obtained a positive Wassermann. After a short course of injections she developed stomatitis. The Wassermann reaction had become negative. A vaginal examination made at the time showed no lesions whatever. A second examination eleven days later showed the portio and vaginal walls the seat of multiple lesions representing an ulcero-gangrenous process, the odor being extremely fetid. A great variety of bacteria was present, but no spirochetes. For several days shreds of mucosa came away. Traces of mercury were for a long time present in the urine. After seven weeks patient recovered with considerable narrowing of the vagina. Fever of a low type had prevailed throughout and the constitution reaction was marked.

Münchener medizinische Wochenschrift.

October 14, 1913.

Regeneration of Axis Cylinders in Vitro.—Ingebrigtsen, who has been working at this problem at the Rockefeller Institute, New York City, states that in his opinion conclusions can be drawn from his experiments which favor the probability of regeneration of axis cylinders within the living mammal. He believes the conclusion justified that the regeneration phenomena of the axis cylinders as we know from the regeneration of mammalian nerves *in vivo* are completely parallel with the regeneration of the same *in vitro*, as to both morphological and tinctorial qualities. The axis cylinder phenomena are therefore *sui generis*, and cannot in either case be in part attributed to any outside causes whatever. The cylinders simply grow, Ingebrigtsen maintains, either from other cylinders or from ganglion cells.

Blood Examinations in Chronic Nephritides.—Borchart and Bennigsop, after much research, arrive at the following conclusions: In a chronic nephritis not accompanied by fever or uremia we find a mild degree of hyperglycemia in all such cases as retain sodium chloride or nitrogen respectively, because of the injury to the kidneys. Conversely, if the excretion of these two substances is normal, the excretion of blood sugar is normal. Sodium chloride retention and hyperglycemia have a common causation—both are conditioned by increased reabsorption of sodium chloride or grape sugar respectively in the urinary canaliculi.

Which Is the Active Constituent of Beck's Bismuth Paste?—Rost states that the number of practitioners who employ this resource for the treatment of fistulous tracts is constantly increasing. The universal use of the remedy is only prevented by the fear of bismuth poisoning, cases of which are reported from time to time. Attempts have been made to substitute for the nitrate the less toxic carbonate of bismuth, the latter also being superior for *x*-ray purposes. A striking point, however, in this connection is the negligence displayed in studying the possibilities of the other ingredients of the paste. The latter is believed to act by causing a more intensive granulation in part, of course, by its germicidal proclivities, but examination shows that singly no one of the ingredients possesses either bactericidal or cell proliferant qualities in any marked degree. Recently stimulation of connective tissue fibers rather than of epithelia has been believed to be the leading factor in artificial healing of granulating surfaces. The paste consists of bismuth, vaseline, soft paraffin and wax. Bismuth is not a promoter of connective tissue proliferation. But vaseline, notably "American Vaseline" does possess such powers when injected into granulating tissue, and so does soft paraffin. The greater the purity of the vaseline the less favorable the effect. On the contrary certain very impure greases have the property in an extraordinary degree. Bismuth without vaseline is without merit in these cases, and vaseline alone can close a fistula. Neither lanolin nor lard exercises such a property. A few surgeons have begun to rely on a Beck's bismuth paste "without bismuth." Some substitute a little iodide of potassium. The results of such pastes, the author says, are equal to those obtained by the original formula.

Deutsche medizinische Wochenschrift.

October 9, 1913.

Kyphotic Sciatica.—Hnátek refers to the known influence of sciatica upon the upright posture of the body. As a rule there develops scoliosis, either homologous or heterologous. To explain how sciatica can cause scoliosis is hardly possible, so many meanings being held on this subject. The only point upon which all are agreed is that sooner or later sciatica is almost surely followed by scoliosis of some sort. The type which was first to be reckoned is the kyphosis which follows bilateral sciatica. Yet, singularly to speak, this is one of the most infrequent forms. This kyphosis is not easily recognizable and somewhat resembles that of paralysis agitans. The archlike kyphosis results from bilateral scoliosis. The lowermost vertebræ are forced forward, the femur extended in the hip joint, while the dorsal portion of the vertebral column is also extended. The author abstracts three cases from literature, all of which differed from one another, but all were examples of kyphoscoliosis, thereby establishing a new type for the author in his pure kyphosis. The author's summary of his own case is as follows: Male, aged 38, free from nervous taint, had as a result of overexertion developed a typical rightsided sciatica with kyphosis of 120°. At night in order to obtain relief from pain he had to assume the knee-elbow position. Flexion of the trunk forward gave relief from pain, which seemed to show that a sensitive twig of the sciatic entered the muscles of the back.

Rupture of an Aneurysm of the Aorta into the Superior Vena Cava.—Klein describes the following case: A man aged 42 entered the hospital complaining of palpitation and dyspnea. No history of swelling in the limbs. Within two days his symptoms had become more pronounced—sudden malaise and dyspnea, with edema and cyanosis of the arms and upper portion of the trunk. He had a history of alcoholism and nicotinism. There was a sharp line of demarcation at the typhoid process. Here the veins were extraordinarily prominent and the seat of pulsation. A venous pulse was felt at the right jugular. The condition of the heart and lungs and urine showed departures from the normal, but the abdominal viscera were intact and there was no temperature. The pulse was small and rapid. The tentative diagnosis was aneurysm of the ascending aorta compressing the superior vena cava. Death supervened suddenly, as if the usury upon the latter had ended in rupture. Autopsy as follows: Sacciform aneurysm of the ascending aorta and arch the size of the fist, thrombosed, with a perforation the size of a bean into the superior vena cava, the latter being strongly compressed. Aorta the seat of endarteritis extending into the aorta descendens. The author is able to find but seventeen similar cases, the first reported in 1841 by Thornton. In 1882 Halla published a case with eight more from the literature. Other cases have slowly appeared. Other cases are known in which death occurred before perforation, which could, of course, be classed here. There has been much discussion as to the sound made when perforation was not at once followed by death (for survival has even extended over seven months). Individual reports, however, differ greatly on this point.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

SELF SELECTION (*Continued*).

Self Selection Among Women: The practice of insuring women has materially and rapidly increased in recent years. There is an undoubted legitimate field for insurance in this class of lives as it includes many who are quite independent in financial matters. On the other hand, there is a powerful force of adverse selection among women applicants which necessitates unusual care in the medical examinations, and in the medical selection at the home offices. This is exemplified by the following table made up by Hunter (*Transactions of the Actuarial Society of America,* Vol. 7) from the statistics of the British Office's experience to 1893 and brought up to an American standard.

Policy Years	Men	Women	Policy Years Summed	Men	Women
	Per Cent	Per Cent		Per Cent	Per Cent
1	85	131	1	85	131
2	105	152	1- 2	96	142
3	104	144	1- 3	99	143
4	97	124	1- 4	98	137
5	96	112	1- 5	98	132
6	96	116	1- 6	97	129
7	103	106	1- 7	98	125
8-10	111	121	1-10	102	124
11-20	118	104	1-20	109	115
21-30	116	107	1-30	110	114

The table shows that men are better risks than women in the first policy years, but that after the eleventh year the converse holds true. In this experience, however, the distribution of the deaths brought the relatively heavy losses among women in the early years before the companies had received much remuneration in the form of premiums. The excessive mortality in the early years was evidently due to a speculative element and it has been proved since that time that, if adverse selection is eliminated by the work of alert examiners and by adequate restrictions at the home offices, the death rate among insured women will compare favorably with that of men.

Improvement in the business of insuring female lives did not become noticeable until all due considerations were given to the following special characteristics and conditions of women:

1. Medical examiners are apt to experience feelings of sentiment or timidity in approaching women applicants and, on this account, they may fail to ply all the pointed and direct questions which appear in the application blanks or to insist on complete examinations.

2. The natural tendency of women to avoid a discussion of the diseases and ailments peculiar to their sex and the skill with which they can hide the state of their health must be counted upon.

3. It would seem that some women are particularly sensitive to hidden infirmities and defects and often have an overcoming presentment of approaching danger, and that they are impelled by these feelings to insure their lives.

4. The lack of business training with the consequent incomprehension at times of the importance of the terms of a contract and of the importance for all statements appearing therein to be straightforward, complete and unbiased.

5. Women, swerved by their impulses and sentiments, too frequently misrepresent or conceal facts in an unconscious way, and are usually shocked when it is shown to them that they have not acted fairly. This form of unintentional adverse selection is fully as costly and prejudicial to the interests of honest policy holders, however, as when it is intentional.

With these points kept in mind, the real motive prompting the insurance must be determined; and it must furthermore be ascertained that the applicant has means of her own, more than sufficient to pay the premiums. The following table, also compiled by Hunter (*Transactions Actuarial Society of America,* Vol. 12) illustrates plainly the importance of a careful consideration of the question of the person who is to benefit by the insurance and the source from which the premiums are to be paid.

Class	Ratio of Actual to Expected Deaths
	Per Cent
Married women with children, premiums paid out of own income, children beneficiaries	90
Married women with children, husband paying premiums, husband beneficiary	113
Married women, no children, husband paying premiums, husband beneficiary	126

The facts given in the table are significant. In the first class, where there was a legitimate reason for insurance, the mortality was quite favorable, but in the other two classes where the husband was the beneficiary and paid the premiums, it was decidedly unfavorable especially when there were no children. Self-supporting unmarried women, a class not referred to in the table, are notably good risks as a class.

A well regulated company will aid in the conservation of its resources by refusing to insure women unless there is a manifestly insurable interest on the part of the beneficiary. This insurable interest, in the case of a woman, should be founded upon an income depending upon her life and which is either derived by her own exertions in support of the family or from property left in trust for her benefit. When the income of the property reverts to parties outside the insured's family in case of her death, the seeking of insurance is quite justified. The specially undesirable risks are married women without individual income insuring in favor of husbands; young women relying upon others for support, especially when applying for cheap forms of policies; and elderly women insuring in favor of grown-up sons or daughters. A wise discretion in restricting this class of business through proper regulations will result in a satisfactory experience with female risks.

Good Faith of the Applicant.—Where the applicant for life insurance certifies that his health is good according to the best of his knowledge and belief, it is held in Smith *v.* Prudential Insurance Company (N. J.) 43 L. R. A. (N. S.) 431, that a recovery may be had, on the death of the assured, if it appear that he had reason to believe, and did believe, that at the time he was in good health, although it subsequently develops that this was not in fact his condition for his statement was not unqualified, but only to the extent of his knowledge and belief.

Book Reviews.

Industrial Poisoning from Fumes, Gases and Poisons of Manufacturing Processes. By Dr. J. Rambousek, Professor of Factory Hygiene and Chief State Health Officer, Prague. Translated and Edited by Thomas M. Legge, M.D., D.P.H., H.M., Medical Inspector of Factories. Price $3.50 net. New York: Longmans, Green & Co., 1913.

Dr. Rambousek's work seems to the translator to treat the subject of industrial poisons in as novel, comprehensive and systematic a manner as is possible within the compass of a single volume and with this opinion the reviewer heartily agrees. In part one is a description of the industries and processes attended with risk of poisoning with the citation of numerous cases. This section is extremely complete and apparently no poison of the slightest importance has been omitted. In part two is included a discussion of the symptoms, pathology and treatment of the various forms of poisoning while part three is devoted to preventive measures. This arrangement results in a certain amount of repetition which however increases rather than diminishes the value of the book. In the third part also are extracts from the German Imperial Regulations for the conduct of such industries in which the laborers are in danger of being poisoned. In the appendix is a very complete list of references. The book is intended "for all who are, or are obliged to be, or ought to be, interested in industrial poisoning." Such readers will find in this volume all the information they desire. The translation has been excellently done and the spirit of the original is well preserved.

Médecine et Médecins en Éthiopie par le Dr. Merat, médecin particulier du Négus. Price 3 fr. Paris: Vigot Frères, 1912.

Now at a time when the eyes of Europe are turned more and more toward Africa this book written by the chief of the imperial dispensary of the palace of Menelik II has a particular interest. The lack of science and empirical type of treatments, including the extreme use of kousso, are brought home to us. There are chapters on medicine, surgery, and obstetrics among these simple, true, isolated people. They can ignore tuberculosis, cancer and alcoholism on account of their natural lives and live to an old age, inspiring us to say "Beati nimium sui si novint." The book is one of considerable interest.

Handbuch der speziellen Chirurgie des Ohres und der oberen Luftwege. Herausgegeben von Dr. L. Katz, Spezialarzt für Ohres-, Nasen-, und Halskrankheiten in Ludwigshafen a Rh.; Dr. H. Preysing, Prof. der Ohren-, Nasen-, Kehlkopfheilkunde, ord. Mitglied der akad. für prakt. Medizin zu Cöln a. Rh.; und D. F. Blumenfeld, Spezialarzt für Nasen-, Hals-, und Lungenkrankheiten in Wiesbaden. III Band, Lieferung 6. Price 5 marks. Würzburg: Verlag von Curt Kabitzsch, 1913.

The present installment concludes the third volume of this remarkable work. It contains an elaborate and profusely illustrated article on the surgery of the lacrymal passages by Gustav Ritter of Berlin and an article on the surgical treatment of malignant tumors of the upper jaw by B. Heile of Wiesbaden.

Marriage and Genetics. Laws of Human Breeding and Applied Eugenics. By Charles A. L. Reed, M.D., F.C.S. Fellow of the College of Surgeons of America; Member and former President of the American Medical Association; Professor in the University of Cincinnati. Price $1.00. Cincinnati, Ohio, U. S. A.: The Galton Press, 1913.

This book contains much with which all thoughtful persons will agree; at the same time, like most of the modern sex literature, it fails when it tries to combine sentiment and logic. The opening sentence is as follows: "The mating of a young man with a young woman to-day in various Occidental countries generally begins by falling in love." This is as it should be, and as it will continue to be for some time to come. By the time we reach page 156 we have impressed on us "the importance of a careful eugenic inquiry *before* the fatal step of falling in love has been taken." The author leaves us in no doubt as to what this "careful eugenic inquiry" means. But the application of the logic to the sentiment seems to us somewhat difficult. Imagine the bashful youth, *before falling in love*, deliberately inquiring if the young lady of his choice has gonorrhea, or a cartilaginous hymen, or if her grandmother was feeble-minded! And on the other hand it might prove equally embarrassing for the young damsel to ascertain if her swain's generative organs are "over-developed to such an extent as to render sexual intercourse intolerable, if not physically impossible to normal women" (page 151), or if any of his ancestors were degenerate. On page 121 the author urges that "every man who *gives the history* of a gonorrheal attack should be subjected to a rigid physical examination"; quite right, but suppose that the man does not give the history, what then? It is quite possible that the young man may be desirous of hiding this important fact; we have heard of men (and women too) who did not "give the history of a gonorrheal attack" and who yet had the disease. The author faces one-half of this difficulty by saying that "it is important that the genital organs of men should be examined in each instance." On the same page he says, "It should be stated at the very outset that in the absence of positive indications no physical examination of the genital organs ought ever be either attempted or suggested in the case of young women." Why this difference, when the plea at the present day is for equality? Indeed, the author himself seems to appreciate the difficulty, for he says (on page 118): "It should be understood, in the first place, that the necessity for the eugenic examination may apply with just as much force to one sex as to the other. It should be understood, furthermore, that the value of the eugenic examination must necessarily depend upon not only the truthfulness but upon the fulness and frankness of answers to the necessary interrogatories. Every fact, whether pleasant or unpleasant, should be laid openly before the consultant." We fear the eugenic marriage under those conditions is an affair of the dim distant future.

The Surgical Clinics of John B. Murphy, M.D., at Mercy Hospital, Chicago. Volume II. Number 3. June, 1913. Philadelphia and London: W. B. Saunders Company, 1913.

This number includes clinical lectures on cases of ileus, intestinal stasis from adhesions, various plastic operations on tendons, the ear and ankylosis of the jaw; fractures and dislocations of various bones and joints; and a description and application of Albee's operation of bone-grafting for the cure of Pott's disease. Dr. Murphy's method of fixing the uterus in procidentia is described and the description and treatment of a case of acute suppurating prostatitis presented. This issue of Dr. Murphy's "Clinics" is deserving of the same attention and commendation as those previously produced and presents most satisfactorily the clinical teaching of this eminent American surgeon.

Aids to Gynæcology. By S. Jervois Aarons, M.D., Edin., M.R.C.P. Lond. Gynæcologist to Lt. Anthony's Hospital; formerly Registrar and Pathologist to the Hospital for Women, Soho Square; Gynæcological Tutor, Extra Mural School of Medicine, Edinburgh. Fifth Edition; Twelfth Thousand. Price $1.00 net. New York: William Wood & Company, 1913.

This is a new book rather than a new edition of an old book; the chapter on Anatomy alone remaining of the former work. Only the bare essentials of the subject are given, and the volume may claim the distinction of being the smallest compend on Gynæcology in the market.

Text-Book of Anatomy and Physiology for Nurses. By Amy E. Pope, Author, with Anna Caroline Maxwell, of "Practical Nursing," and Instructor in the School of Nursing of the Presbyterian Hospital in the City of New York. With 135 Illustrations. Price $1.75 net. New York and London: G. P. Putnam's Sons, 1913.

The special aim of this new volume on anatomy and physiology for nurses is to provide more physiology than is served up in the text-books now in use. Certainly this work contains more physiology than anatomy, but this result has been obtained by the very simple expedient of omitting almost all the anatomy. We know of no book of this kind with so little anatomy in it. The physiology is about equal in amount to that contained in the recognized text-books for nurses. With regard to the quality of the work, when compared with five other publications of a similar kind the volume in question is certainly inferior to three of these books and is about on a level with the other two. In addition to numerous slips (both in text and foot-notes) which have escaped the author's eye, there are some statements which need correction, for example: "The foramen magnum is the opening through which the nerves and blood-vessels pass into the spinal canal"; "chemical affinity is the agency which causes substances to combine, and which holds them together when combined." The index is inadequate; no mention is made therein of saliva, bile, gastric juice, deglutition, defecation, micturition, etc.

Manual of Obstetrics. By John Osborn Polak, M.Sc., M.D. Professor of Obstetrics and Gynecology in the Long Island College Hospital; Professor of Obstetrics, Dartmouth Medical School; Obstetrician to the College Hospital; Gynecologist to the Jewish Hospital; Consulting Obstetrician to the Methodist Episcopal Hospital; Fellow of American Gynecological Society; New York Obstetrical Society, etc. With Three Color Plates and One Hundred and Nineteen Illustrations in Text. Price $3.00 net. New York and London: D. Appleton and Company, 1913.

The writer of this new book on Obstetrics has had an experience of more than twenty years in teaching his subject; he therefore should know what students and practitioners require. We are not surprised to find that the author has produced an exceedingly good and practical work, and one which is sure to find favor with teachers and learners. The book is small, but comprehensive; it is well printed and well illustrated, and contains everything that the student is likely to look for. Theoretical discussions have been omitted, as a rule; though this feature might have been carried a little further, as much of the embryology and organology in chapter II. could be spared from a book of this size. Many of the illustrations are old friends, but there is a general absence of indication of their source.

A Manual of Surgery for Students and Physicians. By Francis T. Stewart, M.D., Professor of Clinical Surgery, Jefferson Medical College; Surgeon to the Germantown Hospital; Out-Patient Surgeon to the Pennsylvania Hospital. Third edition with 571 Illustrations. Price $4.00 net. Philadelphia: P. Blakiston's Son & Co., 1913.

The present revision differs but little from its predecessors; a few slight additions have been made to some of the chapters, but the book remains essentially the same as the first edition. For the undergraduate the volume may be suitable, but the chances are that his book will be selected for him by his college. The practitioner will require a work that goes much more into details.

The Normal Menstrual Cycle in the Uterine Mucosa. Presented in twenty colored charts, with explanatory text. By Robert Schröder, M.D., University of Rostock. Price 16 marks. Berlin: A. Hirschwald, 1913.

The atlas herewith referred to constitutes another example of the careful consideration which our German colleagues extend to these special fields of anatomy and physiology. By means of twenty carefully executed colored drawings of microscopical preparations, Schröder presents the anatomy of the normal menstrual cycle as it involves the mucous membrane of the uterus, for, as he rightly claims, we can only understand and appreciate the pathological processes after the normal appearances have been studied and depicted in all their details. A great deal of uncertainty still exists as to the problematical line which defines the one from the other and a great many specimens taken during curettage are examined and described as of pathological significance when in reality they are merely phases of normal conditions. This atlas serves as a very valuable basis for the comparison of such specimens and is deserving of the special attention of the American profession.

Skin Diseases in General Practice. Their Recognition and Treatment. By Haldin Davis, M.B., B.Ch., B.A. Oxon., F.R.C.S. Eng., M.R.C.P.; Physician in Charge of the Skin Department, Paddington Green Children's Hospital; Chief Assistant in the Skin Department, St. Bartholomew's Hospital; Assistant Physician to the Hospital for Diseases of the Skin, Blackfriars. Price $3.75. London: Henry Froude, Hodder & Stoughton; New York: Oxford University Press, 1913.

The author of this work has adopted the excellent plan of describing the diseases of the skin according to the different regions of the body. This method has been followed by Sabourand on a larger scale in his "Demalologic Topographique," but no other work in the English language has yet been written along these lines. This plan has many advantages from the didactic viewpoint. Thus in the chapter on the face there is given at the outset a list of all the important skin diseases affecting this region. Then follows a discussion of the general hygiene of the face. After this the various cutaneous diseases of the face are taken up in order. There are similarly chapters on the limbs, on the hands and feet, on the nails, on the pudenda and groins, and on the scalp. In the first part of the book there are separate chapters on diseases due to the common pyrogenic organisms, on eczema, on syphilis, and on diseases giving rise to widespread eruptions. There are also chapters on diseases limited in extent but irregular in distribution, on bullous eruptions, on anomalies of pigmentation, and on some modern methods of treatment. There are a large number of excellent illustrations. The book is an eminently practical one, dealing only with the important diseases of the skin. Considerable attention is paid to treatment and a large number of useful prescriptions are given. The book is admirably printed on a fine quality of paper and is well bound. One can have no hesitation in recommending it to the student and practitioner as an excellent text-book.

Modern Ophthalmology. A Practical Treatise on the Anatomy, Physiology, and Diseases of the Eye. By James Moores Ball, M.D., LL.D., Dean and Professor of Ophthalmology, the American Medical College of St. Louis (Medical Department of National University of Arts and Sciences). Third edition, Revised and Enlarged. Price $7.50 net. Philadelphia: F. A. Davis Company, 1913.

General practitioners and specialists alike will welcome this new edition of Dr. Ball's well-known and appreciated treatise on diseases of the eye. The work has always enjoyed popularity not only because of its completeness, including as it does a full account of the development and anatomy of the eye, and the physiology of vision, as well as the usual matter on the hygiene and diseases of the eye and on refraction, the logical arrangement of its subject matter, and clearness of description, but also an account of the excellent illustrations, including 24 colored plates. This new edition contains a new and useful chapter, by Dr. T. H. Shastid on "The Legal Relations of Ophthalmology," and considerable additions to the chapter on "Refraction." Other chapters also give evidences of careful revision. The volume is rather ponderous, containing over 900 pages in addition to the inset plates on thick paper, and for the sake of the reader's convenience a division of the work into two volumes would have been desirable. However, the book is worth holding, with all its weight, to all who seek for the latest and reliable information on the subject of ocular diseases.

Proceedings of the Mental Hygiene Conference and Exhibit. At the College of the City of New York. Under the joint auspices of the National Committee for Mental Hygiene, and the Committee on Mental Hygiene of the State Charities Aid Association. November 8 to 15, 1912. New York: Committee on Mental Hygiene of the State Charities Aid Association, 1913.

The publication of this report of the recent conference on mental hygiene places in the hands of all those who are interested in this subject a valuable exposition of its many aspects as they were presented in detail before the conference. Among the papers comprising this volume may be mentioned the following: "Unsoundness of Mind, a National Handicap," by Lewellys F. Barker; "Nursing in Mental Disorders," by Adele S. Poston; "Syphilis and Insanity," by George H. Kirby; "Heredity in Relation to Insanity and Eugenics," by A. J. Rosanoff; "Alcohol and Insanity," by E. S. Elwood; "Modern Treatment of Alcoholism," by I. H. Neff; "Mental Diseases in General Practice," by T. Salmon; "Daydreams and Thinking," by Smith Ely Jelliffe; "Immigration and Insanity," by W. Williams, and "Mutual Efficiency," by R. S. Woodworth. These represent a few of the articles in this volume, all of which present in popular form a description of many phases of mental derangement and of their prevention.

A Handbook of the People's Health. A Textbook of Sanitation and Hygiene for the Use of Schools. By Walter Moore Coleman. Illustrated by Retta Carroll and Alfred Seiler, and with photographs. Price 70 cents. New York: The Macmillan Company, 1913.

This is an excellent volume on hygiene, presenting this subject in its more practical relations to daily life. There can be no doubt that school children are more interested in hygiene, the significance of which they can understand from their own experience rather than from a study of their own bodies. It is profusely illustrated with drawings and photographs, the captions of which convey a fair idea of the scope of this book. A few of these illustrations are as follows: sanitary milking; testing for adulterations; showing teeth before and after straightening; oiling a sewer drop; Russion folk dance; a sanitary kitchen; testing the eyesight; night shift in a glass factory (child labor); city children on a trip to the country; and sunshine, nature's disinfectant, the best and cheapest. The author has written a book that will be both instructive and entertaining to school children and even to their elders.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

FIRST DISTRICT BRANCH.

Seventh Annual Meeting, Held at Yonkers October 9, 1913.

VICE-PRESIDENT, Dr. HENRY LYLE WINTER OF CORNWALL, CHAIRMAN PRO TEM.

Address of Welcome.—Hon. JAMES T. LENNON, Mayor of Yonkers, welcomed the members and guests of the Society and said that Yonkers was not unmindful of the debt that it owed to its physicians. The campaign at present being waged for the purpose of raising $150,000 for the hospitals of that city bore witness to this fact. In closing, the speaker extended an invitation to those present to visit and inspect the city hospitals.

Address.—Dr. WISNER R. TOWNSEND of New York said that he was present as the representative of Dr. William F. Campbell, the President of the Medical Society of the State of New York. He deplored the small attendance and said that the program presented an embarrassment of riches and was worthy of a large audience. There were 3,500 members of the First District Branch who should have been present, while there were actually scarcely 35 to take part in the election of officers. The officers were well chosen, so that the small attendance could not be laid to that score, and again the place of meeting was not inaccessible. Small places in distant parts of the State had meetings well attended, as for instance at Sonyea recently there were 200 in attendance at the District Branch meeting. Dr. Townsend said they would welcome any suggestions as to means for increasing the interest and attendance at these meetings. He would suggest that the presidents of county societies make it their special duty to see members personally and drum up parties. Dr. Townsend then expressed the opinion that since homeopathic and eclectic physicians were recognized and licensed by the State it would be wisdom on the part of the Medical Society of the State of New York to admit such practitioners to membership, as the State Society could then influence and direct them.

Election of Officers.—The following officers were elected for the ensuing two years: *President,* Dr. Henry Lyle Winter of Cornwall; *Vice-President,* Dr. James E. Sadlier of Poughkeepsie; *Secretary,* Dr. Charles E. Denison of New York; *Treasurer,* Dr. Thomas F. Goodwin of Mount Vernon.

The Treatment of Typhoid Fever.—Dr. W. STANTON GLEASON of Newburg presented this paper, in which he declared that no acute disease was treated today with as deep a knowledge of the practical underlying conditions as was typhoid fever. In fact the advanced ideas applied today in the direction of the treatment of the typhoid fever patient marked the progress of general medicine. Typhoid fever was plainly an accident which could usually be traced to a positive source and it was not only the duty of the physician to skilfully treat the disease, as Osler had said, but to be also solicitous that no other case arose from that patient. After reviewing the various media through which the typhoid bacillus was transmitted and the history of prophylactic vaccination against typhoid fever, he stated that the most important factor in the successful treatment of typhoid fever was the judgment used in keeping the patient's vigor up to the highest standard. The disease was prolonged and enervating and there was a constant and serious drain on the vitality, a greater demand for food and a diminished power in digestion. The diet as prescribed a few years ago in typhoid fever was absolutely insufficient to sustain a patient during a prolonged illness. One should aim to give the patient from 2,500 to 3,000 calories in the twenty-four hours, meeting this average gradually, as the condition of the patient indicated. Solid food had no place in the dietetics of typhoid fever, as its use frequently caused serious gastric and intestinal irritation. Milk, so long considered the ideal food for the patient, was now deemed insufficient. This was proven to be true, as two quarts of milk daily was only equivalent to 1,300 calories. It had been the author's plan to use milk as the menstrum for lactose and to give in addition one or two raw eggs every four hours. Following this method the total number of calories could be made to equal the required number of calories for twenty-four hours. The condition of the patient during the fever and convalescence fully justified this method. In regard to vaccination during the progress of typhoid fever it had been his practice to inoculate the patient at once with one hundred million dead bacteria, repeating the dosage every third day until four hundred million had been given. This procedure in a series of thirty-two cases, both in hospital and in private work, had been satisfactory. The majority of those inoculated showed but slight reactions; the temperature as a rule ranged lower and the activity of the symptoms moderated. Deductions, however, could not be drawn from the experience in one or two epidemics, but one could assume that the therapeutists of the future would continue the inoculations during the early stages of typhoid fever in progressively increasing dosage.

In regard to the use of intestinal antiseptics some of the idols of the past decade had been rudely shattered. A research conducted under the auspices of the Therapeutic Research Committee on Pharmacy and Chemistry of the American Medical Association showed that so far as figures went their investigations did not go to prove that any of the antiseptic agents employed exerted any beneficial action and later cultures plainly showed that antiseptic drugs failed to kill off per gram of feces millions of indol producing bacteria whose habitat was the large intestine. This research covered every drug that could be employed as an intestinal antiseptic. No report was made as to the value of the pure cultures of lactic acid bacilli. Many had faith in the value of the Bulgarian laetic acid bacilli as inhibitors of fermentation in the digestive tract and this had been borne out by practical tests of its utility in typhoid fever and the intestinal diseases of childhood. The pure cultures of the Bulgarian bacilli could be given to overcome the putrefactive bacteria which must be greatly increased in the conditions produced during typhoid fever, and they also took up the defense of the system against impending toxemia. Metchnikoff and his pupils had recently announced that the intestinal lesions found in typhoid fever were not wholly due to the *bacillus typhosus,* but were also produced by several groups of anaerobic bacteria. Of these groups they found the *B. satellitis* in the stools of nearly every case of typhoid fever examined, but they were never found in the stools of the normal individual. The *B. satellitis,* when injected into guinea pigs, always produced ulceration in Peyer's patches, but when the *B. typhosus* was injected there was simply swelling of the patches without ulceration. The argument, therefore, was that the *B. satellitis* was the cause of the ulcerative process. He usually gave four drams of the pure culture of the Bulgarian bacilli during twenty-four hours, and under its use there was little or no discomfort from gaseous distention of the abdomen, and it was reasonable to believe that the patient was at least partially protected from toxemia. It was evident that the use of cold water, as laid down by Brandt, was losing favor and that the cold sponge, wet pack, and ice-water enema were much more in evidence than the tub plan of Brandt. Outside of the lines of treatment laid down, the general management of typhoid fever was largely expectant; it was for the physician to meet emergencies as they arose, using little medicine and large doses of common sense.

Dr. THOMAS F. GOODWIN of Mount Vernon said that the Brand treatment of typhoid fever gave the best statistics, a mortality of 8.2 per cent. However, it was cumbersome and expensive, requiring the services of three nurses, and many devices had been substituted for the tub treatment. There was no doubt but that the oyster sometimes carried the typhoid bacillus, but it should be remembered that lemon juice proved a protection against the infection. Vaccination was as yet unsatisfactory in modifying the duration of the disease, but antiseptics and modern methods of treatment modified the complications. There seemed to be just as many cases of relapses with the use of the vaccine as with the ordinary methods of treatment. The time when it was best to use the vaccine was as yet a mooted question. The caloric requirements of patients differed and it was necessary to study each patient individually in this respect. The *B. bulgaricus* was probably of some value. Tympanites was usually due to local trouble in the intestines themselves. Profound toxemia produced paralysis with the attending train of symptoms, and if the primary tympanitis and toxemia could be avoided by the administration of the Bulgarian bacilli it was certainly an advantage.

Dr. EDWIN I. HARRINGTON of Yonkers said that the typhoid bacillus was allied to the colon bacillus, but presented many important differences. It was more toxic to man, as it was capable of invading the circulation and tissues of the living body. The effects of intestinal growth differed in that the typhoid bacillus did not pro-

duce gas or indol. The colon bacillus made large quantities of gas, and indol moderately, depending on the medium. In most cases of typhoid fever there was present flatus and putrefactive stools; it was evident that there was a mixed intestinal flora consisting of typhoid bacilli together with a greatly increased growth of the anaerobic and colon bacilli. The latter were much augmented in all forms of diarrhea, whether typhoid or otherwise. As the typhoid, like the colon bacilli, would grow in a wide range of acidity or alkalinity, one would expect only a partial replacement of these groups by the lactic acid bacilli. On the other hand, the anaerobic putrefactive forms, mostly indol making, and requiring a neutral or alkaline medium, should be greatly reduced by the lactic acid cultures. Theoretically, taking the intestinal flora as a whole, this treatment would greatly help the local condition, and should also lessen the absorption of toxins in the circulation. While not specific, it seemed to offer a safer and more effective treatment than by antiseptics. The speaker said that his clinical experience confirmed this view. In employing a lactic acid culture it was his custom to use it in conjunction with a calcium salt (calcium carbonate precipitate) in doses of five grains or more; the calcium greatly favored the growth of the lactic acid bacilli, and had probably a desirable effect in preventing or restricting hemorrhage.

Dr. S. W. S. Toms of Nyack said that at the Minequa Hospital in Colorado they carried out the ideas of the Massachusetts General Hospital in the caloric treatment of typhoid fever. The patients were given from one to four eggs, one to three pints of cream, the pulp of baked apples and the juice of oranges in twenty-four hours, and the mortality was less than four per cent. The Brandt treatment was modified as the cases required, cold spongings, compresses, and ice-packs being employed. He had treated a case recently, a large man, to whom he gave a large quantity of food, over a quart of lactic acid prepared milk, together with all the sterilized milk that he could drink. He followed the plan of giving only sterilized food carefully and there was no tympanitis, and the general condition was good throughout the course of the fever though there were some complications. Some creosote was given (5 grains three times daily) and he thought this was a factor in maintaining the favorable symptoms. He also thought that colonic irrigations were beneficial in keeping down the temperature. Cold compresses were also valuable in keeping down the temperature and caused the gas to be more easily expelled. Dr. Toms called attention to the fact that there had been a number of cases of typhoid fever in the vicinity of Nyack traced to the drinking of spring water from springs near the railroad. These were no doubt infected by the dejecta of travellers on the trains and this was a matter calling for attention and control.

Dr. Samuel E. Getty of Yonkers said that in view of the known facts regarding typhoid carriers they were not doing their duty in allowing a patient who had had typhoid fever to pass from their care until an examination of the dejecta showed that typhoid bacilli were no longer present. If typhoid cases were cared for until they were innocuous, typhoid fever would soon disappear to a large extent.

Dr. W. Stanton Gleason of Newburg said that he agreed with the speaker who had said that if they could prevent the primary distention by tympanites they would not get the continued distention so often found later in many cases. The lactic acid bacilli treatment, together with calcium salts, was valuable in overcoming anaerobic bacteria in the intestines. The convalescence was shortened and became a matter of days and not weeks. The number of calories given was a matter of individual adaptibility. Some patients could take four thousand but other anemic individuals could only take twelve hundred. The giving of colonic irrigations seemed to him to approach dangerous ground. Ulcerations sometimes extended into the colon and the distention might cause it to give way. The ice-water enema with the patient in the recumbent position was sometimes efficient in extreme conditions until the temperature was reduced. In regard to watching for carriers, this was done in the Massachusetts General Hospital. No patient was allowed to go away until the stool test was negative.

Menorrhagia and Metrorrhagia: What They Signify.—Dr. J. Riddle Goffe of New York presented this communication. He stated that patients suffering from uterine hemorrhage might be divided into two classes. In those of the first group there was a palpable pathological condition which was readily recognized, such as endometritis, displacement, uterine fibroids, salpingitis, ovarian tumors, carcinoma, etc. To the second group belonged girls from fifteen to twenty years of age or women approaching the menopause where hemorrhage occurred without any pathological condition upon which one could put his finger. These cases attracted his attention oftener during the past few years than previously. He could not say definitely whether the condition occurred more frequently than formerly or whether the apparent greater frequency was simply accidental. These cases might be curetted two, three, or four times and the trouble still continued. The error was that the gynecologist had concentrated his attention on the uterus and had not considered the general condition of the patient. Various theories had been advanced by different authorities to account for these hemorrhages for which there seemed to be no palpable cause, among them hardening of the muscles of the uterus so that that organ could not contract in a normal way, sclerosis of the blood-vessels, or a diminished amount of calcium salts in the blood. However, an examination of a large number of cases showed that these anatomical idiosyncrasies were not constant. Arnold Sturmdorf, in investigating this subject, found that one factor was constantly present, and that was that the blood did not coagulate. Menstrual blood did not coagulate readily and in order to study the subject thoroughly the entire subject of the coagulation of the blood had to be gone into. They had formerly been taught that fibrin caused coagulation, but now it had been shown that fibrin was the result of fibrinogen and fibrin ferment, and that fibrin ferment was itself the result of two other substances, thrombogen and thrombokinase. Thrombokinase was found in the walls of the blood vessels and the tissues surrounding them. It had been maintained that the fibrinogen was diminished at the time of menstruation and again that calcium salts were deficient at that time. It had also been claimed that there was no chemical difference so far as the constituents were concerned between the blood in the veins and the menstrual blood. In order to determine whether there was a difference, Sturmdorf put a tube ilnto the uterus and conducted the menstrual blood into a vessel, and then incised the cervix and collected the blood from that source. The blood from the cervix coagulated while that from the uterus did not. It was found that the blood that had passed through the endometrium, if it commingled with that from the incision in the cervix, prevented the latter from coagulating. In other words menstrual blood prevented the coagulation of normal blood. There was also a substance in the blood called antiferment or antithrombin which prevented coagulation, and an undue proportion of this was formed in the blood in the endometrium. The thrombokinase existed in great abundance in the vicinity of the bolod vessels and commingling with the fibrinogen caused coagulation. This process was regulated by some regulator in the human system and the theory was that the corpus luteum controlled this biological factor in the endometrium. This theory was supported by the fact that amenorrhea was usual in cretinism. The ductless glands were the activating factor. Experience had shown that curetting did not relieve the hemorrhage and this might be accounted for by the fact that by scraping one reached the submucous tissue and stimulated the antifibrin and thus made the condition worse. One curettement for diagnostic purposes was to be recommended. If this failed to give relief or to clear up the diagnosis, successive curettements did not offer hope for a cure. The underlying logical treatment was extract of ovary or of pituitary gland. So far as treatment was concerned these cases might be divided into two classes, namely, women approachnig the menopause and young girls. The young girls were put to bed and treated by organotherapy. In women he used the curette in order to eliminate any possibility of cancer. In women approaching the menopause there was no objection to destroying the endometrium, so in these cases he burned the endometrium with nitric acid. He did not resort to this procedure until other methods of treatment had failed. The use of steam to destroy the endometrium he considered decidedly dangerous and rather than employ it preferred to resort to hysterectomy. He wished to emphasize the point that in treating these cases of hemorrhage where there was no adequate cause discoverable one should no longer think that curettement was the only measure available but should look further afield.

Dr. Edgar M. Hermance of Yonkers said that normal menstruation was dependent not alone on the integrity of the genitalia but that it was also necessary that the blood be in good condition. In these cases to which Dr. Goffe referred there was something in the condition of the

blood that prevented coagulation. It might be some low form of injection, some toxic condition of the blood, the result of digestive disturbance. If they were careful enough he thought that in most cases they would find the cause of the menorrhagia or metrorrhagia. The speaker asked Dr. Goffe if he had secured any effect from the use of thyroid gland in cases of this kind or whether he had noted a lack of results. He, himself, had used mammary gland grains three times a day continuously for some time without any noticeable effect.

Dr. H. Moffat of Yonkers felt that the experiments related by Dr. Goffe were interesting in showing that the hemorrhage was due to local conditions, but he did not feel entirely convinced that the change in the blood was local. Serum ought to have some effect on the bleeding.

Dr. Jerome Morley Lynch of New York said that while he was not a gynecologist he would like to call attention to the fact that local hemorrhage was seen in other localities than those in the field of the gynecologist. He did not know what it was in the walls of the uterus that caused the hemorrhage, but there was a certain balance between the different constituents of the blood which when interfered with resulted in a lack of coagulation. Hemorrhage frequently occurred from the bowels and this was often due to infection. It was true that a low grade of infection would cause hemorrhage from the bowels and possibly this might be a factor in causing uterine hemorrhage.

Dr. J. Riddle Goffe of New York, in closing the discussion, said that in reply to Dr. Lynch's remarks he wished to say that these cases had been examined with the points in view that had been suggested. The idea was that the bio-chemical process that should go on in the endothelium was regulated by the ovary, pituitary, or other ductless glands. There was no doubt but that it was in the mucous membrane of the uterus itself that the process took place. They had been careful to isolate the cases in which there was absolutely no pathological lesion discoverable. In regard to the condition of the blood, in some cases of hemorrhage a Wassermann examination was made and in those cases in which this was positive salvarsan stopped the hemorrhage.

Diagnosis in Rectal Diseases.—Dr. Jerome Morley Lynch of New York read this paper. He stated that the diagnosis of rectal disease in many cases was attended with difficulties since the patient frequently did not seek the advice of a medical man until the diagnosis was so apparent that the patient could make it for himself. This delay spelled disaster. In malignant conditions the symptoms were at first so insignificant that in the majority of cases they were overlooked by the patient and very often by the physician as well. It was important when a patient complained of any symptom that might have reference to the rectum that a thorough examination be made before any measures were taken for the relief of the condition. The laity was apt to term any rectal trouble "piles" and to refuse examination, and this was unfortunate. Dr. Lynch cited two cases which illustrated the importance of making an examination and of doing a radical operation in doubtful but suspicious cases. The examination of the specimens in one of these cases proved it to be a sarcoma and in the other a beginning adenocarcinoma. A good history was of the first importance, as a diagnostic aid, and the physician who aspired to eminence in any branch of medicine should recognize the importance of a complete history. Pain was the symptom which most frequently brought the patient to consult the doctor. It was important to get the patient to describe the exact character of his pain, its relationship to defecation, and its location. Pain occurring during a movement, and lasting for some time after was indicative of ulceration of the anus. A throbbing pain was usually indicative of an abscess. A sense of fullness, or a dull aching pain (especially after exercise or mental worry) shooting toward the prostate in the male would suggest hemorrhoids, or congestion around the anus. The pains of hemorrhoids were often mistaken for disease of the prostate. If the pain was situated over the coccyx, and aggravated by pressure or movement of this bone, the symptoms were rather indicative of coccygodynia. Pain in the back might be due to a prolapse or impaction, or a malignant growth. The history would have to elucidate the problem. When the painful points were situated on either side of the sacrum, almost at its junction with the lumbar vertebræ, it was indicative of intussusception of the sigmoid, especially if associated with a dragging sensation in the left iliac region and a feeling of heat in the lower portion of the abdomen. A burning pain was suggestive of ulceration, or an acid condition of the stools. Pain shooting down the legs and in the lumbar region might mean cancer, ulceration, or an inflammatory tumor of the pelvis. It was sometimes the earliest manifestation of a cold abscess, though under such circumstances the nerve did not always have painful points. The pain differed from ordinary neuralgia in that there were usually signs of blocking of the nerve. It was exceedingly important to be able to differentiate between tuberculosis and other conditions. In rebellious cases of sciatica tuberculin and other diagnostic tests should be applied with scrupulous care, so that when a diagnosis was made, measures could be instituted at once to put the patient in the best possible condition, with or without local intervention. A sharp pain during a constipated movement, followed by swelling, would suggest a thrombotic hemorrhoid. If constantly present during a movement it would suggest a foreign body. Pain coming on when walking up stairs, or standing up was suggestive of a fistula. A bearing down pain, or constant stabbing pain, might be suggestive of inflammation of the crypts. A patient search might reveal nothing, yet with a bent probe and the speculum in place a search of the little pockets around the rectum would reveal inflammation of the crypts if it existed. Pain might also be indicative of neuralgia, though one should hesitate to make such a diagnosis until everything else had been excluded. Protrusion might mean a great many things, such as hemorrhoids, polypi, hypertrophy of the papilla, villous tumor, pedunculated sarcoma, carcinoma, or partial or complete prolapse of the bowel. A tumor which prolapsed and when replaced returned again was very often either a large thrombotic hemorrhoid, or some external condition. It might also be a carcinoma. A hemorrhoidal condition would have to exist a long time before it would prolapse after being replaced. A polypus generally came down when the patient strained. A prolapse of the rectum might or might not remain in place after it had been put back. A prolapse, however, was always associated with bearing down pain and a feeling of unfinished business. It was important to find out all the characteristics of the discharge and of the feces. Hemorrhage was significant of a great many conditions. Bright red blood projected with some force might suggest an ulcerative hemorrhoid. A little blood might mean an ulceration or a fistula. When the blood was dark in color, and thoroughly mixed with the feces, it might indicate a malignant growth high up. Hemorrhage might be due to acute intussusception when it came on at certain periods and was associated with constipation, and when the symptoms were relieved following hemorrhage. When the blood was associated with mucus and pus, with a frequent desire to move the bowels, it was suggestive of a malignant tumor, stricture, or severe ulceration. When the feces were slightly streaked with blood and there was a frequent desire to move the bowels, accompanied by diarrhea, one should look for a polyp in the rectum or sigmoid. An acute hemorrhage might be due to a rupture or to a varicose vein in the rectum or sigmoid, to an injury, a foreign body, an intussusception or a carcinoma. Diarrhea, alternating with constipation, followed later by a frequent desire to evacuate the bowels, with passage of blood or mucus, either separately or mixed with fecal matter, or a sensation as though there was something more to come away all the time might be produced by carcinoma, multiple polypi, single polypus, tuberculosis, syphilis, stricture, intussusception of the sigmoid, or amebic dysentery. One should distinguish between these conditions only by taking a careful history and making a most thorough examination. Dr. Lynch then discussed the details of rectal examination. He said that he found the left Sim's position most convenient for making examinations. He called attention to the various abnormalities to be noted by inspection. By palpation it was often possible to trace a fistula without the aid of a probe, to outline abscesses, and to note painful points. By palpation one got a fair idea of the condition of the sphincter. By digital examination, when tactile sensation was highly developed, the condition of the anus and lower portion of the rectum could be thoroughly explored and the slightest abnormality discovered. These digital examinations could be made with a minimum of pain. Lubricondine was the best lubricant and castile soap jelly a good second. With regard to the introduction of the hand for the purpose of examination Dr. Lynch was of the opinion that it was safer to give a patient an anesthetic and open the abdomen for purposes of exploration than to depend upon this method. He described the use of the proctoscope and sigmoidoscope, showing these instruments could be passed with ease, an accomplishment not generally achieved by the majority of surgeons.

Dr. Henry Moffat of Yonkers said that the paper had touched upon important points that appealed to all who had any necessity for making rectal examinations. Many patients refused a rectal examination and sometimes the physician himself might not think it necessary. The conditions spoken of and the cases referred to served as a warning against neglect to make these examinations. The physician made more mistakes from not working than from lack of knowledge A great deal could be learned without the proctoscope by making an examination as far as the finger could reach. They should also perfect themselves in the use of the proctoscope. Many conditions were amenable to treatment if the trouble was found. With a little practice any one could tell a tuberculous ulcer, a syphilitic ulcer, a fissure or other of the more common conditions, but the difficult point was to make a diagnosis of malignant disease. When there was a bloody dysentery or a hemorrhagic colitic the good pathologist might find cancer cells if malignant disease was present. One should not forget to be on the lookout for foreign bodies. In one instance he had found the breastbone of a chicken, and in another a large piece of wood. One should remember that a diganosis could not be made without a thorough examination any more readily in rectal diseases than in diseases located elsewhere in the human body.

Certified Milk of the Medical Society of the County of Westchester.—Dr. Bertrand Francis Drake of New Rochelle presented the communication. He stated that the requirements for certified milk in the county of Westchester had been made to conform to those prescribed by the United States Bureau of Animal Industry and the New York Milk Commission. The bacterial count could not be more than 30,000 per c.c. and the milk must contain at least four per cent. butter fat. It could not be sold beyond the date stamped on the cap of the bottle. Dr. Drake described the sanitary details enforced at the different dairies and gave a lantern slide demonstration showing a number of the dairies of Westchester County and the methods used to insure a milk supply as nearly perfect as possible. He showed an illustration of a new system of ventilation for barns and the method of cleaning cows with the vacuum cleaner. They had tried the vacuum milker, but found that there was a higher percentage of bacteria in the milk when this was used and consequently had discarded it.

Acute Specific Fever Manifestations in Nose and Throat, with Treatment.—Dr. Earl Parsons Lasher of New York read this paper in which he reminded the family physician that serious lifelong handicaps often had their source in nose, throat, and ear diseases resulting from the acute infectious diseases, particularly measles, scarlatina, and diphtheria. All were familiar with the nose and throat symptoms of measles. In dealing with the nose and throat condition in this disease one should remember the eustachian tube and protect it against invasion in every possible way. One should not interfere with the free discharge that nature had set up. By this free secretion the turgescence of the membranes was relieved and countless bacteria were washed away. Belladonna and drugs having a like effect should be avoided, while codeine or heroin should be used in the smallest doses to control the cough. One should assist nature in her washing by the use of nasal douches and gargles of mild alkaline and antiseptic properties heated to 110° or even to 120° or 130° F. If the child could be properly controlled the nostrils might be washed out every four hours with a warm solution from a fountain syringe. If the acute rhinitis was persistent and tended to become chronic, one might use an astringent solution with douche, either of alum, 1 grain, tannic acid, 80 grains, and distilled water, 10 ounces; or of boric acid, 2 drams, glycerine, 2 drams, tincture of myrrh, 2 drams, and water up to 6 ounces. One should examine for adenoids which if previously existing were much irritated and would require subsequent removal. The eyes should be protected from light and bathed frequently with a warm boric acid solution. If there was a pronounced secretion, a two per cent. solution of collargol might be employed every two hours. In scarlatina it had been claimed that twenty-four hours before any rash appeared on the skin, it was well marked in the throat. The sore throat of scarlatina was responsible for a large percentage of hypertrophied tonsils and otitis media. Otitis media occurred in from 10 to 30 per cent. of all cases of scarlatina. There were more permanently hypertrophied tonsils from this disease than from any other save, perhaps, from repeated attacks of tonsilitis. The most helpful treatment was irrigation of the throat with hot normal saline solution. This markedly relieved pain and removed the secretions. During sleep cold compresses to the neck were helpful if they could be applied without getting the clothing wet. Every two hours a spray was used of from two to four grains of menthol in one ounce of albolene. If carache was evident, gauze saturated with five per cent. phenol in glycerine might be applied in the auditory canal, well back against the tympanum, and left in place for twelve hours. The hot water bag should be applied and the ear and neck kept well covered. If the temperature and restlessness persisted beyond the normal limits of the disease, the ear drum should be examined and if found to be bulging the only treatment was immediate paracentesis. This should be followed with syringing with warm bichloride solution 1-10,000 every three hours. One should watch for swelling behind the ear or tenderness of the mastoid tip. Cervical adenitis was a frequent complication of scarlatina and as soon as observed should be treated by applying an ice-bag and keeping it on for several days and nights. When this was not feasible, ichthyol ointment, 30 per cent., or kataplasma kaolini might be employed. Fortunately diphtheria did not cause so much trouble of this kind as formerly; still it was credited with causing four per cent. of the otitis media cases. In diphtheria gargles doubtless had very little effect aside from that of cleanliness. The throat should be syringed with a warm alkaline solution every three hours. If the larynx was affected one should avoid the steam tent or its equivalent. For particularly septic throats, nothing surpassed the acid solution of potassium chlorate containing free chlorine. This was made by adding to nine grains of powdered chlorate of potassium five minims of hydrochloric acid and shaking, with an ounce of water gradually added. This was mixed with an equal quantity of hot water and used every two to four hours. It should be made fresh every time it was used. In the laryngeal type of diphtheria one should watch carefully for cyanosis and rapid shallow breathing, and not wait until asphyxia seemed imminent before intubating. If the tube got blocked and deglutition became impossible or very imperfect tracheotomy should be performed rather than keep up repeated attempts at intubation. After the disappearance of the membrane from the throat the tonsils should be painted with a two per cent. solution of silver nitrate, being careful not to get any of the solution in the larynx as it caused most uncomfortable strangulation symptoms. If adenoids were present they would tend to act as a nidus for the disease and keep the patient a source of infection, and hence as soon as the patient's condition permitted the adenoids and tonsils if hypertrophied or diseased should be removed.

Late Cerebrospinal Manifestations of Inherited Syphilis.—Dr. Henry Lyle Winter of Cornwall presented this communication. He said that the discovery of the specific germ of syphilis had illuminated the subject of inherited syphilis nearly as well as that of the acquired type. Probably in all cases under ten years of age with even the slightest indication of inherited syphilis of the nervous system would give a positive Wassermann reaction. This was true in the author's cases. All were familiar with the early manifestations of inherited syphilis, but he wished to consider the later manifestations. Formerly if a patient reached maturity or beyond without developing inherited syphilis they had no method of determining its presence and were inclined to overlook its importance. Since the discovery of the Wassermann reaction a change had taken place and it was now believed that inherited syphilis was a much more common cause of cerebrospinal disease of adult life than was formerly thought. Wassermann tests made by the author merely as a part of routine in one case each of progressive muscular atrophy, combined sclerosis (spastic) (ataxia paraplegia), tumor of the cord involving principally the lateral tracts, and myelitis, and in two cases of multiple neuritis, were positive. Examination of the cerebrospinal fluid would throw considerable light on these cases, but patients objected to lumbar puncture and in fact the procedure was not entirely free from danger. The irregular or atypical cases of inherited syphilis were apparently much more common than the usual conditions referred to above. Any irregular manifestation of cerebral or spinal disease without the history or evidences of acquired syphilis should be regarded as very possibly of hereditary syphilitic origin. The age at which those symptoms appeared should not influence the physician to disregard the possibility of inherited disease. Dr. Winter reported the histories of two cases of sisters who began to have epileptoid seizures, one at the age of sixty-three and the other at the age of sixty-four, which he regarded as ordinary cases of arterial degeneration and treated accordingly with no result. After

treating the first case for a year the second case came to his attention and at this time a Wassermann test was made with no expectation of finding anything, but the reaction was positive in both instances. Treatment with potassium iodide was instituted with very gratifying results. The author then cited a case of rather typical ataxia paraplegia. The patient, a woman, thirty years of age, was making a good recovery under antisyphilitic treatment. The functional neuroses and psychoses frequently presented family histories of syphilis. He did not know how large a percentage of these cases would show a positive Wassermann reaction, but he did know that syphilis was a very prevalent disease, much more common than most of them imagined. They were apt to regard syphilis as a disease of the large cities, but this was a mistake; he believed that the percentage of syphilitics would be found to be equally large in the small cities and in the country. The played-out prostitute naturally gravitated to the country where competition was less keen and the results were most disastrous. He mentioned this because physicians in the country were very apt to overlook the prevalence of syphilis, feeling that they knew the families and could eliminate syphilis without careful inquiry. His own routine was a Wassermann test in practically every cerebrospinal case, and he believed it paid. The treatment in these cases was practically the same as in cases of acquired syphilis, but the results were not so brilliant. The effects of salvarsan were excellent, but the results with the use of neosalvarsan had not been as satisfactory in his hands in hereditary syphilis as in the acquired type. The speaker did not agree with the present tendency to condemn the use of the iodides. He felt satisfied that the iodides had a very important place in the therapeutics of syphilis and that they would continue to hold it. Failure with the iodides in his opinion was due rather to insufficient dosage than to the fact that the iodides lacked therapeutic action. In giving iodides it ought to be a question not of how many grains but of how many drams the patient could take.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held June 3, 1913.

THE PRESIDENT, DR. SMITH ELY JELLIFFE, IN THE CHAIR.

Brain of Patient with Cortical Astereognosis.—Dr. LOUIS CASAMAJOR and Dr. SMITH ELY JELLIFFE presented this specimen, which was obtained from a woman, 43 years old, a housewife, born in this country, who was admitted to the Neurological Institute on June 3, 1912, suffering from paralysis of the right side of the body and inability to recognize objects in the right hand. Her father died at the age of 51 of asthma; her mother at the age of 59 of apoplexy. There was no history of neuroses or psychoses in the family. The patient had been married for 24 years, and was the mother of two children, one living and one dead. She also had two miscarriages. The history obtained from the patient was that she had enjoyed good health until July, 1910, when she began to suffer from severe headaches, which were almost continuous. After improvement under treatment the headches returned in May, 1911, and were continuous and severe. About two months after this the right arm began to feel weak, and later the corresponding leg was similarly affected. At that time she consulted Dr. Jelliffe, and he made a diagnosis of brain tumor in the left supramarginal gyrus. The weakness and stiffness in the arm and leg continued, and in November, 1911, both of these extremities became paralyzed, so that the patient could not get out of bed and was unable to hold objects in her right hand. At this time an operation was advised, but refused, and the patient was given a course of mercury and iodide. Examination showed a spastic hemiplegia, with marked astereognosis in the right hand, and sensory aphasia with paraphasic speech. The fundi were normal. Under mercurial treatment, the patient improved considerably; the headaches disappeared, the weakness was less pronounced and she was able to walk about the house and go on the street. Her skin had a distinctly bronze color, which came on rather rapidly about two years ago, but which she thought had not progressed much of late. On account of the bronzing of the skin, together with the *x*-ray findings, which showed a rather indefinite picture of an enlarged kidney on the right side, an exploration of the kidney region was made by Dr. Alfred S. Taylor. The suprarenal body was found to be normal, while the kidney itself was the seat of a chronic nephritis. The patient returned to the hospital on August 9, 1912, with the statement that she had been entirely well until the previous day, when she was taken with a severe headache, with involuntary twitchings and spasms of the right side of the body, but most pronounced in the right leg. At this time she also developed an internal strabismus. An examination of the eyes, made on August 29, showed that the pupils were small and reacted normally. The ocular movements were slow, but complete. There was no mystagmus; no facial paralysis; sensation was normal. The right upper extremity was more spastic than at the time of her former stay at the hospital. The astereognosis in the right hand was unchanged. During the summer of 1912 the patient grew progressively weaker; she seemed confused and at times almost comatose. The ocular movements varied from day to day; sometimes there was double internal strabismus; at other times only weakness of the external rectus. Death occurred in November, 1912. The patient's brain, Dr. Casamajor said, had not yet been examined and the report thus far was to be regarded as only preliminary. The pathological findings would doubtless prove of interest on account of the presence of definite astereognosis, and the results would be reported at some future date. All that could be seen in the brain at this time was a depressed area of softening just above the supramarginal gyrus on the left side, and a general atrophy of the convolutions of the left hemisphere.

Cortical Astereognosis from a Cyst; Operation, with Improvement.—Dr. J. ARTHUR BOOTH presented a young man of 22, who was a perfectly healthy and intelligent lad until July 12, 1906, when he met with the following accident: He was on a spile driver and attempted to descend to the dock by sliding down a rope. When about 35 feet from the ground one of his companions jerked the rope and he fell, striking on his head and right arm. He was taken to the Perth Amboy Hospital, where an examination revealed a compound, comminuted fracture of the right parietooccipital region and of the right forearm. He was unconscious for five days, but finally made a good recovery, and after a period of seventeen days was discharged as cured. After his return home it was noticed that he was dull and stupid and quite changed from his former self. A year later he had what was called one or two "sinking spells," without any spasmodic movements of the muscles. He had one attack in 1908, another in 1909, a third in 1910, a fourth in 1911 and two in October, 1912. In March, 1913, he had three attacks, and during the following month he had two which he described as follows: "I feel a tingling and numbness in the right hand; it is then drawn up and I feel my head turning to the right; then I lose myself." His mother stated that he then became stiff all over and that on one occasion he had bitten his tongue. Besides the epileptoid attacks he frequently had severe headaches, limited to the left fronteopartal region, the pain being so severe at times that he had been noticed to pound his head with his fist. Examination by Dr. Booth, April 15, 1913: From a bright, intelligent school boy standing at the head of his class he was now apathetic and dull; all mental processes were slow in reaction, with a very faulty memory both for recent and past events. He answered questions slowly and hesitatingly, but there were no motor speech defects. The superficial and deep reflexes were present and normal, excepting the knee jerks, which were exaggerated. No ankle clonus nor Babinski. The tongue was protruded in a straight line and there was no paralysis of the facial muscles. The equilibrium was fairly good. There was no marked ataxia. He was right-handed and the right upper extremity was weaker than the left, though it must be remembered that the right forearm was broken at the time of the accident. There was a decided loss of sensation over the right upper extremity, and to a lesser degree on the right side of the face, as compared with the left. The same applied to the right thigh, as compared with the left. The patient was unable to write anything but his name, which he did slowly and with difficulty. He could, however, write from copy. There was no transposition nor misuse of words. He was able to count up to 100, and recognized figures when they were placed before him. He was unable to recognize but two letters of the alphabet, namely, A and P, but could not read the simplest word or sentence. When blindfolded he failed to recognize a bottle, knife, watch, coins of different denomination, chain, key or pipe with the right hand, but readily did so with the left. The pupils were widely dilated, but reacted slowly to light and accommodation. The fundi were normal. Taking into consideration the above findings, a diagnosis was made of a cyst in the left angular gyrus, the result of a former hemorrhage, and an operation for its removal advised. Operation, April 26, 1913, by Dr. George E. Brewer: Upon elevating the usual parietotemporal osteoplastic flap the dura was found tense and bulging just beneath the parietal eminence. It was

incised, and in so doing a cyst was opened in the upper and posterior part of the exposed area. The cyst was about the size of a silver half dollar, situated over the left angular gyrus, extending forward and bound down with adhesions. These were freed and a drain placed in the cyst cavity after it was completely emptied of about two drams of clear fluid. The patient made a good recovery from the ether, but during the next three days he had a number of convulsive seizures which began in the left hand and gradually became general. Dr. Booth then suggested that the drain be removed, and when this was done the convulsions ceased and he had remained free from them since. He continued to improve, and on May 12, three weeks after the operation, he read from a book that was handed him, "Night Orderly Report," and from a newspaper "Giants Win." He left the hospital on May 18. When Dr. Booth saw him again, on June 3, he had gained ten pounds in weight. Mentally he was much brighter and there was a marked improvement in his memory. He had had no further convulsive attacks and no headache. There was still slight weakness of the right hand, with marked astereognosis. He could recognize a majority of the letters of the alphabet, could read a few simple words and two short sentences.

Dr. William M. Leszynsky said that in connection with these two cases with astereognosis he wished to report briefly a case that was recently under his observation. The patient was a boy, six years old, an unusually intelligent child, who entered the hospital with the history of having been well up to three months previously. There was a rather indefinite history of a fall, but no evidence of any injury to the head. On admittance he seemed to be slightly apathetic. He complained of dizziness and had occasional attacks of headache and vomiting. Examination revealed complete astereognosis in the left hand, and in addition a typical Babinski plantar response on the same side. There were practically no other symptoms. No rigidity; nothing in the eye grounds. Within a week rigidity began to develop in the left lower extremity, followed by partial paralysis. Subsequently these symptoms extended to the left upper extremity, and about a week later the first eye symptoms appeared in the shape of a slight papilloedema. A subcortical lesion originating in the upper gyrus of the parietal lobe was diagnosticated and an operation advised. Before it could be undertaken, however, the boy became comatose and died. An autopsy was refused. In this case, Dr. Leszynsky said, the lesion apparently developed in the parietal lobe and extended to the leg and arm centers.

Dr. I. Abrahamson said that in the case reported by Drs. Casamajor and Jelliffe the condition simulated a tumor. The speaker said he had seen four cases during the past year where choked disk and the other symptoms that were present were strongly indicative of a tumor of the brain, but eventually they all proved to be cases of nephritis, and no tumor was found. A number of similar cases had been reported, and the possibility of a chronic nephritis, with vague symptoms of intracranial pressure, which simulated brain tumor and might tempt one to operate, should always be borne in mind. In all of his cases, Dr. Abrahamson said, the blood pressure had been high.

Dr. Leszynsky said that Dr. Strauss might recall a case in the speaker's service at the Lebanon Hospital, where the patient had many symptoms of a brain tumor. Upon exploratory operation an area of thrombotic softening was found in the cortex, secondary to endarteritis associated with chronic nephritis.

Dr. I. Strauss said he had done the autopsy in two of the cases referred to. One of the patients had practically no focal symptoms, but in all of them there was marked choked disk, which was very puzzling. In both of them there was a chronic nephritis, with albumin and casts, high blood pressure and marked choked disk. The latter symptoms advanced very rapidly, and a decompression was done in the hope, principally, of saving the sight. After death an examination of the brain revealed nothing but a very extensive arteriosclerosis, limited chiefly to the smaller vessels all over the cortex.

The President, Dr. Jelliffe, speaking of the patient with cortical astereognosis reported by Dr. Casamajor and himself, said that for a long time they were in doubt whether or not they had to deal with a brain tumor, but in view of the very gradual extension of the process it was decided that if there was a new growth in the brain it was of such a nature that its removal would be practically impossible—that if it was a new growth it was probably of an infiltrating nature. The result showed that it was an infiltrating process in the nature of a diffuse atrophy, with specially intense development in one area, the true nature of the atrophic process had not yet been determined.

A Case of Myotonia Atrophica.—Dr. Foster Kennedy said the rarity of this curious muscular degeneration was his excuse for the report of a single case. Myotonia congenita—the so-called Thomsen's disease—was not very uncommon, but the combination of increased tonus in some muscles, with a primary flaccid palsy in others in remarkably constant distribution was so rare that but four cases had been as yet reported in the medical literature of this country. The disease was apparently peculiar to persons in mdidle life; it was of a very slowly progressive character, and in rather more than half the cases was of the familial type. The symptom-complex was so constant and so characteristic that when once understood, recognition of subsequent cases became simple. In Dr. Kennedy's case the patient was a male, single, 46 years old, a native of Switzerland, who was admitted on March 17, 1913, to the Cornell Medical Division of Bellevue Hospital, under the care of Dr. W. Gilman Thompson, who kindly asked Dr. Kennedy to see the case and by whose courtesy he was permitted to make use of these notes. The patient's parents had both died in old age. He had three brothers and three sisters in good health. One sister, a resident in the United States, had arthritis deformans. There was no neuropathic family history; neither the patient nor his sister knew of any near or collateral relative affected in any way similarly to the case under consideration. For fourteen years the patient had been employed as a farmer in New England. His habits were regular and his general health good. His consumption of alcohol was limited to two or three glasses of beer a day, and he denied venereal disease. His previous health had always been good. In 1893 his left cornea was injured by a burning spark falling on it from a passing engine. In 1887 his hands and feet were said to have been frostbitten. In November, 1911, after hard work in harvest time, he began to suffer from cramplike pain in the lumbar region. These pains were at first intermittent and rare, but later became more frequent, so that at the time of examination he complained constantly of their presence. He could recall no injury to account for this condition, which was more severe when he worked in a bent posture. He strenuously denied having any difficulties in his gait or in the use of his hands, and gave no history of sphincteric trouble. He had not worked for a year, but was never confined to bed. His facial appearance was quite strikingly characteristic, and was the result of an incomplete ptosis of both eyelids, with marked hollowing of the temporal fossæ and flattening of the masseteric region on each side. The orbicular muscles of the eyes were very weak, and there was no movement in the temporal or masseter muscles. The left pupil was hidden by a corneal scar, the result of the injury just related. The reaction of the right pupil was normal. A well marked and advanced cataract was present on each side; that on the left side might have been thought traumatic in origin had not that in the right lens been so obviously otherwise. A slight, bilateral divergent strabismus was evidently a result of defective vision. The patient's articulation of both English and French was slurred and difficult to follow; no structural defect was found which could account for this symptom. The sternomastoid muscles were completely atrophic, and there was some wasting in the extensor muscles of the forearms. The position of rest of both hands was one of slight flexion, the thumbs being strongly adducted. All movements were present, but it was found that after making a strong grasping movement with either hand he was unable quickly to again extend the fingers, the involved muscles, apparently, being in a state of cramp. If the grasping movement were frequently and quickly repeated, this cramp became less and less noticeable, until after perhaps a dozen efforts it would completely disappear. This phenomenon was not present in any other muscles or group of muscles. The abdominal muscles and those of the back and chest were normal, as was also the spine. The vastus internus and externus of the right thigh were diminished in bulk, though no change was found in the intervening rectus femoris muscle. The knee jerk on the right side was difficult to obtain—a reduction in response directly proportional to the reduction of the muscular mechanism involved. There was almost complete atrophy of the anterior tibial and peroneal muscles, with complete bilateral foot drop as a result. The ankle jerks and plantar reflexes were absent. The abdominal and arm reflexes were normal. The gait was of the steppage character peculiar to paralysis of the dorsiflexors of the feet. There were no sensory changes. No reaction to faradism or galvanism in the orbicular eye muscles, the temporals, masseters or sternomastoids, and almost complete loss in the anterior tibial groups of both sides. In the muscles of

the forearms and in the intrinsic hand muscles the reactions were strong, but enormously prolonged. There were no pathological changes in either the blood or urine. The Wassermann test in the blood serum and the cerebrospinal fluid was negative.

Dr. J. Ramsay Hunt said the case reported by Dr. Kennedy corresponded very closely to one which the speaker showed at a meeting of the Society some years ago. In that case there was the Charcot-Marie type of atrophy of the extremities, with involvement of the facial muscles. The phenomena of myotonia were quite active in the tongue and the masseter muscles, and this was also observed in a later case that he had seen. The myotonia electrical reactions were also well marked.

Dr. I. Abrahamson referred to a typical case of myotonia atrophica that had come under his observation. The patient was a woman whose brother had been shown at a meeting of this Society by Dr. Stieglitz about ten years ago as an example of the peroneal form of dystrophy. In his own case, the speaker said, the patient also had bilateral cataract and there was a congenital absence of certain muscles, such as the sternal portion of the pectorals. In another case, now under observation at the hospital, the symptoms were strongly suggestive of myotonia atrophica. The patient was a man who presented a fibrillary twitching of the tongue, etc., with weakness of one sternomastoid; yet, owing to the fibrillary twitching, etc., it was most likely not a case of myotonia.

Dr. Kennedy, in closing, said a peculiar feature of myotonia atrophica was the extraordinary uniformity in the appearance of these patients. They all looked as though they belonged to the same family—like brothers and sisters. There was more uniformity in their symptoms than in other forms of dystrophy. The electrical reactions showed a quantitative change in the atrophied muscles, but in the forearm there was increase in the reaction to both galvanism and Faradism, and the reactions were very long drawn out. The muscles easily went into a tetanoid condition, which was at complete variance with the action of the atrophied muscles.

Cauda Equina Neuritis.—Dr. Kennedy presented an Italian, 49 years old, who was admitted to the Neurological Institute on May 8, 1913, with the history that five years ago he developed a severe pain in the middle of the back, subsequently extending to the left leg and later to the right. It was shooting in character, and after persisting for several months it was said to have disappeared after the injection of morphine. Later he noticed a "dead" feeling in both legs; this progressed, and walking became more and more difficult until he was bedridden. There was no history of incontinence, but he stated that since the onset of his illness he had to strain before passing urine. He was bedridden for two years, when he began to regain power in the legs, and the improvement slowly continued until he was able to walk. He now walked fairly well, but was handicapped by double drop-foot. The upper extremities had never been involved. There was now no pain, but occasional pin-and-needle sensations in the feet. Examination showed marked atrophy of the tibialis anticus and peronei muscles, and the symptom complex was referable to a lesion of the cauda equina which at one time we might have attributed to the presence of a tumor in that region, but in the cases which the author had reported at the recent meeting of the American Neurological Association in Washington they had found no tumor, but a congested appearance of the nerve roots. In the case shown tonight the patient, after being bedridden for two years, had gradually improved, which we would not expect to find with tumor, and we were therefore justified in believing that these cases were due to a lesion which was not luetic, nor to the presence of a new growth, but rather to an infective, inflammatory state of the cauda equina, possibly a neuritis.

Dr. Leszynsky said that in certain cases of this type, in which the patients presented symptoms of tumor of the cauda equina, puncture of the spinal canal had failed to give any fluid, and this might serve as a differential point between neuritis and neoplasm.

Dr. William B. Noyes asked Dr. Kennedy whether muscular atrophy in this case was a prominent symptom. How far was muscular atrophy to be expected in neuritis and lesions of the conus medularis? The speaker had been puzzled by this symptom in various cases. He recalled one case presenting the general symptoms of a double sciatica, excepting that the knee jerks were increased rather than diminished. This patient had a tubercular involvement of the left ankle joint, and there was a prominence of one of the lower lumbar vertebræ which the surgical advisors considered an evidence of incipient Pott's disease, but this idea was disproved by the fact that two years later the condition remained unchanged, and there was evidence that it had always existed. In this case there was double sciatica, plus a slight involvement of the lower cord, and the question naturally arose whether the exaggeration of the reflexes was not caused by the extension of the process beyond the cauda. In another case, Dr. Noyes said, in an adult, a diagnosis of a tumor of the cord or chronic anterior poliomyelitis seemed obvious on account of the atrophy, added to other symptoms of the nature of those in the case of Dr. Kennedy. In that case marked improvement took place in two months after thorough electrical treatment, and an ascending neuritis with the most marked symptoms in the cauda or conus medularis was probably the correct diagnosis.

Dr. J. Ramsay Hunt said that while primary neuritis of the cauda equina was admitted by some authorities, and had been described by Raymond, yet the case presented by Dr. Kennedy showed such an extreme degree of degeneration for a neuritis that he thought the diagnosis was open to question. The condition, which was now old and apparently stationary, resembled what we saw after syphilis of the cauda, and following myelitic affections in the region of the conus. A neuritis, accompanied by such a degree of degeneration and strictly localized to the cauda, was rather difficult to conform with our ideas of the pathology of neuritis in general, especially degenerative neuritis, which involves the distal portion of the neural tree. Such severe degeneration was not observed in the brachial or sciatic types of neuritis, which were rather a peri-neuritis, and here we had a man who was bedridden for a long time and who even now, after all these years, showed evidence of foot-drop, with areas of anesthesia, and the gravity of whose symptoms was apparently disproportionate to the cause to which Dr. Kennedy attributed them. The possibility of an old syphilis should not be lost sight of, in spite of the negative Wassermann, as well as a myelitis of the sacral cord from some other cause.

Dr. I. Strauss said he wished to take exception to the remark made by Dr. Hunt that the Wassermann test had its uncertainties. That might hold good in some instances, but given a case where the spinal fluid showed no change by the Wassermann reaction, no increase of cells nor globulin, it was fairly good evidence that we were not dealing with a specific lesion. Dr. Strauss said that in a case seen at the Montefiore Home about two years ago the patient presented marked symptoms of a lesion of the cauda equina and the conus as well. This patient had been treated with mercury in various forms and very vigorously, but without benefit, and despairing of ever getting well he committed suicide. At autopsy his cord showed a remarkable condition, because not only were the meninges the seat of an active syphilitic process, but the cord itself was the seat of a very active myelitis. In that case, no doubt, an early puncture would have shown the evidence of a syphilitic process, while later on no fluid would probably have been obtained.

Dr. Abrahamson said that in one case of specific involvement of the cauda equina which refused to yield to salvarsan and mercury, the patient showed symptoms similar to those in the case presented by Dr. Kennedy, excepting that the clinical picture of a caudal lesion was more complete. In that case the Wassermann was positive.

Dr. Alfred S. Taylor said that Dr. Hunt was possibly influenced in his view that this case might be syphilitic by the patient's nasal deformity, which the patient stated, however, was the result of an injury. This statement was borne out by the appearance of the deformity, which was a traumatic saddle-nose. The nasal bones here had not lost their contour, while in true saddle-nose the bones were necrosed and the saddle was much higher up.

Dr. Kennedy, replying to Dr. Noyes, said that in his other cases of this condition the atrophy was very distinct and complete, and occurred in the affected root areas, corresponding with the sensory areas. Dr. Kennedy thought the position taken by Dr. Hunt was an interesting one, but not entirely logical. The speaker said he had made no claim that a lesion of the cauda equina could not be produced by syphilis: in fact, the cases mentioned by Dr. Abrahamson and Dr. Strauss, as well as those reported by Oppenheim and in French and English literature showed definitely that we may have lesions of the cauda equina produced by syphilitic pachymeningitis, but those facts did not disprove that in the case he had shown tonight as well as in the cases he had reported previously we had to deal with a non-luetic lesion of the cauda equina. If we placed any reliance at all on the Wassermann test—although we knew that in a certain

number of cases the reports led to a false conclusion—we had to give some weight to it in the six cases he had reported. All of these patients gave a negative syphilitic history; they claimed they had never been infected, and we had no grounds for disbelieving them. They had not been given anti-syphilitic treatment, but both the Wassermann test and the test of the cerebrospinal fluid were negative, and it seemed that under those conditions we were justified in assuming that the individual was not syphilitic. Possibly, in these cases we had a degenerative process of the cauda equina due to some toxin the nature of which we were ignorant, and which gave rise to symptoms similar to those caused by the syphilitic virus.

A Case of Multiple Sclerosis Treated for Incontinence.—Dr. I. Strauss reported this case. The patient was man, 47 years old, who was admitted to the Mount Sinai Hospital on December 5, 1912. His family history was unimportant. The patient was moderately alcoholic and gave a history of gonorrhea and syphilis twenty years ago. Two years ago it was noticed that the patient had difficulty in remembering things, with slowness of speech and motor aphasia. Eight months ago he complained of weakness in the legs when walking, and two months later he developed vesical incontinence, with occasional rectal incontinence. There was also diplopia and loss of weight. An examination at the time of his admission to the hospital showed, in addition to the above symptoms, nystagmus and tremor of the head, exaggerated knee jerks, slight Romberg, slow speech and diminished abdominal reflexes. A cystoscopic examination showed a trabeculated bladder, with a mild cystitis. The Wassermann test at this time was negative. Under repeated injections of salvarsan and epidural injections of sterile alboline, the patient gradually regained control of his bladder function, and when he left the hospital, on May 1, 1913, he was urinating about five times in the course of 24 hours, and was able to retain urine from six o'clock P. M. to six A. M. without discomfort.

Dr. Abrahamson said that Dr. Edwin Beer had advised the introduction of alboline into the bladder for incontinence. By this method, however, the effect was more transient and not to be compared to the results of the epidural method.

Hysteroepilepsy (Piblokto) Among the Eskimos.—Dr. A. A. Brill presented a paper on this subject, in which he said that while reading Peary's fascinating book "The North Pole," he was especially interested in what Peary called a peculiar form of nervous affection found among the Eskimos of the Western Coast of Greenland from Cape York to Etah which they called piblokto and which he designated as a form of hysteria. Peary stated that he had never known a child to have piblokto, but that some of the adult Eskimos would have an attack every day or two, and that one day they had five cases. Concerning the attack proper, Peary spoke as follows:—"The patient, usually a woman, begins to scream and tear off and destroy her clothing. If on a ship, she will walk up and down the deck, screaming and gesticulating, and generally in a state of nudity, though the thermometer may be in the minus forties. As the intensity of the attack increases, she will sometimes leap over the rail upon the ice, running perhaps half a mile. The attack may last a few minutes, an hour or even more, and some sufferers become so wild that they would continue running about on the ice perfectly naked until they froze to death if they were not forcibly brought back." Peary goes on to say that when the attack takes place indoors, nobody pays much attention to it unless the sufferer should reach for a knife or attempt to injure someone. The attack usually ends in a fit of weeping, and when the patient quiets down, the eyes are bloodshot, the pulse high, and the whole body trembles for an hour or so afterwards. It was also remarkable that the Eskimos dog suffered from a morbid condition by the same name. Peary stated that it did not seem to be infectious, though its manifestations were similar to those of hydrophobia. For diagnostic purposes, Dr. Brill said he tried to ascertain whether these attacks of piblokto were accompanied by a loss of consciousness. Prof. Donald B. MacMillan, an anthropologist, and one of Peary's trusted lieutenants during the successful quest of the North Pole in 1908-1909, was certain that all of the cases he saw showed a loss of consciousness and that they were all in a confused state. Thus, they were perfectly harmless when left to themselves, but showed a blind resistance if prevented from following out their various vagaries. Granting this loss of consciousness to be so, it would not simplify matters as regarded diagnosis. Loss of consciousness might be a concomitant symptom of hysteria or epilepsy. So far as could be ascertained, none of those afflicted ever showed a typical *grand mal* attack. On the other hand, everything pointed to hysteria. The disease was almost exclusively confined to the female sex: Prof. MacMillan quoted Peary as saying that in 20 years he saw only one man who had what he thought was piblokto, and the disease was practically unknown in children. Of the 20 women aboard the "Roosevelt," eight had piblokto. The Eskimos themselves thought that the disease had something to do with the evil spirit, and for that reason they were reluctant to touch the afflicted during the attack. The only probable cause of this affliction mentioned by Peary was of a psychogenetic nature. He said, "The immediate cause of this affection is hard to trace, though sometimes it seems to be the result of a brooding over absent or dead relatives, or a fear of the future." In other words, in the ultimate analysis, it was love and hunger. Prof. MacMillan believed the attacks were caused by abuse. Most of the Eskimos women who had this disease were of a jealous disposition; they either imagined themselves ill-treated, or they actually suffered abuse at the hands of their husbands, who beat them with their fists. Many Eskimos were cruel to their wives. Speaking of the attacks he said they reminded him of a little child discouraged and unhappy because it imagined that no one loved it nor cared for it, and therefore ran away. This plainly showed, Dr. Brill said, that as in civilized people, it was hunger and love—especially the latter—that played the great part in the causation of hysteria. It was also interesting to note that it was not the lack of the gross sexual, but the ungratified desire for love that was the determining factor.

Dr. M. J. Karpas said the description of these cases given by Dr. Brill was too indefinite to permit one to form an opinion as to the true nature of the mental upset observed among the Eskimos. The attack, *per se*, presented no definite landmarks of diagnostic validity. It might have been a manic, catatonic, hysterical or epileptic reaction; also such episodes one might observe in constitutional inferiors. Since we knew nothing of the make-up and psychic abnormalities of Eskimos in general, the speaker said he would be reluctant to offer a definite terminology for this mental upset. It appeared to him that it would be more conservative to look upon these episodes as peculiar psychic manifestations whose nature could not be understood.

Dr. Brill, in closing, said that these attacks resembled the "running amuck" of the Malays, but that it was difficult to say whether there was really a total loss of consciousness or not. He saw no objection to calling such an attack a peculiar psychical manifestation, but he saw no reason why Dr. Karpas should think that these attacks showed any resemblance to manic depressive insanity or to catotonia. There was absolutely nothing in these attacks to suggest these diseases.

"Transference" in Psychoanalysis.—Dr. Smith Ely Jelliffe read a paper on this subject, in which he said that as yet, the whole psychoanalytic situation, so far as successful therapy was concerned, was intimately bound up in transference, and one whose purpose it was to attempt to get at the causes for good or bad therapy, must needs view this situation as comprehensively as possible. Stated categorically and baldly, it might be said that without proper transference, a successful therapy for the psychoneuroses was impossible. In speaking of rapport or transference, it was well known that we were not dealing with any new phenomenon: it was older than the Mosaic law, and, like other old truths, it was constantly being stated and re-stated from epoch to epoch, in new forms and at recurring times with sharper and sharper differentiation. The psychoanalytic method fortunately enabled one to deal with the subject of transference much more definitely than ever before. It afforded positive criteria whereby one was enabled to watch its development, realize its tendencies, guide its directions, and, at times regain its losses for the sake of the patient. At the same time it provided the most exquisite sensitizer which, rightly used, compelled the psychoanalyst to search his own resistances, and forced him to keep clearly the goal in view, *i.e.* the patient's best interest, and not his own gratification or glorification. If psychoanalysis, as a method, really permits any great advance over earlier methods of handling the psychoneuroses, it must in some measure be through its better knowledge of and modes of dealing with transference.

Dr. A. A. Brill said he appreciated the truth of Dr. Jelliffe's remarks, but he could readily understand how they might fail to impress one who had done no actual work in the field of psychoanalysis. He believed that every physician, consciously or unconsciously, came in contact with these cases of "transference," which played

an important part in the success of his practice. We knew that certain drugs were effective in the hands of one man, while they were inert in the hands of another, and that the impression made on the patient often depended more on the personality of the physician than on the drug he prescribed. This was only another phase of transference. Hysterical accusations not infrequently made against physicians were often due to an overtransference and subsequent transformation into hate. A general knowledge of this subject might prove of great value to every physician.

Medicolegal Notes.

Malpractice—Causal Connection Must Be Shown—"Disease"—"Pain."—A married woman, suing a physician for malpractice, alleged that she employed the defendant as her physician to treat her for a backache, but that he diagnosed her case as one of pregnancy, and that he negligently failed to ascertain her true condition, and that by reason thereof she was rendered sick and injured in her health and rendered weak and nervous. It was held that this complaint stated no cause of action because it failed to show that the plaintiff's condition was one of disease which by the exercise of ordinary skill the defendant should have discovered. It was of no importance whether the plaintiff was pregnant or not, for either condition is normal for a married woman who has not passed her sexual climacteric, and neither is a disease or a malady. "Disease" was defined as an alteration of the state of the body or of some of its organs interrupting or disturbing the vital functions, or a particular instance or case of this. "Pain" was defined as a disagreeable feeling usually in its intenser degrees resulting from or accompanying deranged, overstrained, or otherwise abnormal action of the physical powers and serving as a warning of danger. If sound health and steady nerves were absolute conditions of every human being, it would be sufficient in so many words to charge that a departure from these conditions was due to the negligence of the attending physician. But a continuous condition of perfect health in every or any individual does not accord with human experience, and it does not necessarily follow that the ills of which the plaintiff complained were attributable to the treatment given her by the physician merely because they occurred during his attendance. While it is sufficient to charge in general terms that an injury was negligently inflicted, the acts done must be stated, and it must appear from the facts averred, and not from mere conclusion, that the negligence caused or contributed to the injury.

The testimony did not make the situation any better for the plaintiff. She testified to stating symptoms which were common signs of pregnancy, and that she desired to give birth to a child. The principal treatment by the defendant was advice to keep quiet and free from excitement, and medicine to regulate her stomach and bowels, precautionary measures to prevent premature parturition. Lapse of time showed that there was no pregnancy, and consultations with other physicians resulted in her being treated first for a tumor and afterwards for excessive fat on her abdomen, which last diagnosis proved to be the correct one. The evidence thus showed that her condition was one of health and that no injury could have resulted because of the diagnosis of her case as one of pregnancy. It was held that the plaintiff should have been nonsuited.—Merriam v. Hamilton, Oregon Supreme Court, 130 Pac. 406.

Hypothetical Questions—Conclusions.—A physician who had conducted a post-mortem examination of an insured testified that such examination revealed softening of the tissues of the right ventricle of the brain, arterial sclerosis, patches of bronchial pneumonia, and chronic vesiculitis. He then testified that he decided, from the brain tissue and the conditions found there and from the condition of the arterial walls, that a sclerotic condition existed, generally of a syphilitic character, and expressed the unqualified opinion that death resulted from syphilis. It was held that the physician's statement that the various conditions mentioned by him were syphilitic in character was a conclusion from the facts, and not a statement of the facts, and hence such conclusion was properly eliminated from hypothetical questions asked of other experts, as to whether it could be told from the conditions found by the doctor, in the absence of a positive blood test or the finding of germs in the tissues, whether decedent's death was due to a syphilitic affection.—McIntyre v. Modern Woodmen, 200 Fed. 1.

Therapeutic Hints.

The Treatment of Atony of the Stomach.—L. Pron outlines the dietetic and medicinal treatment of this condition as follows: The patient may eat meat and a small quantity of bread. He may partake at dinner of a glass of light wine diluted with plain mineral water. A small cup of coffee at the close of this meal is permissible. There are indicated all those medicinal agents that favor the evacuation of the stomach—whether or not their action is a chemical one. For the loss of appetite the following mixtures have been found of distinct value:

℞ Tincture of gentian,
Tincture of quassia,
Tincture of calumba,
Tincture of anise (Russian Pharmacopeia),
āā 5 grams.

The dose is 20 to 40 drops in a quarter of a glass of water twenty minutes before meals.

℞ Tincture of nux vomica,
Tincture of gentian, āā 5 grams.

The dose is the same as the above.

℞ Tincture of condurango,
Glycerin, āā 60 grams.

Of this mixture the dose is one teaspoonful in a little water and should be taken fifteen minutes before each meal.

Another remedy is tincture of jaborandi in twenty-drop doses, one-quarter of an hour before meals, or its alkaloid pilocarpine, in the following solution:

℞ Pilocarpine nitrate, 0.05 gram.
Distilled water, 150 grams.

The dose is a tablespoonful before each meal. Ipecac may be administered in doses of 10 to 20 drops of the tincture (German Pharmacopeia). Of similar efficacy is bicarbonate of sodium, one-half gram in a little water, one-half hour before meals. The postprandial distress is relieved by the following:

℞ Potassium sulphate,
Potassium nitrate, āā 0.05 gram.
Powdered ipecac, 0.01 gram.
Amorphous quassin, 0.01 to 0.02 gram.
Powdered nux vomica, 0.02 gram.

This powder is to be taken immediately after each meal.

Another important stimulant of smooth muscle is magnesium chloride, which may be given as follows:

℞ Magnesium chloride, 1 gram.
Distilled water, 150 grams.

Of this solution a tablespoonful is given before or after meals.

If the gastric atony is accompanied by pain one may give 10 to 15 drops of equal parts of tincture of condurango and tincture of hyoscyamus, one-quarter of an hour before meals; or the following:

℞ Sodium sulphate,
Sodium phosphate,
Sodium bromide, āā 2.50 grams.
Distilled water, 250 grams.

One tablespoonful is given twice a day, ten minutes before meals.

Dover's powder in 0.2 gram doses may be given after each meal, or one-half teaspoonful of Hoffman's anodyne in a little sweetened water.—Thérapeutique Clinique des Maladies de l'Estomac."

REST AND EXERCISE FOR THE TUBERCULOUS AND THE PREDISPOSED CHILD AT SCHOOL.

WITH PRACTICAL DEMONSTRATIONS OF BREATHING EXERCISES AND A DEVICE COMBINING OPEN-AIR STUDY AND THE WINDOW TENT.*

By S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

There exist such a great variety of opinions among phthisiotherapeutists as to the amount of exercise and rest the individual tuberculous adult should take that it is obvious that to regulate the matter of exercise and rest in children must be still more difficult.† It is not an easy problem to solve. No tuberculous individuals are constituted alike, be they adults or children, yet in order to manage or supervise a class of tuberculous children, or even those predisposed to the disease, it must be necessary to have some general conception of what is good and bad for such a pupil.

It goes without saying that I cannot here consider the child afflicted with tuberculous joint disease where the surgeon feels that the particular member must be kept absolutely at rest. We must also leave out of consideration that class of cases which have pulmonary lesions and a temperature approaching or exceeding 100° F. In all such cases individualizing is of prime importance and no general rule is applicable. Thus, for example, a child who is surgically treated for hip-joint disease may not be allowed to walk but may be permitted to take regular breathing exercises. Another child with pulmonary lesions and febrile in the afternoon may be allowed to take a short walk in the forenoon during the afebrile state, but cautioned to breathe quietly.

But to come to general rules which should be the guidance of the teacher managing an open-air class composed of nonfebrile children, not actively tuberculous, or only predisposed, as first maxims let us put down the following: Never overwork the tuberculous child; never start the child to work when it is evident that it is tired. Every tuberculous child or child predisposed to the disease tires less easily in the open air than indoors. This class of children should be allowed to rest 10 to 15 minutes before and at least half an hour after meals. This rest they should preferably take on portable cots provided with a pillow. During rest time it is good to enforce silence in order to assure complete rest and quiet for those desiring it. In cold weather it is essential that the children be warmly covered during rest time.

It must likewise be borne in mind that during hot weather the children need more rest than in winter. In summer they should always rest in the shade, while in cooler weather they may be allowed to rest in the sunshine, providing their heads are protected from the direct rays of the sun. All these children must have the privilege of reporting to the teacher whenever they feel that they are not sufficiently rested or that the work assigned to them tires them too much. In such a case their temperature should be taken and the child referred to the physician for individual advice or care.

And now as to exercise. Let us first consider those which can be taken in conjunction with studies. All outdoor recitations and singing constitute healthful exercise for the lungs. Singing, particularly, has a beneficial effect on lungs and heart, on the pulmonary circulation, on the blood, the vocal apparatus, the upper air passages, the general health, on metabolism, and on the activity of the digestive organs. Season and weather permitting, short botanical and geological excursions, visits to zoological gardens and aquaria, should form a part of the regular curriculum of the tuberculous, the anemic, or otherwise predisposed child. These promenades in the open constitute the very best exercise, providing, of course, they are not overdone.

What other kind of exercises may we add to recitation, singing, and walking in the open air? While all kinds of calisthenics may be productive of good, I have found in my experience that when we can combine the movements of upper and lower extremities and trunk with deep breathing such exercises are doubly efficacious.

Before demonstrating to you a series of exercises whereby every member of the body, including the head, neck, trunk, and the lower and upper extremities, comes into motion, may I be permitted to defend my enthusiasm for respiratory exercises judiciously taught and judiciously practised, which I consider one of the most valuable means to prevent pulmonary tuberculosis, particularly in children? I confess that I am an adherent to the Freund[1]-Hart[2] theory, that the phthisical thorax arises very often from arthritic or rhachitic changes in the first rib or the adjoining vertebra, thus producing a stenosis in that region, preventing expansion of the apex and its bony covering. The sooner we anticipate these changes in the upper portion of the thorax by constitutional treatment aided by proper respiratory exercises the more certain are

*Read before the Fourth International Congress on School Hygiene, Buffalo, August, 1913.

Discussions on this subject by Minor, Ritter, Pottenger, Knopf, and Cabot, in the same issue.

we to combat successfully the development of pulmonary tuberculosis.

And now let me in brief demonstrate to you these exercises. To begin with, the pupil has to learn to stand straight, assuming the position of the military attention, heels together, body erect, and hands on the sides. With the mouth closed, he takes a deep inhalation (that is, breathes in all the air possible), and while doing so raises the arms to a horizontal position (Fig. 1), remains thus, holding the air inhaled for four or five seconds, and while exhaling (breathing out) brings the arms down to the original position. The act of exhalation, or the expiration, should be a little more rapid than the act of inspiration.

Fig. 1.—Exercise A

The act of inhalation occupies about four, the act of exhalation about three seconds, and as has already been said, the act of retention of the air about five seconds. The child should be taught to count mentally during these three acts so as to be systematic about holding the air. One can move the hands up and down twice, counting four, and on the fifth second begin to lower the arms and exhale.

When the first exercise (A) is thoroughly mastered, one may commence with the second exercise (B). The pupil places the hands one above the other in front of the chest, with the fingers bent (Fig. 2). The arms and shoulders make a backward movement, the hands moving apart with a motion as though wanting to tear open the chest (the fingers remaining bent), while he takes a deep inhalation, holds the breath, counting four by tapping the chest four times with both hands, and at the fifth second he starts to exhale, bringing the hands and forearms into the position from which they started. This exercise has the advantage that it can be taken in the sitting position, or even when lying on the back.

The third exercise (C) consists in raising the arms from the sides to the horizontal and then above the head (Fig. 3), taking a deep inhalation during this act; then bending back as far as one can and remaining in that position four seconds while retaining the air, counting the seconds by moving the hands alternately forward and backward, and on the fifth second one exhales gradually while resuming the original position. During this exercise it should be borne in mind that when the arms are raised until the hands join, one should not bring the arms close to the head, but rather form a circle above the head by bending the arms outward enough so that the meeting of the index fingers and thumbs form a triangle.

Fig. 2.—Exercise B.

The fourth exercise (D) is for the purpose of bringing the abdominal muscles also into play, or, in other words, combining abdominal and chest breathing. To this end one assumes an erect position, like the beginning of all the exercises, the hands meeting in front, with the little fingers and the edge of the palms touching the abdominal muscles (Fig. 4). While taking a deep inspiration, raise the diaphragm, concentrating all attention on this act, and while doing so move the joined hands upward, sliding them along the thorax up to the chin, then turn them and continue to raise them until they are above the head, as in exercise C (Fig. 3). Remain bent backward during the four seconds while retaining the air, and then exhale, lowering the arms gradually to the horizontal and to the original position of "attention."

Fig. 3.—Exercise C.

The fifth breathing or respiratory exercise (E), which may also be called a dry swim, requires more strength and endurance. It should not be undertaken until the others have been practised regularly several times a day for a few weeks, and until an evident improvement in breathing and general well being has been observed. One takes the usual military position of "attention" and then stretches the arms out as if in the act of swimming (Fig. 5), the backs of the hands touching each other. During the inspiration one moves the arms outward until they finally meet behind the back, remains in this position for the usual four seconds, counting by moving the hands while retaining the air, and on the fifth second exhales, bringing the arms forward again ready to start for another swim; or, if this is the end of the dry swim, the arms return to the original position of "attention." This somewhat difficult exercise can be facilitated and be made more effective by rising on the toes during the act of inspiration and descending during the act of expiration.

It will be seen that with the aid of these five respiratory exercises every muscle of the body, from the nostrils down to the toes, is put into play. The face alone is at rest and can serve as an indicator that the exercises are properly done, for it must be borne in mind that they should be taken with the muscles not actually in use, relaxed, and all unnecessary contraction of muscles or tremorlike movements must be avoided.

Of course, when out of doors, one cannot always take these exercises with the movements of the arms without attracting attention. Under such conditions one assumes a position similar to "attention," raises the shoulders, making a rotary backward movement during the act of inhaling (Fig. 6), remains in this position, holding the breath for four seconds, and then exhales while moving the shoulders forward and downward, assuming again the normal position. This exercise (F) can be easily taken while walking, sitting, or riding in the open air.

Fig. 4.—Exercise D.

Young girls and boys, especially those who are predisposed to consumption, often acquire a habit of stooping. To overcome this, the following exercise (G) is to be recommended: The child makes his best effort to stand straight, places his hands on his hips with the thumbs in front, and then bends slowly backward as far as he can during the act of

inhaling (Fig. 7). He remains in this position from four to five seconds while holding the breath, and then rises again somewhat more rapidly during the act of exhalation, assuming the original position with hands on hips.

The strikingly beneficial results obtained by the regular practice of breathing exercises in schools is shown by the effect on height and chest expansion and chest capacity. This has been recently beautifully demonstrated in one of the common schools of Paris by Professor Meunier and his coworkers. It was observed that the children learned the exercises easily and performed them with pleasure. There were fewer absences from school during the six months of experiments than during the other part of the year. The results were universally good, especially in sickly children.

Fig. 5.—Exercise E.

The following is a table showing the gain of height, chest capacity and vital capacity:

Age	Height in Centimeters		Chest Girth in Centimeters			Vital Capacity in Liters and Centimeters			Number of Pupils
	Beginning	Sixth Month	Beginning	First Month	Sixth Month	Beginning	First Month	Sixth Month	
6.....	115	118	51	53	57	0.54	0.78	0.85	19
7.....	125	125	52	55	59	0.66	0.80	0.93	14
8.....	124	126	53	56	60	0.79	0.86	1.13	27
9.....	130	132	55	59	63	0.89	1.00	1.17	29
10.....	141	143	59	62	64	1.20	1.36	1.51	28
11.....	138	142	58	62	66	1.05	1.31	1.70	18
12.....	145	149	59	63	67	1.47	1.67	1.95	22
13.....	148	151	70	74	77	1.93	2.26	2.26	16
14	147	153	62	66	74	1.83	1.92	2.15	7

How much this increased lung capacity must mean to a child in danger of developing pulmonary tuberculosis must be evident to you when you recall that careful physiological experiments on the process of respiration in the adult have shown how much more oxygen can be inhaled into the lungs by deep inspiration and expiration, in spite of the fact that in the adult the bony frame of the thorax has become ossified and yields but very little. In the child the relative softness of bone and cartilages allows them to yield considerably to the pressure from within.

Fig. 6.—Exercise F.

For the purpose of demonstrating to you the value of an additional respiratory exercise, indicated for the individual with a nonactive tuberculosis or one with a strong predisposition and a badly developed chest, let me recall to you the following figures: The amount of tidal air, that is to say, the volume which is inspired and expired in quiet respiration, is only 500 c.c., the complemental air, the volume which can be inspired after an ordinary respiration, 1500 c.c., and the supplemental or reserve air, the amount which can be voluntarily expelled after a deep inspiration, amounts to about 1240 c.c. There remains of course a good deal of residual air even after such an increased respiratory act as would be accomplished by any of the exercises above described. Now, if it is desirable to increase the process of hematosis, a second expiratory movement can be accomplished and as much as 500 to 600 c.c. of supplemental and residual air expelled. To do this effectually, the individual should inhale and exhale as deeply as he can, accompanying this action with movement or not, and then immediately after the act of expiration make an additional effort to exhale, without, of course, any preceding inspiratory movement whatsoever. This second expiration can be greatly facilitated by supinating the arms and pressing the thorax with them. This exercise is somewhat difficult to teach, and at the beginning it may be well to have the pupil pronounce the German word "eins" or the English word "inch," prolonging the sound during the second expiratory effort. The accompanying figure No. 8 shows the attitude the pupil should assume during this forced expiratory effort.

Fig. 7.—Exercise G.

Leaving aside the above mentioned frequent phthisical thorax due to bony deformation, it is a well known fact that even in a seemingly normal thoracic frame the tuberculous process begins very often in the apices. The frequency of an apical beginning has been explained by an inherent bad inspiratory function of that part of the lung. This supposition is, I believe, erroneous. I agree with Hanau[3] who demonstrated as far back as 1887 that the apices inspire excellently well, almost too well. for dust and all sorts of microorganisms enter and lodge there most easily. Careful post-mortem examinations have demonstrated this fact too often for it to need any further proof. What is faulty is the expiratory function of the apices. A thorough expiration, followed by a forced expiratory effort. as described above, is, to my mind, the only possible way to improve this defect and prevent stagnation and congestion, which, as is well known, produces excellent media for the development of bacilli.

It must be self-evident that in a school for tuberculous and predisposed children individualizing in prescribing breathing exercises is as essential as with all other exercises. As a general rule I can only state the following: Commence with the easier exercises (A), and do not go on to the more difficult ones until the former are completely mastered. Take from four to six respiratory exercises (one of A, one of B, one of C, one of D, or one of E), or when outdoors simply exercise F, four to six times every half hour or hour, or at least four to six times a day, and on rising in the morning and retiring at night. Continue this practice until deep breathing has become a natural habit.

Fig. 8.—Exercise H.

When judiciously regulated, I believe these breathing exercises to be of incalculable benefit as a means to help a tuberculous child to combat its affliction and to aid the predisposed child to increase its resistance to the development of the disease. I recommend to your consideration the careful practice and study of these exercises.

In conclusion, let me call your attention to one more point. Judiciously supervised rest and exercises in the open air are not only essential for the

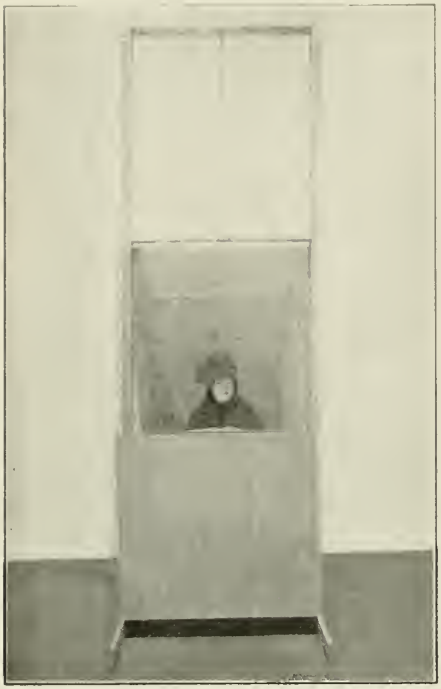

Fig. 9.—Open-air study. Tent and screen in position. Pupil looking out of the window.

tuberculous or predisposed child while attending school, but should also be carried on at home. If we really wish to cure the child of its affliction or its

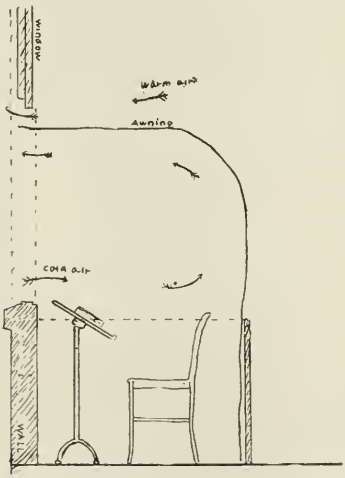

Fig. 10.—Diagram showing the circulation of air in the combined open-air study and window-tent.

inclination to become tuberculous, we must provide for it exercise, rest, and sleep in fresh, pure air during the entire twenty-four hours of the day.

To facilitate the open air regime—rest and exercise at home as well as at school—I beg leave to present to you a device showing a combination of an open air study and window tent.

To give a pupil attending public school or college, particularly when he is tuberculous or strongly predisposed, an opportunity to attend an open air class is, of course, most laudable. But if we wish to be in earnest to thoroughly strengthen this child we must give it a wellnigh constant outdoor life. We must not be contented with giving this boy or girl lessons in the open air for a few hours during school lessons.

My experience with the little device which I brought before the medical profession some eight years ago under the name of the window-tent, intended for the consumptive tenement house dweller, has given me the inspiration to devise a scheme which will give to the pupil not only outdoor life

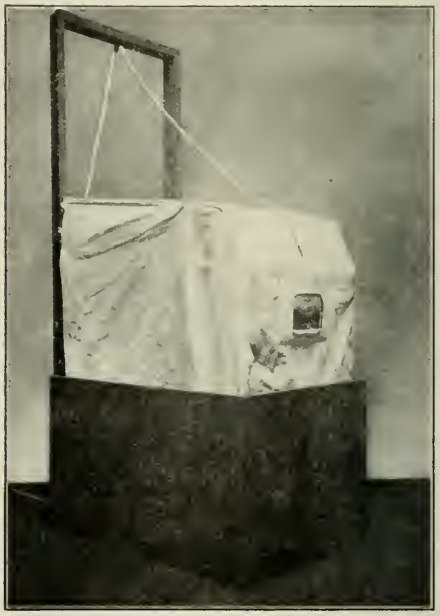

Fig. 11.—Window-tent and wainscoting in position as seen from the room. The little window is of celluloid and serves for parents to observe the pupil and for the latter to look into the room.

during sleep, but also while doing his lessons at home and while resting or reading for amusement.

I am indebted to the Kny-Scheerer Company for their great courtesy in carrying out my ideas on this subject and enabling me to present to this Congress a model which will give a splendid idea of the workings of the device.

I take pleasure in presenting to you to-day this combination of an open air study and window-tent Fig. 9). As you will see, it resembles in the main my original window-tent, only it is larger, extending out from the window 4½ feet instead of 2½ feet, so as to allow room for desk and chair for the pupil when at work. This device consists of an awning which instead of being placed outside of the window, is attached to the window pane inside of the room. It is constructed so that the air from the room will not enter or mix to any extent with the air in the tent.

It is composed of four frames of Bessemer steel rods, suitably formed and furnished with hinged terminals operating on a stout hinge pin at each

Fig. 12.—Interior of the open-air study. Pupil at work and wrapped up in Mann's sitting-out bag.

end, with circular washers interposed to insure independent and easy action in folding the frame.

This frame is covered with an extra thick yacht-sail-twill, attached to the metal frames by tapes on the inside to admit of its removal for the purpose of being laundered or disinfected. The tent is attached to the frame of the window a few inches below the upper sash, so that when the lower part of the window is pushed up there will be a space to allow the hot air from the room to pass out. By lowering the window the space can be reduced according to need. The cold outdoor air enters from without at the bottom of the open window, describes a half circle and makes its exit at the top, carrying with it the exhaled carbon dioxide.

My friend, Professor Sherman G. Bonney, of the University of Colorado, has verified this action by the use of a delicate instrument, known as the air-meter, which showed the current to be perceptibly inward at the bottom and outward at the top. In cold weather it is apparent that the outward direction of the air current at the top is facilitated by the passage of the heated air from the room through the aperture above the window-tent.

While in the typical window-tent the flaps of the awning need to be only long enough to allow them to be tucked under the mattress, in the combination device the awning is long enough to touch the floor. When used for a study, a screen composed of three pieces of wainscoting, 34 inches high, hinged together, surrounds the entire tent (Fig. 11). The lower portion of the canvas is attached to the interior of the screen. The screen and canvas protect the pupil sitting in his study from drafts from beneath and help to keep his feet warm.

In winter the pupil must, of course, be warmly dressed, and I believe there is nothing better for the purpose in the market than the ingenious sitting-out bag (Fig. 12) devised by Mr. Frank H. Mann, the Secretary of the Tuberculosis Committee of the City of New York. This garment provides adequate warmth for the upper part of the body without having the more or less cumbersome bag portion extend up any further than those usually manufactured. Freedom of movement of the hands and arms is, of course, a necessity for work in the tent and is fully provided for by the cape idea without sacrificing the needed warmth about the shoulders.

The garment is made of heavy brown felt. The bottom is square in shape and reinforced with extra heavy material about one inch in thickness to protect the feet from the cold. In addition, the bottom is covered with a special detachable piece of canvas to insure against wear and tear. The system of fastening was specially devised to facilitate convenience in getting in and out of the bag. A series of snap catches all the way from head to foot make the means of access far more practical than the old way of stepping in and out from the top. Hooks around the garment at the center enable the wearer to buckle it snugly about his waist. Another interesting new feature is the pocket at the side provided for handkerchief and mittens.

In the middle upper portion of the tent is inserted a transparent celluloid window (Fig. 13), 8 x 10 inches, which, however, can be made larger. Through it the pupil can be observed during his lessons or he can look into the room and converse without raising the flaps.

Fig. 13 shows the study transformed for the

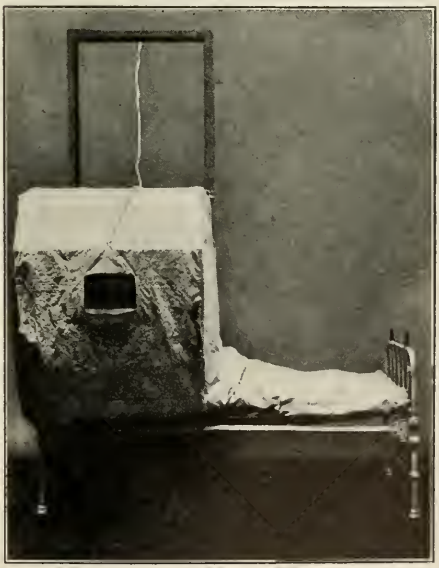

Fig. 13.—The open-air study transformed into a window-tent.

night into a comfortable window-tent. With the aid of a pulley, the frame and canvas can be raised (Fig. 14) so as to be entirely out of the way while

arranging for day study or preparing to retire for the night. On extremely cold nights the pupil can close the window before retiring so that he can dress in a warm room and then open the window from his tent-bed. He can, of course, also close the window in the same way in the morning and have the room get warm before rising to dress.

The entire tent is attached to the window frame simply by two hook-clamps so that, if necessary, the entire device can be lifted off with ease.

It is, of course, desirable to have outside shutters on the window, but if that is impracticable a Venetian blind may be attached on the inside. These shutters or blinds may often be needed in stormy, rainy, or snowy weather. In very cold or windy weather an ordinary wire screen can be placed in the window or a light frame made and covered with cheese cloth. Dr. J. B. Todd, of Syracuse, has

Fig. 14.—Awning raised to facilitate changing the open-air study into a window-tent for open-air sleeping and vice versa.

recently devised a ventilating screen made of such material which will serve the purpose admirably.

Congenital Hypertrophy of the Right Leg: Scoliosis.—J. G. Saner reports the case of a girl, aged 13, whose right leg was generally larger than the left. The hypertrophy appeared to affect all the tissues, and gave the child an adult appearance on the affected side. There was a general nevoid condition of the skin. It had been tentatively suggested that a resection of some inches of the shaft of the right femur, followed by plating, should be tried.—*Proceedings of the Royal Society of Medicine.*

THE ARCHITECTURE OF OPEN-AIR SCHOOLS.*

By JOHN V. VAN PELT, A.D.G., A.I.A.,

New York.

Formerly Professor in Charge of the College of Architecture of Cornell University.

The number of words and time at my disposal are so limited and the subject of Open-Air School Architecture so large that I shall have to confine myself to dogmatic statements or to expressions of personal belief, without adducing the arguments that uphold the statements. Unlike the architecture of the ordinary school where experiment has prescribed the type, open-air schools have not yet been built and tried out. Ferryboats have been adapted to the use, open-air school rooms have been built or altered from old school rooms as minor parts of buildings, roofs covered and uncovered have been turned to the purpose, but the complete school, planned in all its details toward the one end and of an advanced type, is yet to come.

In describing the ideal conditions to which I think such a school should conform, I have in mind a type slightly less radical than what is sometimes known by the title, namely: a school that is entirely out of doors with little more than a roof, and is typified by those at Shrewsbury House and Bradford in England. On the other hand, something that is considerably more open that what has been styled the low temperature school, such as the Graham School, or than such schools as School No. 21, in New York, where the rooms have been adapted from the regular type by merely changing the pattern of the windows and keeping them open. In other words, I propose a building so constructed that the air in all parts of rooms where the children remain will be continually replaced by outdoor air that has only sojourned a few seconds within the limits of the building, yet not a building that is entirely without heat.

First, I wish to consider general aspects of the plan formation. The ground for such a school should be sandy or gravelly without too much clay, so as to preclude a humid condition in the entering air. It should be protected from the wind, pines or spruces forming an excellent screen; but these trees should not be too close to the building and should not cast a shade upon it. City schools should be so situated that sun will not be cut off from them by adjacent skyscrapers. This is also important because the high buildings of our later construction cause concentrated air currents that would render work in an open-air school almost impracticable by blowing papers and material about and forcing dust and dirt up and through the school. Exposed conditions, such as Riverside Drive in New York City, would be objectionable, rendering it difficult to protect the school rooms from violent storms.

The orientation of the school should be such that sun will enter all class rooms during a part of any day in the year. This is especially important in such rooms as study rooms, where the children sojourn for a protracted period. As the rooms are all open, it is not so important that the greatest length of the building be across the direction of the prevailing wind, and it is important that it be not across the direction from which storms are likely to come; but no room dedicated to the children

*Read before the Fourth International Congress on School Hygiene, Buffalo, N. Y., August 25, 1913.

should be in a pocket so that free circulation is impeded.

Toilets are to be placed so that odors cannot reach the open class rooms. An unsanitary condition of this kind will become particularly objectionable in warm weather.

It is essential that the plan be so arranged that all class rooms, study rooms, the auditorium and wherever the children remain shall have ventilation on two or more sides, and to really fulfill conditions properly the room should be open on at least two sides that are opposite each other. Corner rooms with windows on the sides perpendicular to each other may be satisfactory when there is a sufficient amount of wind; but when there is little movement in the atmosphere, a dead corner with eddies is likely to retain the air in certain portions of such rooms. On the other hand, if rooms are entirely open on two opposite sides without protection, a storm or misty rain will carry completely across the room. For this reason an open gallery is advantageous. Such an one is shown in the Ideal Open-Air School originally prepared to illustrate the important contribution to this subject made by Dr. S. A. Knopf in his paper at the International Congress on Hygiene and Demography in Washington, D. C., September, 1912,* and will be seen in the plans and model on exhibit in the Exhibition Hall of the Congress (see illustration).

General plans may be divided into three classes: The "U" or "H" plan, where the wings are about open courts, the "T" or "Star" plan, where the wings radiate from a center, and the enclosed court plan. The last-named is not so good, and all plans should so surround the courts that the latter are open on at least one side which is not the north. This is to insure the entrance of the sun into all parts of the court during some part of the day.

I see no objection to building three stories high above basement or higher, if means of ascent can be provided. Open galleries and open staircases are good provided they are protected from snow and sleet. A great advantage is that children passing between the cold rooms do not undergo a sudden change of temperature. Snow and ice are particularly dangerous in the staircases.

An objection to placing class rooms on the ground floor is dust and odors from the street and the general impurity of the air.

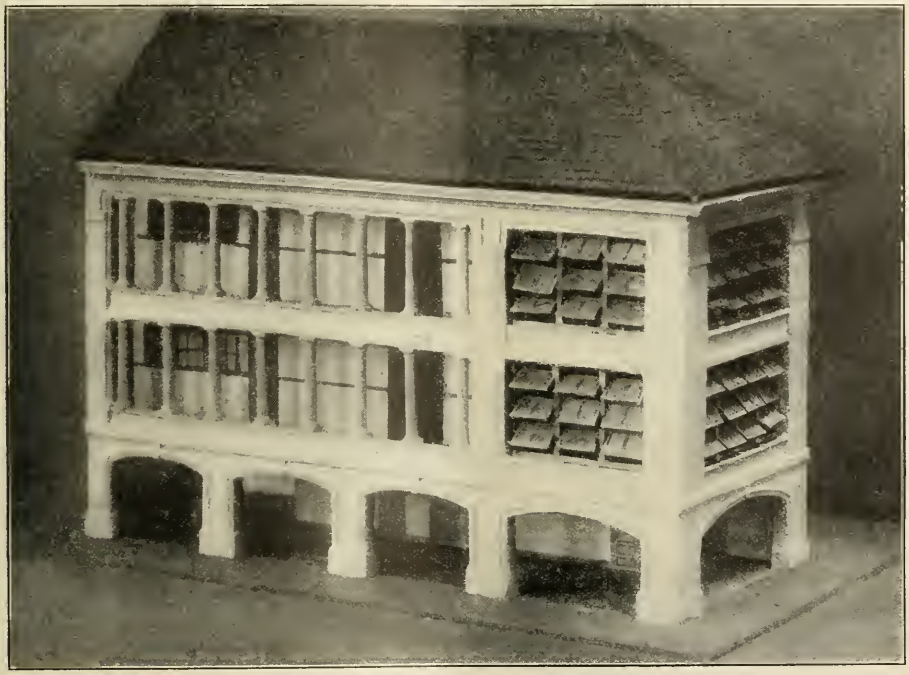
Overhanging cornices are good, because they afford protection from rain for the open windows; but on the top floor they cast a shadow. A glass cornice, like a marquise, might be extended at the top of the building, or such protection might be constructed over each of the large windows. It would certainly be unusual in its appearance and difficult to make it appear architecturally attractive.

The auditorium should be so situated that it can be thrown entirely open. It may be convenient to have it arranged so that it can be closed for special exercises, when visitors are present.

Under a second head I am grouping some recommendations for the details of the building.

Class rooms should have predominant unilateral light; that is, the light on the left of the pupils should be stronger than that from other directions.

Blackboard space must be preserved, especially behind the teacher.



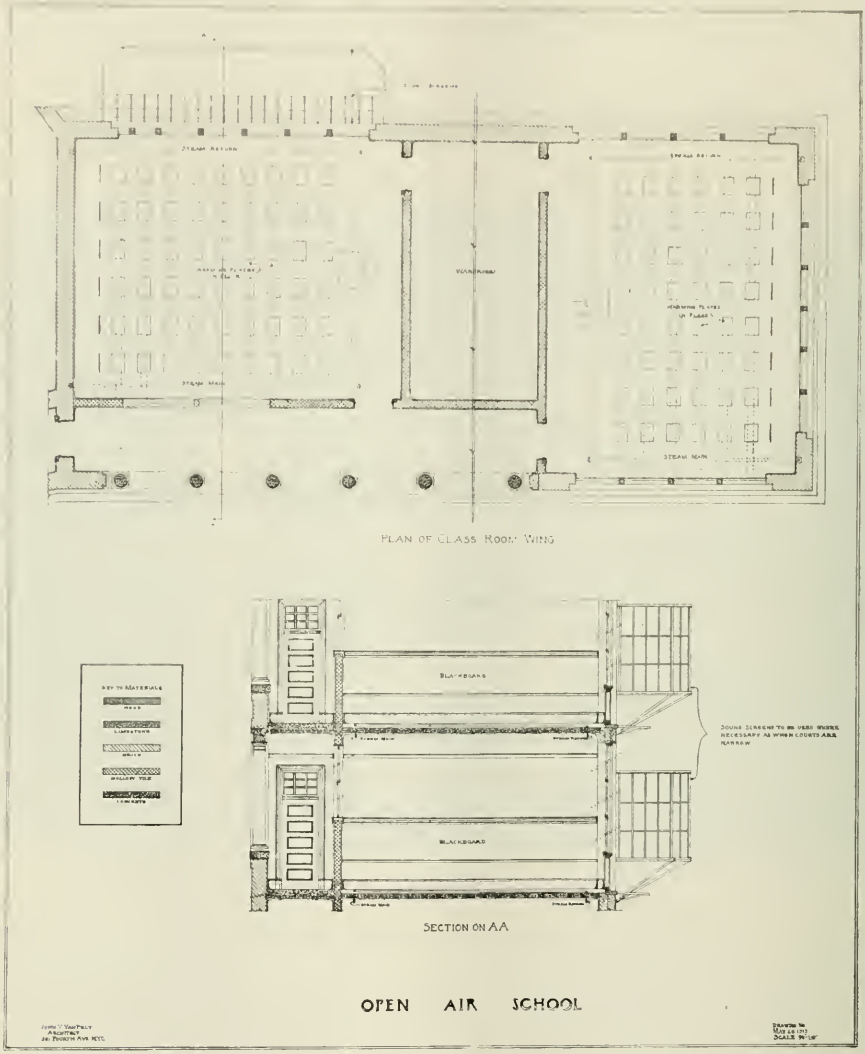
Model of an open-air school.

*Knopf: "Tuberculosis and Other Diseases in Schools and Colleges," *N. Y. Med. Jour.*, January 25, 1913; and in the Transactions of the International Congress on Hygiene and Demography, 1912.

Sills may be three feet high on the side whence the light comes, namely: the maximum for the ordinary sill. Higher than that they cast a shadow. It has been found in the experiments made by Mr. C. B. J. Snyder, architect of the Board of Education of New York City, that low sills are disadvantageous, because they create draughts around the pupils' feet, taking away warmth, do not materially improve the general condition of the air, and are of no advantage to the respiratory organs.

If blackboard space is maintained opposite the lighting windows, large windows should open up the room above these blackboards; but it is not good to place children immediately under a high sill, as the cold air dropping down on them may be objectionable.

Class room windows must be so arranged that any side from which comes a heavy driving storm or a drifting mist can be closed. In such schools as the Providence School, one of the first open-air schools of the country, hinged windows were tried. Mr. Snyder has experimented with these and they have not been found as advantageous as pivoted sash dividing the windows into three parts, the upper half of the lower sash opening in so that it projects above the head of a full-grown person. Still more recently the scheme of operating the two upper sash together and the lowest sash independently has been adopted. Such sash somewhat inclined to the outside form a protection from slanting rain, throwing the water out of the building. Double-hung windows are possible running up into pockets in the head of the windows and below the sill of the window above so as to leave the entire

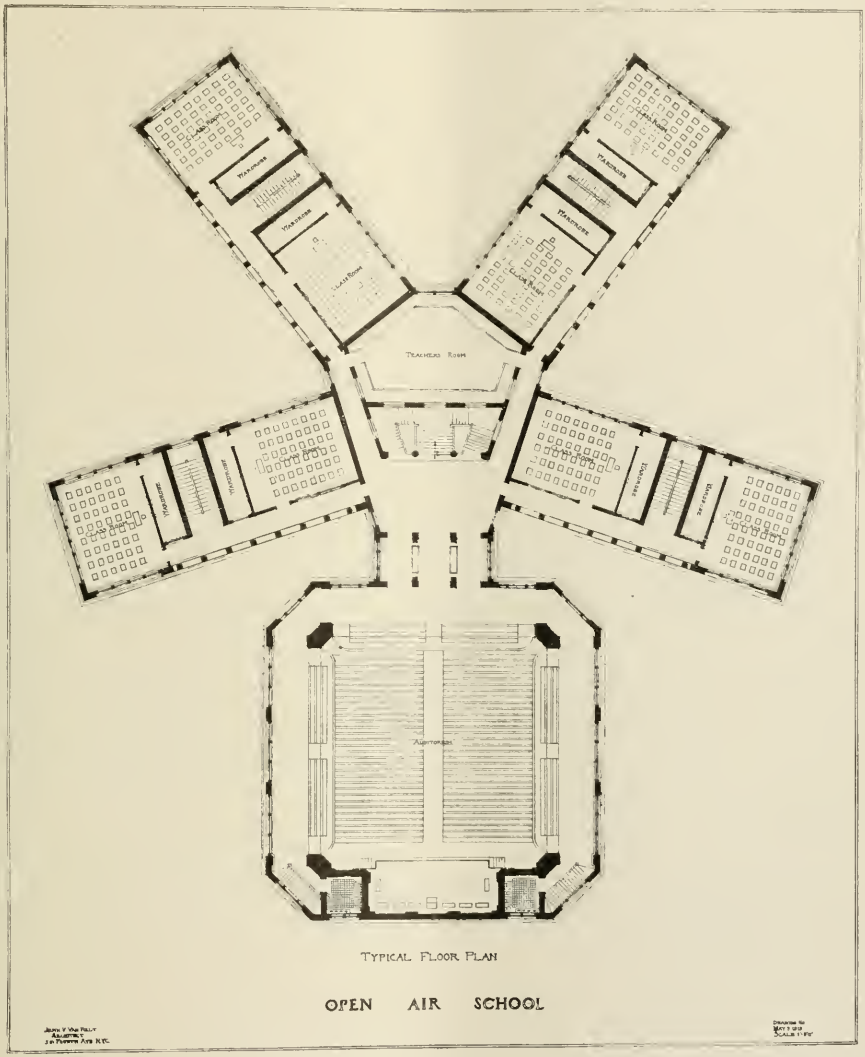


opening free. They are somewhat difficult to operate and do not afford any protection.

In the "U" or "H" plan, if the court is not wide, the noise from class rooms opposite each other is objectionable. I will take up preventives later, in discussing acoustics.

Class rooms may have the floor warmed. This would slightly temper the air and keep the children's feet from becoming cold, tending to dry them if selected that is not too hard under foot. If the floor is heated, it must necessarily be of a material that will not be affected by the heat. For this reason the warmed floor shown in the design is attained by metal plates separated by composition.

Coat rooms should be well ventilated, but kept reasonably warmed, that is about 65° F. This will appear quite warm to the pupils coming from the class rooms and halls, and a higher tem-



they had not come to school with rubbers. This will also be referred to later. Wood floors are good to walk on, as they are not too hard and very durable; but rain, snow, and dampness soak into them and this is objectionable. Linoleum is good, especially if it can be cemented down. It wears out rather easily and is therefore expensive. What is known as composition floors are somewhat expensive, but come within a possible range of prices. They can be made in different ways and a type should be

perature would be uncomfortable before the smaller children could succeed in adjusting their clothes. It may be suggested that coat rooms could be omitted, in that the children wear about the same clothing in the class room that they do out of doors. If they have to come to school through snow and storm, their outer wraps should be taken off and dry wraps put on, and I believe it would be better to provide a proper place to keep such wraps, allowing the damp ones to dry.

Furthermore, exceptional cases occur where fragile or anemic children suffer from time to time from the cold. This has been noted in the Graham School reports, and the warmed cloak room offers an excellent place where their vitality may catch up. Although limited space may seem to force wardrobes in the class rooms, I consider it a bad solution. In such case a warmed room for recuperation should be provided on each floor.

Toilets must necessarily be warmed, as the children have to remove some of their clothes, and in very cold weather plumbing pipes would freeze. A temperature of 60° to 65° is ample. Anything higher than this would be bad. Toilet rooms should be screened to prevent insects from entering through the open windows. As in all schools, an automatic means of flushing toilets should be provided, as the children cannot be relied upon to do this properly.

In laborities, manual training rooms, etc., provision often has to be made to maintain such a temperature that liquids under study will not freeze, and where fine and delicate work is done the temperature cannot be allowed to go quite as low as where some protection for the hands may be worn in cold weather. Furthermore, below a certain temperature it is not easy, and, for some persons, not possible to perform very delicate work. Steam radiators should be introduced in such rooms and if a number of small radiators are scattered about the heat can easily be graduated by turning on one or more and allowing the others to remain empty. Provision must be made for draining these radiators rapidly.

Rooms for visitors should be provided where the temperature is not allowed to fall too low, and heat will probably be required in the principal's and teachers' rooms.

In spite of the fact that such a school is open and a considerable amount of heat lost, the fact that the average temperature of the building is kept so much lower than is ordinarily the case will probably show a slight saving in coal over the usual type of school house. Sufficient experiment along this line has not yet been made to definitely determine the proportion.

Hot water systems cannot be used owing to the danger that pipes and radiators may freeze. Hot air is useless, as it cannot be controlled in such a building. Steam or water vapor are therefore the only possible means of heating, and water vapor is hardly effective enough under the conditions that usually obtain.

Heating the floors of the rooms has already been mentioned. The floors should not be overheated; chilblains would probably result to the children; in the cold rooms the steam that would form would probably be objectionable; a high degree of heat would cause odors. About 40° C. is a maximum temperature for a floor surface.

The acoustics in such a building play an exceedingly important rôle. In an auditorium they must receive special study, as the open windows supply the equivalent of total absorption, and, furthermore, allow exterior sounds to penetrate. This would make speaking in the rooms more dead, and in the noisy quarters of a city exterior sounds would become predominant. In the class room the question becomes quite important. Up to the present time sufficient attention has not been paid to the acoustics of the ordinary school. At the new Brierly School in New York City an effort has been made to introduce a reasonable proportion of deafening material. Absorbent felt has been placed on the ceiling and this has been covered by a muslin blind-nailed, on which paper has been pasted, the latter being decorated in waterproof color to give a smooth surface. In the open air room where class rooms are opposite each other, across a somewhat narrow court, the sound would be thrown over to the opposite room and would cause reverberation in the court. This would be increased by a non-absorbent wall in and opposite the windows of the first room, notably if large blackboard spaces covered the reflecting wall. In certain cases it is possible that the reverberation in the room would be sufficiently reduced if absorbent material were placed on the ceiling of the rooms and sound entering the class room might be sufficiently absorbed if the reverberation were kept down. On the other hand, conditions might exist as previously noted, where a concentration of sound from a reciting class might be thrown out of the window and into the opposite class room in sufficient proportions that the direct sound would be objectionable. It will appear from this that a special study of the acoustics for each class room should be made. In order to obviate the difficulties mentioned in the drawings here exhibited I have shown a glass screen that might be built in front of the windows, deflecting the travel of the sound to a certain extent, without preventing light from penetrating the room. If the screen were inclined away from the head of the windows and Luxfer prisms introduced the sound would be dissipated and the light increased, but such increase might not be desirable.

It is surprising that the medical profession which has occupied itself so considerably with the light and color of the walls in class rooms should have been so oblivious to the nervous strain created by the discordant sounds in recitation in class rooms, or, on the other hand, brought about by imposing too rigid silence and restraint on small children.

In the matter of light the general color of the class rooms should be that of the ordinary room, except that it must be kept in mind that too light a wall reflecting a glare from the snow on a winter's day would be trying. As a much larger quantity of light will probably penetrate the rooms than ordinarily enters a class room having glass areas of only 20 per cent. to 25 per cent. of the floor area, the walls of the room might advantageously be somewhat darker.

It is due my audience to explain that although the complete open-air school contemplated in the foregoing paper is still unrealized, I have felt that I could speak authoritatively because of extended experience on the one hand in building schools of various types and on the other in some twenty years of theoretical study and practical experiment in the construction of sanatoria for the treatment of tuberculosis. These are the two types of building that must be parent to the new ideal, and in closing I cannot do better than urge that as you investigate details beyond the scope of this curtailed résumé they be studied simultaneously in exponents of both of these types.

381 Fourth Avenue.

The Etiology of Tuberculous Meningitis.—H. Koch was able to demonstrate a hereditary basis in 23 per cent. of his cases. In most instances, the children who were less than 2 years of age had had some other infectious diseases just prior to the onset of meningitis.—*Wiener klinische Wochenschrift.*

PREMONITORY AURÆ IN INEBRIETY.*

A STUDY OF SOME SPECIAL SYMPTOMS.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

SUPERINTENDENT, WALNUT LODGE HOSPITAL.

The term inebriety describes a neuropsychosis, the symptoms of which are convulsive demands for spirits, to the stage of complete narcotism. Then the psychosis disappears and a free interval follows, of indefinite duration, and later a return of the drink paroxysm. This paroxysm is literally an obsession, noted by manias, exaltations and dementias, and other mental changes.

In the free interval there are health, sanity and normal conditions of physical and mental activity.

The term alcoholic is applied to a different condition. Here spirits are taken regularly, without free intervals, and the person does not seem to be abnormal in any particular way. There are toxemias and palsies in such persons, but they are concealed and are not very evident for a long time. There may be a sudden cumulation of abnormal forces, in which symptoms of mental derangement occur. These are of short duration, and alcohol is continued as a beverage and medicine.

The inebriate is in a different class of neurotics, with a great variety of psychical symptoms, in which auræ and premonitory conditions may be marked. The alcoholic has no such symptoms. There are no intervals of abstinence, hence a continuous obscure anesthesia exists, marked by coarse physical symptoms and abnormalities which seem to be fleeting and not prominent over the organism.

The auræ in the inebriate indicate oncoming neuroses and psychoses, both functional and organic. Many of these have been tabulated, and one of these divisions may be called motor auræ, and refers to muscular activities in great excess. Thus the inebriate, after a period of abstinence and apparent good health, will suddenly display intense muscular activity, working far beyond his usual custom, putting out great muscular efforts without any reasonable explanation.

This is commonly seen in persons who are without occupation, or who have some business that has been going on in a monotonous way. Suddenly they will display intense anxiety to promote business, working far into the night, and showing unusual energy and care, apparently afraid that unless they give it the closest attention the business will fail. If without occupation they will suddenly take up exercises, such as golf, baseball, walking, rowing, and pursue these with great energy and pleasure. Then all at once they begin to drink spirits, and their muscular activity and business energy subsides.

Later, when the drink paroxysm passes, they come back to a normal condition, and seem not to have any desire to engage in business and muscular efforts, but go on in a normal way, without being able to explain the changes and unrest which preceded the drink attack.

A repetition of these incidents seems not to impress the patient's mind with any sense of danger or significance of their meaning. When the muscular delirium comes on there is egoism that explains it as due to other causes than the possible outbreak of a drink craze, with intense confidence in their own conceptions of the import and meaning of these unusual auræ and symptoms.

Another grouping of premonitory symptoms refers to sensory functions. Thus a person of ordinary serenity will suddenly become very irritable and sensitive to conditions and surroundings. He will be angry at any little change, or at words which he can construe as a reflection. This irritation is so unreasonable, and sometimes associated with egotistical pride, or loss of pride, and assertiveness in his own conception of acts and use of words, as to attract attention.

Often language will degenerate into coarse expletives, and confidence in his family and associates will be lowered. Then the drink craze will break out, and all these symptoms will pass away. These sensitive auræ and premonitory symptoms take on most complex forms, and appear and disappear in a most bewildering way.

Frequently there are marked changes of circulation, noted in the face and on the surface of the body, pallor, flushing, cold hands and feet, with hurried respiration, seeming to be very intense from any little overexertion, or derangements of the heart's action, which disappear when spirits are taken.

These vasomotor derangements are often associated with psychical symptoms of fatigue and pain, as well as derangements of secretion and nutrition, with sudden chills and perspirations, excessive activity of the bowels and kidneys, derangements of the stomach, all of which disappear suddenly. Physicians who fail to recognize the significance of these symptoms and give spirits or medicine in the form of tinctures will be astonished at the sudden change, and startled to find the patient drinking to great excess.

Another premonitory symptom is extreme pessimism. The person wakes up in the morning with symptoms of dread and a certainty of oncoming danger to himself and family. This condition is alarming to himself and friends. When reminded that in the past similar pessimisms ended in drink crazes the patient is indignant and asserts that this condition cannot possibly end in that way, but persists in believing that it is the ominous sign of a final dissolution.

Later an alcoholic obsession breaks up these symptoms. There are a certain number of persons suffering in this way who realize the significance and possible termination of such disturbances, and make great efforts to overcome them.

John B. Goff was a distinguished example. After a week of most strenuous effort, lecturing once or twice a day to crowded audiences, he would develop the most intense anxiety to talk on the temperance question, anywhere, to anybody who would listen.

After giving six or seven lectures during the week he would insist on getting opportunities to speak once or twice on Sunday, voluntarily. On these occasions he was thought to be at his best, and was particularly emotional and excited. He told his best stories with an energy that was overwhelming. This was simply a consciousness of the auræ of the drink obsession, and the possibility of breaking them up by intense appeals to the audience to sign the pledge and give up all use of spirits. It was his own mental condition that was receiving strength by an intense battle to overcome the psychic states.

In reform circles similar instances are noted

*Read before the American Medical Association at Minneapolis, June 17, 1913.

where men of intelligence and culture suddenly display intense desire to help others by prayer, exhortation, and personal appeals. The M'Auley Mission in New York furnishes very striking examples. Persons will appear in the audience, apparently become converted, and make the most passionate appeals to others, and assist in most energetic efforts for many days, then suddenly disappear.

Sometimes after the drink craze is over they will come back and work with greater energy than ever. These men are inebriates, who recognize the oncoming drink storm and try to prevent it by convulsive efforts to help others. An example was that of a noted lawyer, who every four or five months would have an attack of what his friends called a craze for slum work. He would suddenly drop all business and go down into the lowest districts and exhort and pray with anybody who would listen to him. After a short period he would return to his business and be silent as to the reasons for his philanthropic activity. In reality he had overcome the drink storm by diverting his energies and expending them in ways that were helpful to others.

In another instance under my care a very active business man would become alarmed about his spiritual condition. He would go to some distant place, engage in reform meetings, speak and pray in a most passionate manner, without any sense of fatigue or weariness. Coney Island was one of his favorite resorts. He would go down and hold a meeting on the sand, sing, pray, and exhort for hours, then go home and remain in a stuporous condition for a day or two. This was another outlet for the drink obsession. Later this same man would come home after two or three days of active service and bring a bottle of spirits, remain in bed a day or so, then recover, without any clear memory of where he had been or what he had done.

Some years ago very striking examples of similar cases were noted in persons who conducted temperance meetings following the revivals of Sankey and Moody. In almost every town men and women suddenly became great revival workers, and exhibited unusual energy and skill in keeping up the religious excitement and efforts to help others. These persons disappeared from public life, and in many instances they were suffering from drink psychosis in the premonitory stage, or the same psychosis after the drink stage had passed off in remorse, and exaggerated manias and melancholias prevailed.

In all this there is a most confusing complexity of symptoms which are rarely studied, and often refer to the oncoming drink obsession or follow from its termination. The physician who blunders here, and who lacks the psychical instinct to understand the significance of these abnormal changes of mental and emotional conduct, is often a very dangerous man. Friends of persons and laymen who realize the significance of these unusual acts appeal to me for advice in increasing numbers. To them it is mysterious, and no explanation is satisfactory. There is another aura that is equally difficult to explain and often very distressing. It is that of criminal instinct breaking out in persons highly respected and reputable.

Kleptomania often precedes the drink attack, where persons appropriate things of no value to themselves in the most senseless way. In nearly every city there are men and women who at certain times have this mania and display much skill and cunning, and later they make every effort to return the goods stolen or repair the injury done.

A leading literary man, who is a secret inebriate, will steal books for days before the drink paroxysm breaks out. Later he will return the books or pay for them. The method of taking them shows cunning and secretiveness equal to that of a most expert thief.

In the business world sudden attacks of dishonesty, cheating, lying, taking advantage of persons in the most senseless way, often precede the drink attacks. The public reason that when such a man is convicted he drinks to cover up and lessen the magnitude of his crime. In reality the dishonest acts were obsessions, and the drinking was the neurosis. Sudden dishonest acts should suggest careful study as a psychosis and not a vague moral lapse, but something with a distinct significance of mental disease.

Not infrequently the inebriate will show extraordinary cunning and skill to absent himself where he can drink to great excess without interruption or publicity. Every year incidents of this kind cause more or less distress and attract attention in the papers. Thus a man of character will suddenly disappear, and after a time will be found in some out-of-the-way place where he has drank continuously, or on other occasions he will reappear and give some very childish explanation for his absence.

Instances are not uncommon of persons taking with them lewd women to some obscure place and drinking to great excess; some accident happens, or death follows, then public exposure. The act is so extraordinary and unusual as to bring great distress to the family and friends.

The person realizes the oncoming drink storm and what it involves, and the danger of publicity, and tries to cover up the conditions which he cannot avert. In my book on "A Clinical Study of Inebriety" (The Harvey Publishing Company, Cincinnati), I have described at some length groups of persons in whom the drink storm occurs at distinct intervals, and these are often predicted and prepared for with certainty and skill. The return of these storms is often very exact as to time. I have noted many persons who drank at distinct intervals of days and months, which never varied more than a few hours.

The auræ or premonitory symptoms would vary some, but the drink paroxysm never. Sometimes the auræ would be marked by great generosity, credulity, or parsimony, or severe criticisms of men and events; conduct and character that were unusual, but of very short duration, always ending in the use of spirits. Many persons who live in abnormal conditions of constant over-excitement or extreme monotony, or persons who are overworked, both mentally and physically, and those who have no occupation, all show these premonitory symptoms of disturbed mental conditions. Emotional changes, as well as other derangements of the mind and body, react on nutrition and produce very alarming disturbances. Acute gastritis, obstinate constipation, or persistent diarrhea, attended with great fears, end quickly when the patient begins to drink.

Often patients complain of excessive fatigue and nervous depression and inability to concentrate the mind on anything. These end in about the same way. In the alcoholic there is continuous anesthesia and insidious depression in the functional activities. There are no premonitory symptoms

that are recognized, except in a general way, such as toxemias, nerve, and nutriment disturbances, which are explained as due to other causes.

In both the alcoholic and inebriate there is inability to appreciate the danger of their own conditions. The memory seems incompetent to register the exact impressions. There is a steady weakening of vital forces and covering up of the depressive states.

Some inebriates are morbidly conscious of the drink storm and give way with fatalistic submission. Others struggle against it and exhibit a medley of confusing and disturbing symptoms. In a study of these premonitory symptoms there are possibilities of successful treatment which the empirics have realized and made practical, while the average physician, trusting to the moral theories, has ignored them.

The various cures which have been exploited so vigorously have been based on this one fact, that the obliteration of the drink craze is the cure of the patient. Anything to stop the morbid impulse to drink was curative and when once accomplished this could be held in abeyance for all the future.

The powerful eliminative measures and the intensification of the anesthetic effects of alcohol make a profound impression on the organism, particularly of alcoholics. The sense of physical relief which follows is strengthened by the suggestion that the obsession has been permanently destroyed. In some cases this proves to be true, and in the alcoholic it is always successful for a time. In the inebriate new conditions are created, and unknown depressions and changes provoked, equally perilous. The drink craze dies out, as it would have naturally, with or without any remedy. To this there is added a psychical element of suggestion and a physical reliance on drugs which in the future will fail.

In addition to this there are depression, lowered vitality, and toxic conditions unknown, which have to be overcome in the future. In epilepsy, to remove the exciting causes and prevent the return of the convulsion is the object of all treatment. This is true in inebriates. The auræ and premonitory symptoms, while lacking the spectacular muscular contractions and spasms seen in epilepsy, are far more profound in their effects on the organism.

There is a period in which these premonitory symptoms would give way to active treatment and thus the convulsions be postponed. A number of persons who have been under treatment in hospitals and sanatoriums go back, not so much for specific treatment of the alcoholic craze as for relief from the premonitory symptoms, which, unless checked, will lead up to the drink storm. There is a great wealth of illustration along this line.

Persons who have not drank for years have premonitory symptoms and auræ which call for medical help. A vigorous temperance lecturer, who was an inebriate for many years and then recovered, and has for years been on the lecture platform, has what he calls "fits of blues," or periods of unusual depression, irritability, and paranoiac notions which pass away. Sometimes he calls for medical help and distinctly realizes that these are premonitory symptoms of a drink storm.

One man of this class has an attack of asthma for two or three days at a time and then recovers. Another has a distinct continuous fever, a third has insomnia, which after a time passes off; these are always referred back to the degenerations from alcohol and are regarded as dangerous periods in which the desire for drink may suddenly break out. One fact should never be overlooked and that is, in both inebriates and alcoholics, particularly in the former, some physiological change may take place in the brain and nervous system in which the drink obsession disappears permanently. In most cases there is positive aversion for the smell and taste of spirits. In others there is simply a profound indifference and disinclination to use it in any way.

There may be psychical symptoms and neuroses of most complex character, but the former fascination for the effects of spirits has passed away. Should spirits be given in any form there is distress and suffering and profound disgust, which prevents their further use. In reform circles examples of this are very common. Inebriates who have suddenly stopped all use of spirits ascribe this change to common, simple causes, either mental or physical. Evidently the causes are insufficient, because they do not act the same in other cases.

Certain remedies are credited with being curative and certain special specific moral powers are supposed to have the same effect. This is not confirmed by any careful study. The central fact remains that the drink obsession dies out, in obedience to unknown laws and forces, and other psychoses take its place.

In hospitals and sanatoriums for inebrietes there are a large number of persons who have been treated and restored and who return from time to time with premonitory symptoms which they fear will lead up to relapse. After a short treatment these pass away and they return home restored. Such persons are sometimes called hospital tramps, or repeaters who have the sanatorium habit, who go for treatment on every occasion of mental and physical trouble.

The terms neurasthenia, psychasthenia, hysteria and an endless variety of neuroses are used to describe what are really auræ and premonitory symptoms of inebriety.

Various forms of dyspepsia and obscure mental symptoms have the same meaning and significance. Another very curious fact which I have studied in my book on Inebriety is the reappearance of the toxic symptoms of the drink craze from some unusual strain and excitement in persons who have been abstinent for years. As an example, a man formerly an inebriate, who for ten years had been abstinent from all use of spirits, manifested distinct symptoms of intoxication upon receiving news of the death of his son. He was excited, delirious, foolish, rambling, then stupid.

There was no possibility of his having used alcohol in any form. A general in the Civil War on one occasion appeared to be wildly intoxicated and yet it was ascertained that he had not used spirits for years. Some sudden shock to the nervous system provoked the return of the anesthesia and all the symptoms which followed from alcohol, and yet no alcohol was used. The former impressions made by spirits on the brain and nervous system suddenly came into prominence.

In one instance a clergyman, who had abstained for nearly two years, suddenly became delirious, with all the symptoms of alcoholic intoxication. This was really psychical intoxication. There are many examples of this character that are practically unknown and misinterpreted, all indicating the

persistency of physical degenerations and disorders, being reproduced long after the original causes have passed away.

Active treatment of these obscure premonitory symptoms promises very excellent results and already a wealth of illustrations show how much could be done by an early scientific recognition of the significance of mental and physical changes in both the alcoholic and the inebriate.

Some of the conclusions which a study of these early symptoms would seem to support may be grouped as follows: Inebriety is a neuropsychosis and when carefully studied will be found to have very distinct premonitory stages and aurae that forecast the full attack.

The aurae are very complex and are referred by the patient to causes that are insignificant, and to the physician who is not familiar with the history of the patient they may be confusing and mysterious. A simple attack of violent anger may have a physical significance which, if recognized and treated, would be followed by the most satisfactory results.

When these symptoms appear in the history of periodic drinkers their gravity would be recognized and their complexity centering about the motor, sensory, organic or psychic activity should attract the most careful attention. The inebriate is a masked epileptic in many ways and this condition is equally as complex in the variety of symptoms manifest.

The alcoholic and so-called moderate drinker is always more or less a paretic and toxemic, with degenerations and depressions of every organ of the body. The premonitory symptoms may be localized in deranged metabolism circulation and psychic capacity.

Laboratory studies show that the continued use of spirits, even in small doses, is anesthetic, corrosive, and cumulative; that toxins from without and within are constantly present and being formed. Bacterial infections and inflammatory conditions always follow in various degrees. The premonitory symptoms are so general and are often so masked as to be overlooked.

The common congested face, furtive eye, and diminished muscular activities of the alcoholic indicate an internal condition which is increasing constantly. The final conclusion I wish to make prominent is that the neuroses of inebriety and the toxemias of alcoholism constitute a distinct field for medical practice, which has not yet been occupied. To-day the quacks with their boasted discoveries are doing the work which the educated physicians should do.

Every physician has patients of this class, who need care and treatment, and yet he is rarely able to understand their condition, much less to give proper means and measures for relief and help.

There are hundreds of these neglected men and women in every community who could be restored and permanently cured who now, through neglect, drift into the ranks of criminals, paupers, and dependents, becoming incurable and burdens. Physicians themselves furnish a proportion of victims, which is pitiful, because preventable.

If our medical schools would teach the facts that are at present known a revolution would follow at once. The few workers on this frontier land realize possibilities that are startling in the study and treatment of inebrietes and alcoholics.

What we need is to put aside the traditions of the past, which have come down to us as settled facts, and when examined in the light of modern science are delusions of the most pronounced character. Teachers, leaders, and varied interests, both commercial and otherwise, hold us back from scientific investigation and the application of means and remedies that will effectually clear away the fogbanks of delusions and traditions that hang about this great modern plague.

CASES OF TUMOR OF THE LUNGS AND MEDIASTINUM SIMULATING PULMONARY TUBERCULOSIS.*

By WILL HOWARD SWAN, M.D.,

COORADO SPRINGS, COLO.

Several cases of intrathoracic tumor, which had been mistaken for pulmonary tuberculosis and sent to Colorado on that account, have come under the observation of the writer. These are not reported with any desire to criticise those who made the diagnoses; for it is well known that, early in their course, these cases may simulate tuberculosis so closely and the physical findings be so similar or indefinite as, in some cases, to make differentiation extremely difficult or even impossible.

Case I.—*Lymphosarcoma of the Mediastinum.*—Mrs. H. M. G., age 30, seen the day of her arrival in Colorado. Family history not important. Well till last year when she felt run down and nervous; cough, expectoration, sweats, fever, and chills. Much emaciation. Glands in neck and axillæ swollen and tender. Vague pain in front of right lower chest early in illness, none since. No dyspnea. Greatly troubled by itching over whole body. Had had local treatment for supposed tubercular laryngitis. Arrived in Colorado desperately ill, with family of five, having sold their home to realize sufficient funds for the journey.

Physical examination showed enlarged glands above right clavicle; flatness in right front, from fifth rib to near iliac spine and to umbilicus. Abdomen tense and very tender over this area. Also area of dullness corresponding to lower half of sternum, continuous with cardiac dullness and extending half way to right nipple. Absence of respiratory and voice sounds over this area.

Right back showed signs of fluid up to lower fourth of scapula. No other abnormal signs in the chest. Dilated deep epigastric veins on either side. Sputum on one examination showed no tubercle bacilli. Died from uremia after ten days.

Autopsy showed a tumor the size of a child's head in lower anterior mediastinum, with metastatic areas in both lungs and considerable serofibrinous exudate in right pleural cavity. No macroscopic evidence of tuberculosis anywhere. The liver was greatly enlarged and pushed down to the brim of the pelvis. Spleen somewhat enlarged. Microscopic examination of the tumor showed it to be lymphosarcoma.

Case II.—*Primary Carcinoma of Lung.*—Mr. J. H. B., 53, merchant, came to Colorado in December, 1908. Family history not important. Previous history good except for hemorrhoids and stone in the bladder. Cough with slight expectoration for four months. Lost 28 pounds; moderate fever. Sputum had been blood-stained a few times, but had showed no tubercle bacilli on several examinations; positive skin tuberculin test. Chest examination had caused only a suspicion of trouble in left lung.

Physical examination. Looks very pale and ill. Chest shows slight dulness in left front from second to fourth rib and from left border of sternum to nipple line; fine moist râles after cough, with harsh respiration over this area; no change in voice. In left back, harsh respiration over whole interscapula space and slight dullness over lower half of area noted. No other abnormal signs. X-ray examination showed the right apex clear, enlarged bronchial glands; heart somewhat to the right. Left side; apex clear, few nodules from clavicle to second rib; from second rib to bottom of the fifth is a distinctly outlined consolidated area, which is being excavated. Several examinations of sputum failed to show tubercle

*Read before the American Climatological Association, Washington, D. C., May, 1913.

bacilli. At the end of a month the signs in chest had become more marked; the patient became restless and spent two months traveling in Arizona and California. Returned March 15, 1909, having lost much ground in every way. Nearly the whole left chest was flat on percussion, with respiration diminished above, bronchial in type, and absent in lower portion; heart displaced to right. Aspiration removed 30 ounces of slightly turbid fluid, not blood stained, and showing no tubercle bacilli or other organisms, but a definite predominance of lymphocytes. The aspiration gave little relief from dyspnea. From this time till his death, April 16, 1909, he had rapid respiration, gradually increasing dyspnea, moderate fever, slight expectoration which was free from blood and tubercle bacilli on numerous examinations, and marked weakness. Each of four aspirations yielded about 30 ounces of fluid of the same character as described above.

Autopsy. Left lung was simply a tumor mass—in areas softened, but mostly hard; pericardium, upper portion of the pleura and of the lung were practically inseparable and indistinguishable and firmly adherent to the chest wall. The mediastinum contained a mass of enlarged glands. The right lung showed no evidences of tuberculosis, but an area of metastasis near the apex, with hypostatic pneumonia at the base. There were metastases in the liver and spleen, found only on section. There was a chain of mesenteric and post-peritoneal glands extending from the bifurcation of the aorta to the diaphragm, but no other lesions in the abdomen. Unfortunately the specimens were lost and there was no microscopic examination, but it appears to have been a case of primary carcinoma of the lung.

Case III.—*Persistent Thymus—possibly Hodgkin's Disease.*—Mrs. C. P., age 40. Family history not important. Never strong; much pelvic and digestive trouble for years; always sallow and anemic; suspicion of gallstones several years ago. Eleven years ago spent a winter in Florida because of cough and weakness. Two years ago, during severe illness of a son, lost much weight and has never been well since. Eighteen and six months ago had pain in chest which required strapping. For a year cough with slight expectoration, fever, and a few night sweats. One year ago glands removed from right side of neck. No microscopic examination was made, but they were considered by a competent surgeon to have been tuberculous. Said to have had moist râles at both apices, but sputum not examined. Menses scanty. In bed past two months with afternoon temperature 99° to 101°. On arrival felt very weak, considerable dry cough, moderate dyspnea, and much indefinite abdominal discomfort.

Physical examination showed a woman poorly nourished, very pale and sallow, but scleræ white; skin almost bronzed throughout but not especially in axillæ or groins, and discoloration not seen on mucous membranes. Says this discoloration has been present many years, though some pigmented spots on abdomen and loins are recent. Systolic blood pressure 112. No enlarged glands except one above right clavicle, about the size of a pigeon's egg, movable, firm, and not tender. Spleen and liver considerably enlarged and the latter is very tender. Indefinite tenderness in right lower quadrant. Uterus large, retroverted, and tender. Hemoglobin 65 per cent.; reds, 3,400,000; whites, 12,500; color index 1. Stained film negative. Urine showed a trace of albumin and a few hyaline casts. Wassermann test, negative. Heart negative; lungs negative except moderately diminished respiratory murmur at right base behind and slightly harsh respiration in right front, in the third interspace.

For a time the patient seemed to improve with large doses of quinine and cacodylate of sodium, but on the whole she gradually grew weaker and lost much flesh. The temperature varied from 99.5° to 101° and the pulse was rapid. Respiration was not rapid nor embarrassed and there was but little cough, till shortly before death when there was distressing paroxysmal cough with attacks of dyspnea. There had also appeared dullness and a systolic murmur over the upper portion of the sternum.

X-ray examination showed a shadow in upper mediastinum, centrally located, 7½ cm. wide at second rib, front, and extending to the upper border of the clavicles. The heart shadow was normal in size, shape, and position. There was no evidence of tuberculosis or other involvement of the lungs. The fluoroscope seemed to show expansile pulsation of the mediastinal shadow.

A hurried autopsy, after the body had been embalmed, showed in the uper mediastinum a mass about the size of the fist, composed partly of a persistent thymus, 2½ x 1½ inches in size, and partly of firm, discrete lymph-glands which surrounded it and extended about the roots of the lungs. The individual glands varied in size from a cherry to an English walnut. The trachea and esophagus, though somewhat surrounded by the mass, were not involved. Heart and aorta normal. Pleural cavities smooth. Lungs showed no microscopic changes. The peritoneal glands formed a mass about twice the size of the pancreas, the individual glands being discrete, and measured up to 1½ inches in diameter. Both liver and spleen were enlarged, the cut surfaces showing nothing but the usual evidences of passive congestion. Stomach, intestines, pancreas, and kidneys, normal. Microscopically, the thymus showed small scattered lymphoid areas surrounded by fatty tissue, and areas of calcareous deposit. The lymph-glands, on numerous sections, showed nothing but a diffuse hyperplasia.

Case IV.—*Malignant Disease of Lungs.*—Male about 50, seen in consultation shortly before his death. Had been supposed to have pulmonary tuberculosis, till rapid emaciation, frequent "prune-juice" expectoration, absence of fever and of tubercle bacilli in the sputum, and finally the appearance of metastases established the diagnosis of malignant disease. No autopsy was obtained.

The following cases were never considered to be tuberculosis, but are related because of the pulmonary signs and conditions.

Case V.—*Malignant Disease of Lungs.*—Male, about 60; gradually increasing weakness, dyspnea, and dry cough; aspiration of blood-stained fluid from left chest; gradual loss of weight; bloody sputum without tubercle bacilli; several aspirations. No autopsy.

Case VI.—*Small-round-celled Sarcoma of First Rib, Involving Lung and Pleura.*—Widow, 68. Past history not important except rheumatism for ten years and shingles nine years ago. Pain in left shoulder, accompanied by an eruption said to have been herpes; later, numbness and severe pain in left arm; lost 15 or 20 pounds; in bed most of the time for four months; slight dry cough.

Physical examination showed a woman poorly nourished, sallow, dry and foul tongue. Temperature slightly elevated; evidence of arteriosclerosis, with hypertrophied heart; slight dullness above and below left clavicle with diminished breath sounds; no râles. Liver somewhat large and tender. Marked tenderness in left supraclavicular fossa, along inner side upper arm and front of forearm; some muscular atrophy and reaction of degeneration. Edema of legs. In two months it was noted that she was weaker; had greater paralysis of left arm and hand; that cough was increased, with slight expectoration which was free from blood and tubercle bacilli, but contained elastic fibers; that dullness at left apex extended to second rib in front and to middle of scapula behind, with diminished breath and voice sounds. There were a few fine moist râles. Above clavicle were to be felt several small hard glands. Patient died eight months from first symptoms.

Autopsy showed a small round-celled sarcoma of the first rib, involving the pleura and apex of left lung, and pressing on the brachial plexus and vessels. It was densely adherent to all neighboring structures. The first rib was largely disintegrated, from the spine to within 1½ inches of the sternum. The right lung and pleura showed no change.

It seems, perhaps, worth while to report these cases and particularly to discuss some of their symptoms and signs with reference to the differential diagnosis from pulmonary tuberculosis. It is of value to compare the actual findings in cases, as they present themselves for observation to the practising physician, with the more general accounts to be found in the literature. It will be seen that they present problems in diagnosis which are by no means easy.

Most intrathoracic tumors are malignant and what follows has chiefly to do with malignant cases.

Dr. Isaac Adler in an excellent recent monograph, entitled "Primary Malignant Growths of the Lungs and Bronchi," quotes Williams as follows: 55 per cent. of all cases were carcinoma, 9 per cent. sarcoma, 25 per cent. non-malignant and 11 per cent. cysts.

Our late and lamented Curtin, in his paper last year, quoted statistics indicating that primary cancer of the lungs occurs about once in 2,000 routine autopsies, or once in about 800 cases of cancer.

Babcock, in quoting several sets of autopsies,

found one case in about 1,500 autopsies.

They may occur at any age, carcinoma being most frequent between the ages of 50 and 60; sarcoma, between 30 and 40. They are considerably more frequent in males. Secondary growths are very much more frequent than primary, and generally cause fewer symptoms relative to the chest, because they do not attain such size, are generally multiple, and their local manifestations are obscured by those of the primary disease and other metastases.

Sarcoma appears to be more frequent in the mediastinum, while carcinoma is very much more common in the bronchi and lungs. It is probable that most cases of lung carcinoma originate in the bronchi and that the pleura is involved as part of the process. Whether the disease begins in the lungs or in the mediastinum, there is generally an extension from one to the other, during the course of the disease. So that the symptomatology is likely to be much the same in either case, except as to sequence.

All writers agree that there may be, in different cases, great variations in the relative prominence of different symptoms. There have been instances reported in which there have been almost no symptoms till a sudden fatality. The early symptoms in most cases are cough, expectoration, and dyspnea.

Cough may be dry or with moderate expectoration. If there is obstruction of the trachea or large bronchi or pressure on the recurrent laryngeal nerves, it is likely to be husky, rasping, or "brassy." In general it is not troublesome and may be absent. It was a symptom in all of this series of cases. Adler says if no cause can be found for a persistent cough, lung tumor should be thought of.

Expectoration may be absent or insignificant, but Adler considers it one of the most important things in diagnosis. In 10 per cent. of his 374 carcinoma cases there was no sputum; and in 40 per cent. it was not mentioned, being present in 50 per cent. It was present, though slight, in 83 per cent. of my cases. Homogeneous, tenacious sputum of a color resembling currant jelly is said to be characteristic; and Curtin laid stress on the appearance of globules of such sputum enclosed in a transparent gelatinous coating.

Occasionally there may be small masses of the tumor or cells in layers held together by a stroma, which may establish the diagnosis (Babcock). Lenhartz finds large spherical cells filled with multitudes of fatty granules and associated with many epithelial cells, which are curiously deformed and have club or tail-like projections. He thinks these are characteristic of carcinoma and that co-existent tuberculosis does not modify this feature. Adler says that since his attention has been called to these cells he has found them in every case of primary carcinoma of the lung that he has seen; and he regards them as probably pathognomonic for carcinoma. He says, however, that their appearance is very inconstant and that the sputum should be examined repeatedly.

Dyspnea is often the first and may be the most prominent symptom; yet, like all other symptoms, it may be absent. In Adler's cases of carcinoma it was present in 44 per cent. and not mentioned in 50 per cent. In 90 cases of sarcoma it was present in 60 per cent. absent in 2 per cent., and not mentioned in 40 per cent. It was present in 83 per cent. of my cases. It is apt to be progressive and may be most distressing. When severe it is often paroxysmal. Death may occur from suffocation, due to compression of the larger air passages. The worst dyspnea occurs with mediastinal growths and is therefore more common in sarcoma, which is more frequent here.

Pressure symptoms may be of much aid in diagnosis. Obstruction to venous return causes dilatation of the veins of the head, neck, chest, or arms, and there may be edema. There may be hoarseness or loss of voice from pressure on the recurrent laryngeal nerves; inequality of the pupils; or there may be dysphagia from pressure on the esophagus. Babcock and J. N. Hall mention the occurrence of "tracheal tug" and pulsation in cases of tumor adherent to the trachea, or located under the aortic arch, and above the bifurcation of the trachea. There were pressure symptoms in 50 per cent. of these cases. In Case III. the pulsation of the shadow seen by the fluoroscope led to the suspicion of aneurysm.

Pain is often absent and generally only a discomfort. The occurrence of much pain means the involvement of the pleura or pressure on nerve trunks, for the lung parenchyma is not sensitive to pain. It may be referred to different localities. Babcock says that marked persistent pain in the chest, without evidence of pleurisy, is probably not due to tuberculosis and may be from tumor. Pain, in a slight degree, was present in only 33 per cent. of this series.

Pleural involvement and effusion generally occur in malignant cases. The fluid may be clear, sometimes fatty from disintegrated tissue, but is likely to become bloody, as shown by repeated aspirations. This also occurs in tuberculosis. The amount of fluid is generally small; it is sacculated and tapping rarely gives much relief from dyspnea and other symptoms.

After aspiration there may be opportunity to make out conditions that were obscured by the effusion; and Adler points out that the failure of a dislocated heart to show any tendency to return to its normal position after aspiration, should lead to suspicion of tumor. Of course fibrotic and pleural contractions on the opposite side of the chest might lead to permanent dislocation of the heart. There was pleural effusion in half of my cases.

Fever is not constant and is irregular in character. This may be of some help in distinguishing it from tuberculosis. In all of my cases there was more or less fever, irregular in type. It is probable that the fever is chiefly caused by complicating conditions.

Night sweats are said to be uncommon, occurring in 33 per cent. of this series.

The blood count appears not to have been well worked out, but there has been a fairly constant leucocytosis in the reported cases, when the blood count was mentioned. It is possible that here may be some help in differentiating tuberculosis. There was a slight leucocytosis in one-third of my cases. In two-thirds no record of this detail was made.

Course and Termination.—The disease may run its course in from a few weeks to five or six years. It is always fatal, death occurring from asthenia or suffocation.

The physical signs of course vary greatly according to the location and extent of the disease, the pressure on different structures, and the existence of complications. Early in its course there may be no signs at all. If the mediastinum and roots of the lungs are much affected, there may be some of the pressure effects already mentioned. In Cases

I. and III. there were enlarged liver and spleen from passive congestion. Case I. also showed dilated veins.

There is likely to be dullness over the sternum or interscapular spaces, and there may be a prominence, perhaps with pulsation of tumor, either palpable or visible by the fluoroscope, as in Case III. If the growth obstructs a bronchus, there may be the signs of atelectasis and bronchiectasis in the lung and bronchi beyond. These signs may occur also if the disease is confined to the lung and bronchi.

The heart may be displaced and there may be pleural effusion, which will complicate all findings. Enlarged glands in the neck or axilla, or other metastases are likely to occur in late cases.

Respiration over the growth may be loud and bronchial in character, with exaggerated voice sounds, if the underlying or supplying bronchus is patent; or there may be absence of both if it is obstructed. The heart sounds are likely to be well conducted in either case.

The coincidence of poor transmission of voice and respiratory sounds, with good conduction of heart sounds is a very suggestive sign.

Babcock speaks of Fraenkel's observation of the transition from dullness to tympany and the return to dullness over the same area.

There may be signs of cavity, due either to excavation or to bronchiectasis. There may be all the physical signs of pulmonary tuberculosis. The lesion is more likely to be centrally located than is tuberculosis and the *x*-ray shows its outline to be more definite.

Direct examination of the bronchi through the bronchoscope and the excision of pieces of the tumor have established the diagnosis in some cases.

Coincidence of Tuberculosis and Malignant Disease.—Rokitansky believed that tuberculosis and carcinoma were incompatible diseases, but it has been shown that the two conditions are more or less frequently associated in the lungs as elsewhere in the body. Adler found this to occur nineteen times in his series of 464 cases of carcinoma and sarcoma. Weller, in the *Archives of Internal Medicine* for March, 1913, tabulates 90 cases of primary carcinoma of the bronchi, all submitted to autopsy. In 11 of these there was coincident pulmonary tuberculosis.

Kurt Wolf points out that bronchial carcinoma begins most frequently near the bifurcation of the larger bronchi, where there is most irritation from aspiration of dust, smoke, and other irritants; and that there are frequently found in these localities small pigmented lymph glands which are apt to be tuberculous. He advances the theory that these glands break down, perforate the wall of the bronchus, and may be sufficient local irritant to start carcinoma in persons predisposed to the disease. This theory, according to Adler, has not been generally accepted. It has also been claimed that the irritation of any chronic process, tuberculous or not, may determine the incidence of cancer.

Differential Diagnosis from Tuberculosis.—We have seen that the two conditions may coexist, and the diagnosis has been made during life in a few reported cases; but such coincidence is generally not recognizable. In the early stages differentiation, as has been pointed out, may be extremely difficult or impossible; but in many cases some of the following points may lead to a correct diagnosis. Age does not seem to be of much help, for we see both conditions at all ages. The knowledge of reasons for lowered vitality, the occurrence of fever, night sweats, marked general symptoms, and lesions at the apices or bases, with distinct moist sounds or evidences of excavation point to tuberculosis.

On the other hand, early loss in weight, dry hacking cough, marked dyspnea, persistent pain, the occurrence of pressure symptoms, dullness over the upper part of the sternum or upper interscapular spaces, with definite outline, as shown by *x*-ray; and, particularly dullness, diminution or absence of respiratory murmur and voice sounds over an area where the heart sounds are well conducted, should lead to very strong suspicion of tumor.

Of course the finding of tubercle bacilli in the sputum stamps the disease as tuberculosis; while the occurrence of the globules of bloody sputum, referred to by Curtin, and the cells described by Lenhartz, may go a long way toward establishing the diagnosis of tumor. The repeated absence of tubercle bacilli and presence of elastic fibers in the sputum are suggestive, and too much importance cannot be given to careful and repeated examination of the sputum. Unexplained leucocytosis should probably suggest tumor in an early case.

Bloody pleural effusion is more likely to indicate tumor, but it is not very infrequent in tuberculosis. Finding relatively small amounts of fluid, getting little relief from dyspnea by aspiration, and failure of a displaced heart to tend to return to its normal position after tapping, are points strongly suggestive of tumor.

Small pieces of a growth brought out on the needle point, or found in the aspirated fluid may establish the diagnosis.

Displacement of the heart, apparently not caused by pleural effusion or cicatricial contraction; enlarged cervical or axillary glands or other metastases, give pretty definite evidence.

In conclusion it may be said:

1. Intrathoracic tumors are probably more frequent than has been supposed.
2. They are occasionally coexistent with pulmonary tuberculosis.
3. Early in their course they are likely to suggest tuberculosis, and differentiation may be impossible.
4. In cases of doubt it is very important that all hygienic measures for the treatment of tuberculosis be instituted at once pending a definite diagnosis.

1440 North Nevada Avenue.

PRURITUS ANI PERTINAX

By WILLIAM P. CUNNINGHAM, M.D.,

NEW YORK.

CLINICAL LECTURER ON DERMATOLOGY AT FORDHAM UNIVERSITY; CLINICAL ASSISTANT AT THE NEW YORK SKIN AND CANCER HOSPITAL; ASSISTANT PHYSICIAN AT THE HARLEM HOSPITAL DERMATOLOGICAL DEPARTMENT.

Whoever has had to treat pruritus ani or its inevitable result, eczema ani, knows the full bitterness of disappointment. Hell hath no torture like an itching anus. The sufferer is almost distraught from the infuriating insistence of his apparently trivial malady. Therapeusis is barren of effective medication. Let him brave enough to tell the truth declare that along the lines of routine endeavor no impression has been made upon this maddening symptom. I say "maddening" advisedly, because many of the afflicted, after months and even years of ineffectual striving for relief, become neurasthenic to the point of complete incapacity. I say "symptom" advisedly, because it seems perfectly absurd to describe as a

disease a condition that is reflex in the anus, usually from some pathological focus of unknown character and situation. It is reflex in the anus because all the antipruritics applied to the anus have failed to subdue it. It persists interminably despite the most vigorous assaults. Sometimes it gets well, but that is due either to our accidentally blundering on the cause, or to a fortuitous conjunction of circumstances wherein the cause is obvious to the eye, or to the "vix medicatrix naturæ" operating without the least assistance from us. No application suggested by reason, hope, or desperation, has been left untried. Phenol, menthol, camphor-chloral, tar, ichthyol, nitrate of silver, ammoniated mercury, permanganate of potassium, have all been used in dosage steadily increased to the point of marked irritation, and the pruritus in most instances has either not been affected at all or has been aggravated by the production of a dermatitis.

Much is expected from the discovery and cure of fissures. This is certainly a rational attempt to get at the cause, but it is very often an illustration of *mettant la charrue devant les bœufs,* because the fissures are frequently the result and not the cause of the patient's scratching. Naturally after he has torn at his skin for months, sufficient trauma will have been inflicted to produce a fissure. However all fissures should be cut, stretched, or cauterized, in any given case, in the hope that we have stumbled on the etiology. Hemorrhoids are regarded as a cause of pruritus ani and probably with reason in some instances. It is well to clear away this possibility by excising the hemorrhoids. But there are many cases where neither fissures nor hemorrhoids exist, and these are often the very cases least amenable to treatment. Constipation has been given much prominence as an etiological factor, but we are very little encouraged by the effect of laxatives. Threadworms and lumbricoids may be the irritant we are searching for. Pediculi are rarely the offenders. Eczema marginatum, "ringworm of the crotch," may extend to the anus.

Disease of the crypts of Morgagni, about one inch within the rectum, is looked upon by many authors as a common cause of the symptom under discussion. Do not overlook the possibility of a damaged coccyx having to do with the disturbance of innervation. The injury may have occurred long before, and may not have been severe enough in its immediate effects to excite marked attention, and yet remotely it may be the solution of the problem.

Having eliminated these possible local causes, are we to content ourselves and discontent our patients with a blind persistence in the use of impotent antipruritics? Can we search no further than the immediate vicinity of the anus for the reflex irritation? Interrogating the general system, is it possible to find there anything provocative of pruritus ani? Dr. Bulkley's proposition that smoking may be an exciting cause is well worth careful consideration. He recites the case of a physician who got an attack of pruritus ani every time he smoked, even if he consumed but half a cigar. It seems rather a peculiar limitation of the effect of so general a cause, but idiosyncrasies are many and must be taken into account in an investigation of this kind. And this peculiar circumstance emphasizes the necessity of searching for the source of the pruritus not alone in the neighborhood of the anus. Alcohol would probably have an effect similar to that of tobacco in one predisposed. It would also exert an action, apart from its irritation of the nervous system, in causing local congestion through its well known engorgement of the portal circulation. *A fortiori* organic disease of the liver should produce the same result. Diabetes mellitus and chronic nephritis are credited with the production of generalized pruritus, and in a patient with an idiosyncrasy it is conceivable that they might arouse the local variety. This is not meant to include the direct effect of diabetic urine dribbling over the tissues, which is a dermatitis removable with care. Gout, rheumatism, and lithemia are supposed to be at the bottom of some of the cases, as are neurasthenia, hysteria, and melancholia. With regard to the last three, I believe they are the result and not the cause of the pruritus in no inconsiderable number of the afflicted. Hereditary and tertiary syphilis sometimes produce a brittle condition of the mucous membrane near the anus, akin to that of atrophic catarrh, and may thus arouse this prurient paresthesia.

If a child with pin worms becomes the victim of enuresis, may not a man with a stricture become the victim of pruritis ani? The innervation of the anal region is from the pudic nerve, which also supplies the penis, scrotum, clitoris, vulva, bladder, rectum, and the muscles and skin of the perineum. The pudic is derived from the pudendal plexus, which is made up of branches from the second, third, fourth, fifth sacral, and the coccygeal nerves. The sympathetic nervous connections are about the same. It is clear that irritation may occur at widely different points, and still be capable of transmission to the anus. Any abnormality of the pelvic viscera may find expression in reflex anal itching. Stricture has already been alluded to. Prostatitis, cystitis, vesical calculus, irritation of the ureters or pelvis of the kidney, by urine highly concentrated or charged with the products of imperfect metabolism, may be responsible for the same result. In women, who are much less prone to it than men, we have the added etiological possibilities of derangements peculiar to themselves. Vaginitis, endocervicitis, ovaritis, acute chronic and neoplastic, are instances in point. Urethral caruncle, in addition to its own peculiar distress *in situ,* has been in my experience the cause of pruritus ani. This appalling combination of infuriating pain and distracting itch cleared up immediately on removal of the caruncle.

It is demonstrable that appendicitis, attaching the tip of that organ to some one of the other viscera, may, after the subsidence of the acute condition, leave a source of irritation transmutable into terms of anal itching. All this may sound very farfetched, but it is not a farther cry from the appendix to the anus than it is from the anus to the nose, and pruritus nasi is a common symptom of pin worms in children. Pathological conditions high up in the rectum, such as erosions, ulcers, and polypi, must be considered as possible causative factors.

Having exhausted all possible sources of reflex irritation, how shall we apply our hypotheses to the practical management of the concrete case? We shall probably apply them with very indifferent success in the majority of instances, because, while we know what the possible sources are, we are often very much at sea as to what is the actual source in the particular case that presents itself for elucidation. It is all very well to display our knowledge of anatomical relations, but in the working out of our problem along those lines we may be confronted with difficulties that are insurmountable. We may search diligently for every conceivable etiological factor, and either fail to find one, or, having found

it, fail to achieve success by removing it. Occasionally success is phenomenal, as in the instance of the urethral caruncle mentioned above. But usually it is elusive, the focus of irritation escaping our most determined efforts, or, having been discovered, proving to be a jack o' lantern leading aimlessly afield. If you can retain the confidence of the patient long enough to minutely overhaul his being and correct all discoverable abnormalities, your persistence and his endurance may be rewarded. But the chances are largely against any such ideal situation as that. Being hyperesthetic and erethistic, he is quickly translated from the heights of enthusiasm to the depths of despair. The fruitless performance of an operation for stricture, of which much was expected, shatters his faith and severs his allegiance. Granted the phenomenon of a patient with an all-abiding faith, how shall we carry him along while we are seeking to get to the root of his difficulty? Do not forget that we are dealing with an actual or inchoate neurasthenic, whose mind must be influenced, *au moyen d'une grande parade d'effort.* Assiduous attention, especially with mechanical appliances, may so engross his introspective propensity as to relieve his nervous system of much of its tension, and thereby remove one potent element in the production or maintenance of his malady. For this purpose electrical apparatuses are decidedly efficacious. These may be employed in any manner best calculated to impress the patient. Static electricity is credited with an actual relief of the itching, aside from its more devious action through the mind. In my own experience the galvanic current passed through the affected region via the sacral plexus (one electrode in or on the anus, the other passed up and down the sacrum) has mitigated the intensity of the pruritus for several hours.

If the obscurity of the causation cannot be cleared away, a tentative diagnosis of portal obstruction will serve as a reasonable basis of internal treatment. Many years ago I had a very impressive experience of the reflex possibilities of hepatic engorgement. A vigorous young man had been complaining for years of pain behind the upper third of the sternum. Searching examination of his chest, several times repeated, failed to discover any reason therefor. There was no aneurysm, no mediastinal adenitis, no pulmonary or cardiac abnormality. The patient was not neurasthenic. Apparently there was nothing amiss with him except this irremittent, mysterious pain. When the victim's patience and my ingenuity in inventing explanations were both exhausted I sent him to a celebrated internist. The decision was that the pain was due to a nipping of one of the terminal branches of the pneumogastric by a slightly hypertrophied liver. Much impressed, I went over his liver again, and, even with the aid of my imagination, could not discover the hypertrophy. However, the diagnostic acuity of the celebrated internist was justified by the result. He ordered a markedly modified diet, and two and a half grains of powdered rhubarb with twenty grains of bicarbonate of sodium to be taken in a whole glass of water just before eating. In a very short time (a week or ten days) the patient was free from pain. If we are justified in suspecting the liver for a pain in that situation we are equally justified in suspecting it for pruritus ani. The mixture given above, with variations to meet particular indications, will answer very well indeed. Tea, coffee, and sweets are interdicted. Indicanuria will be a reliable guide as to the proper adaptation of the diet. Sponging the hepatic region with a mineral acid solution, while an old-fashioned procedure, has the testimony of long experience to support it. Use three ounces of nitromuriatic acid to a gallon of water.

Intestinal putrefaction, responsible for so many reflex disturbances, such as acne rosacea, trigeminal neuralgia, and a whole tribe of "eczemas," will not have its productive power overtaxed by fathering pruritus ani. And the treatment just outlined is the treatment best calculated to limit its cacogenic fecundity. Now we have reached the point in our disquisition where all attempts to discover the etiology have failed. What are we to do next? Are we to abandon the patient to his deplorable fate, or is there any measure of hope to be extended to him? Shall we conveniently declare that he is a hopeless hypochondriac and devoutly wish him on to some other practitioner, or shall we fight it out as long as he will allow us, and, by the inadequate means at our command, strive to make his life as little miserable as possible? Some topical applications are sometimes of some avail. In general terms we have asserted their impotency, but occasionally they alleviate temporarily, and should be employed one after another, in the hope that we may strike an idiosyncrasy operating in our favor. Crocker is optimistic regarding ammoniated mercury in ointments of 4 per cent. and upwards. Sabouraud favors pine tar pure or in lanolin. Pusey claims to have had good results from solutions of permanganate of potassium, 1 per cent. in water, or nitrate of silver 1 to 2 per cent. Stelwagon distributes his appreciation among several remedies—namely, menthol in liquid albolene, 5 to 20 grains to the ounce: cocaine, 1 to 10 grains to the ounce; chloroform, ½ to 1 dram of each to the ounce of simple cerate; and camphor and chloral, ½ to 1 dram of each to the ounce of vaseline.

The .r-ray is credited by the three authorities last mentioned with some gratifying results. Walker is rather non-committal, and faint-heartedly gives a list of half a dozen ointments, from each of which some good is to be expected. Bulkley puts carbolic acid in water or in oil at the head of the anti-pruritics. The ointment of tar and zinc with ½ to 1 dram of ichthyol to the ounce is also recommended by him. He asserts that marked temporary amelioration can be effected by cloths rung out of hot water and applied as hot as the patient can stand it. The changes may be rung on these topical applications, but they comprise the nucleus of our armamentarium.

It is a sad confession that very frequently we are forced to the use of narcotics to enable the patient to sleep, for the agony is keener at night, the nervous system accentuating all perversions of sensation during the hours needed for repose. Cannabis indica is serviceable in many cases. The dose is ten drops of the tincture cautiously increased if necessary. Tincture of gelsemium in the same dose, repeated at intervals of two hours approaching bedtime, will sometimes give a good night's sleep. Extract of belladonna with or without morphine may be used in the form of a suppository, "and exorcise the demon for the nonce." This brings us to the question of "morphine or no morphine" in pruritus ani. The weight of authority seems to be on the negative side. Morphine produces pruritus, and therefor would seem to be contraindicated where there is an existing pruritis. It may be urged in rebuttal that the action of morphine in diseased conditions is very different from its action in normal conditions. Morphine al-

lays the sensitiveness of the nervous system.

An itch is a paresthesia, a perversion of sensation due to irritation, and a pain is the very same thing. Morphine will relieve the pain by benumbing sensation, and it will relieve the itch in just the same way. Years ago the use of morphine was denounced in the convulsions of nephritis, because, forsooth, it diminishes the output of urine and diminution of urine already exists in that condition. Now everybody uses it in uremic eclampsia, realizing that, through its sedative action on the nerves in the diseased organs it actually equalizes the circulation and permits a better flow of urine than before. I am quite decided that morphine is no more contraindicated by an itch than by a pain. Contraindications may exist in the pruritus case, but the itch itself is not one of them. Great discretion must be employed, of course, in prescribing such a drug in any chronic condition where a habit may be established. I would discourage its use as long as possible, but if circumstances arose where it seemed urgently demanded I would not be deterred by fear of aggravating the pruritus.

The "eczema" that almost invariably complicates pruritus ani must be treated on general principles. Soothing applications are usually called for, because even if the affection is chronic it is in a constant state of acute exacerbation from the constant scratching.

Some of the surgeons offer to operate in aggravated cases, but there is a lack of unanimity as to the wisdom of the procedures. T. C. Wallis advocates dissecting out the complete ring of ano-rectal tissue and bringing down the healthy mucous membrane to the skin. He maintains that the irritation is always in the lower inch of the rectal mucous membrane.

Ball's operation of dissecting up a skin flap and dividing the cutaneous nerve twigs is extolled in certain quarters, but the warning is raised of the possible risk of suppuration and stenosis. Matthew's operation of removing the superficial skin around the anal margin is open to the same objection, only to a greater degree. Burrow's operation of cutting the terminal nerve twigs subcutaneously through small incisions in the skin would seem to be the least objectionable. What the risks of this procedure are remains to be seen, possibly those of the Ball operation, but to a less degree. Furthermore, some of the itching is inside the anus, and he could only relieve that by cutting the nerves to the anus itself, which would put the patient in about the same position as a tabetic who is the victim of obstipation, because the sensory connection between the anus and the spinal cord is interrupted. Kelsey advocates the use of the Paquelin cautery. Tuttle is averse to operating and suggests deep-seated and persistent pressure on the parts by means of a small plug inserted in the anus and retained over night by a bandage.

From the foregoing the prognosis would appear to be rather gloomy. But it is with intractable conditions that medicine has its sternest duty to deal. We must strive to the limit of our resources in every case, not only in the hope of curing the individual, but in the larger hope of discovering something of general application. Discouragement will lead us nowhere. Persistence in the face of tremendous odds will eventually bring forth the idea that will cut the Gordian knot. Perhaps Burrows has it in cutting the cutaneous twigs. *Ipsi di propitientur!*

323 West Fourteenth Street.

THE VALUE OF TYPHOID VACCINATION IN CIVIL COMMUNITIES.

By R. E. EBERSOLE, M.D.,

Passed Assistant Surgeon, United States Public Health Service, Ellis Island, New York.

Typhoid vaccination, which had its beginning in its use by Wright in the British Army in India and has proven of such value in the armies of the leading powers, notably in those of England and the United States, is finding a further use among civilians who are exposed to typhoid infection. Wright, who has vaccinated approximately 100,000 persons, quotes a typhoid morbidity for those exposed in the vaccinated of .914 per 100 with a mortality of .161 per 100 and a morbidity in the unvaccinated of 1.665 per 100 with a mortality of .444 per 100. In the British Army in India of an approximate strength of 70,000 men, the increase in the number of vaccinations has been followed coincidently by a marked decrease in the number of typhoid cases occurring, as follows:

	Vaccinations	Typhoid Cases	Deaths
1906	4,682	1,095	224
1907	10,155	910	192
1908	16,009	1,001	190
1909	43,566	639	113
1910	54,481	350	47

In this latter year there were approximately 823 vaccinations per 1,000 strength, the morbidity being 4.6 per 100 and the mortality 0.63 per 100. The value of this vaccination in the United States Army may be seen by contrasting the number of typhoid cases occurring among the 10,759 troops encamped near Jacksonville in 1898, where no vaccinations were made, with the very small number of such cases occurring in the 20,000 troops encamped and on the march along the Mexican border, during the recent uprising in that country, among which latter troops vaccination was used. In the former case 1,729 cases of true typhoid occurred and if we include all cases probably typhoid there were 2,693 cases with 248 deaths, while in the latter case, although a large body of men were in camp, only two mild cases of typhoid were noted. In these latter troops vaccination was compulsory for all under 45 years of age so that after allowance has been made for the decrease in the number of typhoid cases due to the greatly improved sanitary conditions of the camps as a result of the lessons learned from the camps of 1898, the main credit for improved conditions must be given to the use of the vaccination since the troops were free at all times to visit the nearby towns where typhoid was present. It may be noted in this connection that typhoid vaccination was made compulsory for all army recruits June 9, 1911, and for the entire army personnel under 45 years of age, September 30, 1911.

Following the early work in the British Army in India voluntary vaccinations were made in the troops destined for the campaign in South Africa before their embarkation in England, these being continued in garrisons there, its value being shown as follows:

In Ladysmith, from November 2, 1899, to February 28, 1900, 1,705 were vaccinated, among which occurred 35 cases of typhoid with 8 deaths, giving a morbidity of 2.05 and a mortality of .47 per 100 respectively, while among the unvaccinated during the same period 1,489 cases of typhoid with 329 deaths

occurred—a morbidity of 14.14 and a mortality of 3.12 per 100 respectively. In the campaign of the Modder River, 2.3 per cent. of the typhoid cases that occurred were among the unvaccinated, while 1 per cent. were among the vaccinated. The record of one regiment, the 17th Lancers, which is worthy of notice, shows that of a strength of 593 men, 150 were vaccinated once; 127 were vaccinated twice, and 316 refused vaccination. Of these, two cases of typhoid occurred among those vaccinated once; no cases in those vaccinated twice, and 59 cases, a morbidity of 18.67 per cent., occurred in the unvaccinated.

Equally as good results were shown in the personnel of hospitals in South Africa. In the personnel of seven hospitals in the Modder River campaign, of 297 who were vaccinated, 32 cases with 2 deaths occurred, while in 398 not vaccinated, 111 cases with 18 deaths were reported, giving a morbidity of 10.77 per cent. for the vaccinated and 35.85 per cent. for the unvaccinated. In a number of hospitals in the Transvaal and Natal, the records give a morbidity for the vaccinated of 5.9 per cent. and for the unvaccinated 12.5 per cent.

Good results have followed its use in civil hospitals in this country. Over a period of three years, in 23 hospitals in Massachusetts 1,361 persons who were exposed to typhoid contagion were vaccinated and among these only two cases of typhoid occurred; while among 674 persons who were under the same conditions but were not vaccinated, eight cases of typhoid occurred. In the Massachusetts General Hospital where for a period of three years 80 per cent. of the personnel were vaccinated no cases of typhoid were reported among the vaccinated. Since March, 1910, 2,044 persons have been vaccinated with vaccine from the conjoint laboratory of the City and State Boards of Health laboratory, Baltimore, Maryland, among which no cases of typhoid have been reported, although 184 were closely exposed to infection as physicians, nurses, laboratory workers, etc., and 887 were inmates and employees in a hospital whose morbidity the previous year had been one per cent. In this latter hospital among 333 persons who were not vaccinated three cases of typhoid were reported.

Good results have followed the use of this vaccine by those exposed to infection in small epidemics, as follows:

In a small epidemic in a Vermont town, due, probably, to contamination of the water supply, in which 65 persons were exposed to typhoid contagion, 17 being primary cases; of the remaining 48, 29 were vaccinated within a week and no cases occurred among them, while among the 19 who were not vaccinated, 5 cases occurred.

In a small typhoid epidemic in Connecticut, 80 nurses were employed; of these 45 were vaccinated and no typhoid cases occurred among them, but among 35, who refused to be vaccinated, 5 cases of typhoid were reported.

Typhoid vaccination, it is believed, is of decided value to physicians, nurses, and all employees of hospitals where typhoid cases are cared for. It is also of value to the city resident who goes to the seashore or country for his vacation, where he may be exposed to infected or suspicious food or water supply or to the same individual who may be exposed in the city by reason of contamination of the food or water supply or exposed by reason of the occurrence of cases of typhoid in close proximity to him; to the residents of small communities who may likewise be exposed to contaminated food or water supply, and to the laboratory worker whose work brings him into close contact with typhoid cultures.

TRANSPLANTATION OF BONE FOR FLAIL JOINT PRODUCED BY INFLAMMATORY DESTRUCTION OF JOINT.

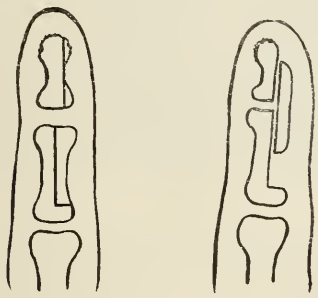
By A. O. WILENSKY, M.D.,

NEW YORK.

ATTENDING SURGEON, MT. SINAI HOSPITAL DISPENSARY; ADJUNCT ATTENDING SURGEON, BRONX HOSPITAL AND DISPENSARY.

The following case is reported from my service in the Mount Sinai Hospital dispensary:

J. W., age 40, janitor.. In the spring of 1913, a violent infection of the left index finger resulted in complete destruction of the tendons and tendon sheath, and in necrosis of the adjacent ends of the two last phalanges. It was necessary to curette out the destroyed bone, and thereafter there was prompt healing.



A B

FIG. 1.—A, showing line along which the bones were chiseled to fashion the transplant. B, the transplant in its final position.

This left the patient with a flail joint between the two distal phalanges, and inasmuch as there was no muscular control, the tendons having entirely sloughed away, the condition that resulted was a positive hindrance to the man in his daily work.

There were two methods available for the correction of this disability: to transplant or create a new joint, or to accomplish an ankylosis between the two bones, and give the man a useful finger. The first method was immediately discarded, for the reason that in the event of a successful joint transplantation there would be no muscular control, the joint would still be flail, and consequently there would be no bettering of the condition.

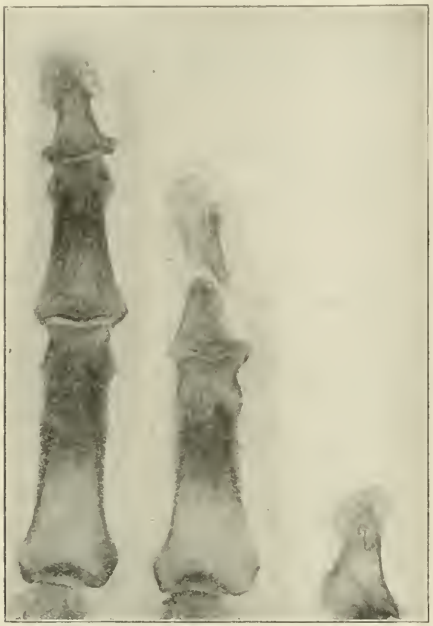
It was, therefore, determined to treat the finger as if a fracture had taken place, and non-union had occurred. The principles of bone transplantation were applied.

Operation.—Regional anesthesia with alypin two per cent. Base of finger constricted with rubber ligature, and the four cutaneous nerves at the sides of the finger injected; perfect anesthesia ensued.

Incision at the side of the finger, from tip to near the second joint, was deepened through the peritosteum, the latter being lifted away from the bones. Scar tissue between the ends was dissected out, and the ends of the bones were freshened. The cortex was removed from the side of the distal phalanx, leaving a fresh area of cancellous bone. The second phalanx was then split longitudinally, from a little below the second joint, and the fragment slid down, so that it overlapped the first and second phalanges (Fig. 1—A and B). No sutures were thought necessary to hold the transplant in place. The wound was closed without drainage, and primary union occurred.

At the end of three weeks there was solid bony union (Fig. 2). At the end of four months the man had a perfectly useful finger.

This report is made to demonstrate another practical application of the principles of bone trans-



Fig—2

plantation. Emphasis is also put on the fact that in this case a subperiosteal transplantation was done.

1200 Madison Avenue.

A DIPHTHERIA CARRIER TREATED WITH CULTURE OF STAPHYLOCOCCUS PYOGENES AUREUS.

By I. E. BISHKOW, M.D.,

CHICAGO.

While reporting nothing new in the treatment of diphtheria carriers with the cultures of *Staphylococcus pyogenes aureus*, this case contributes certain features of interest in its clinical course, and again demonstrates the apparent specificity of the use of this culture in cases resistant to the ordinary means employed to combat the disease.

Male, age 30, married. On June 19 was called to see the patient who had then been ill three days with sore throat, headache, anorexia, and malaise. He had never had sore throat before and there was no history of diphtheria in patient or family. He was a well-nourished and fairly well-developed young man. There was a marked swelling at the angle of the jaw on the left side, extending down the side of the neck; swelling was very tender to the touch and felt very firm. Examination of the interior portion of the mouth showed a dark grayish patch of membrane on the posterior portion of the left tonsil, very adherent, and the tonsil protruding toward the median line. On palpation fluctuation was felt behind the tonsil. No nasal secretions. Other physical findings negative. Temperature, 99.6° ; pulse, 90. Direct smear and throat culture showed Klebs-Loeffler bacilli present.

June 19 the peritonsillar abscess was lanced and 5,000 units of antitoxin injected. June 20 temperature 100°; pulse, 88. Slight muscle pain. By June 23 the membrane had disappeared; culture still positive; direct smear positive. From June 23 to July 14 cultures taken at three and four-day intervals remained positive. During this time a spray of Dobell's solution was used in the nose and throat, throat swabbed with 3½ per cent. tincture of iodine and a gargle of 70 per cent. alcohol used. During this period the throat and pharynx were pale and clean and no systemic symptoms were experienced by the patient. July 14 a 12-hour culture of *Staphylococcus pyogenes aureus* was obtained from the laboratory of the Michael Reese Hospital and we had the patient spray the throat with this bouillon culture every four hours. July 15 another fresh 12-hour culture was used and from July 16 to 20 a normal saline suspension of *Staphylococcus pyogenes aureus* was employed. A slight inflammatory reaction of the throat resulted without any rise of temperature or pulse. On July 20 the first negative throat culture was obtained, six days after starting this treatment; three days later another negative report was obtained. The cultures have remained negative since. The peritonsillar abscess complicating the diphtheritic infection was of interest, but quickly subsided after lancing, and probably played no part in prolonging the presence of the Klebs-Loeffler bacilli in the throat. The mild pharyngitis produced by the culture spray quickly subsided under a Dobell's solution spray.

1240 South St. Louis Avenue.

A NEW COLOSTOMY APPARATUS.

By H. BEECKMAN DELATOUR, M.D.,

BROOKLYN, N. Y.

Having observed on several occasions the distress of patients after a colostomy operation from the soiling of their clothes and the ever present fear of escaping gases and fecal matter, I set about to devise some scheme to protect the patient and to collect an ordinary amount of discharge.

In 1907 I devised the double cup apparatus, which was made for me by Messrs. Tiemann & Company, and which proved very satisfactory. This consisted of a round cup which was large enough to extend about an inch outside the intestinal opening. The rim of this was made double, as if one cup larger than the other had been placed together, giving a rim as is well shown in the illustration. This cup was held to the body by a spring belt similar to the belt of a truss. When the cup was pressed against the skin the tissues would bulge up into the groove of the rim and thus seal the opening. Inside the cup a packing of absorbent gauze was placed. This acted very well unless there was an excessive fluid discharge and then there might be some leakage.

In fitting the apparatus to subsequent cases, Mr.

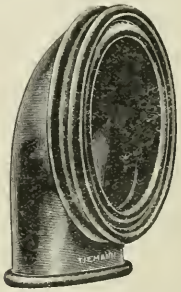


Fig. 1.—Dr. Delatour's colostomy apparatus.

J. A. Pfarre found it necessary to change the shape of the cup somewhat and also provided it with an opening to which a rubber receptacle could be attached and the excessive discharges collected.

The improved cup is so shaped that it fits well

beneath the clothing without being noticeable. The appliance consists of a solid hard rubber shield or cup, made in one piece with an oval outlet at its lower part to permit the outflow of the discharges. The rim face of the cup, which approximates the

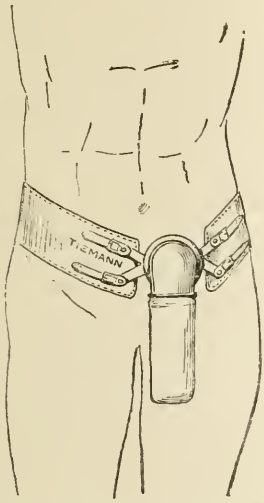

Fig. 2.—Colostomy apparatus with receptacle in position.

tissue surrounding the fissure, has a depression or groove into which the skin will project upon very slight pressure, thus forming practically an air-tight contact. To the cup is attached a rubber bag to hold the discharges. This bag has a constricted neck or opening which is slipped over the outlet of the cup. The bag has a capacity sufficient for any normal discharge and can be removed in an instant and another substituted. The apparatus is held in place by a spring and a light washable belt not unlike an abdominal supporter.

The comfort of the patient depends to a considerable extent on his care of the bowels. My directions are that each morning the bowel is to be washed out through the artificial anus and after the colon is cleared the apparatus is put in place. Then for twenty-four hours there is little or no discharge of feces. In some cases washing the bowel on alternate days has been sufficient.

A number of these appliances are now being worn, my oldest case being the patient operated upon in 1907. He is still free from recurrence and able to be about his business. The apparatus in this and other cases has proved so satisfactory that I new feel it my duty to present it to the profession.

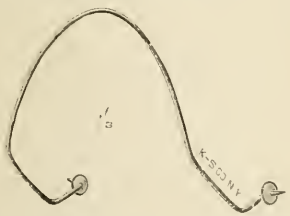
73 Eighth Avenue.

PERINEORRHAPHY RETRACTOR.

By A. REICH, M.D.,

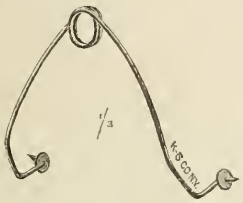
NEW YORK.

This instrument is made of phospho bronze wire, No. 10 and No. 13, with a spring; in both the resiliency can be adjusted. The sharp points pull the parts in a horizontal plane; two small copper washers are fastened few lines from the points to prevent any tearing of the tissue. The sharp points of the retractor are introduced just above the last caruncle or where the highest point of denudation will be. The vulva is held apart by the retractor producing a beautiful exposure of the rectocele; a pair of artery forceps is clamped to the median line at the mucocutaneous junction at the lowest point which will retract the skin posteriorly. A triangu-



lar line along which the denudation should be made is well marked. The retractor has been found to be useful in Goffe's cystocele and prolapse operation. If the rectocele is in the way a selfretaining posterior retractor will be used in addition. In inguinal hernia it can be used, the operation being then completed by one man without any assistant. The principle can be applied in the construction of abdominal selfretaining retractors.

After forceps delivery this retractor will afford the best exposure of parts. If the woman is in bed the spring end of the retractor should be turned up toward the symphysis pubis.



The advantages claimed for the retractor is that it is simple in construction, self-retaining, and not expensive. The instrument is made by the Kny-Scheerer Company.

245 West Twenty-fourth Street.

Hair-Ball Removed from the Stomach of a Child.—Barling reports the case of a girl, aged 7 years, who was admitted to the hospital for vomiting and severe pain in the upper abdomen of two days' duration. The child was rather small for her years, anemic, but otherwise healthy and normal mentally, except that she was described by her parents as being rather sly. Since an attack of dysentery four and one-half years ago she had been in the habit of chewing up pieces of string, tape, etc., and occasionally fragments of such things had been found in the motions. Her appetite was good up to ten days before the time she was taken ill, food being taken in normal quantity and without discomfort. On examination a hard lump exactly resembling the outline of the stomach could be felt descending from beneath the left costal arch, and passing transversely across the epigastrium. The outline of the tumor together with the history led to a correct diagnosis. At operation the specimen was easily removed through a longitudinal incision into the anterior wall of the stomach about 3 inches long, the dilatation of the organ allowing the mass to be turned on itself and delivered endwise through the opening in the stomach. The opening in the stomach was closed by a double layer of sutures, and the child made an uneventful recovery. The specimen consisted of a felted mass of hair and string, the former predominating; it presented an exact cast of the stomach showing the fundus, greater and lesser curvature, pyloric antrum and pyloric canal. When dried it weighed 4 ounces and measured 10 inches from the fundal to the pyloric end.—*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

New York, November 15, 1913.

THE MORTALITY OF MIDDLE AGE.

DURING the past half century the expectation of life has been markedly increased for the earlier age groups, but for the later age groups, from 45 years upward, the improvement has been much less noticeable. The statistics for the registration area in the United States in the years 1900 to 1911 inclusive show a gratifying decrease in the death rates for all ages under 44, but from 45 upward in males and from 55 upward in females there has been a progressive increase in the mortality. This is of course due largely to the fact that all must die some time, and if they do not die young they must die older. Still the increased mortality should not begin at 45, and it would not if some of the preventable causes of death at this and later ages were, as they could be, more effectively controlled. What some of these causes are may be learned from a study of the death rates in the registration area for 1900 and of those in the same area for 1911. A comparison of these rates shows that there has been a slight increase in the mortality from cirrhosis of the liver, a somewhat greater increase (about 18 per cent.) in that from cancer, a little more (22.5 per cent.) from cardiovascular diseases (including apoplexy and Bright's disease), and an increase of no less than 53.6 per cent. from diabetes. These diseases, with the exception perhaps of cancer, are in large measure preventable, or at least postponable. The cardiovascular affections are degenerative in nature and fall naturally in the involutionary period of life, which should not begin, or at least should not give much evidence of its existence, until long past the 45-year period.

In an interesting address delivered before the American Public Health Association in September last Dr. Louis I. Dublin, statistician of the Metropolitan Life Insurance Company, whose figures we have quoted above, considers the causes of, and the possibility of reducing the mortality at the higher age groups—that is, after 45 years. He rightly says that we must look to the conditions of life in the earlier ages for an explanation of the mortality from the degenerative diseases after 45. While heredity counts for something, no doubt other influences are much more in evidence. These influences are chiefly: (1) acute infectious diseases, such as scarlet fever, rheumatism, diphtheria, and typhoid fever, which so often leave their permanent mark on some one or more of the vital organs; (2) habits and modes of life, and (3) occupation. Of these three influences, the last, namely occupation, is the one that the author regards as most important, although he does not underrate sequelæ of the acute infections or the evil effects of alcohol and the venereal diseases. Potent as it may be for evil in the individual case, Dr. Dublin does not look upon the stress and strain of modern business life as affecting the mortality statistics appreciably, for the class from which these cardiovascular and diabetic recruits are drawn is not numerous in comparison with the vast industrial army whose means of livelihood is at the same time the cause of their early death. Even in trades where the workers are safe from the material causes of disease—metallic poisons, dust, etc., there is danger in the mere monotony of the occupation. Fifty years ago the worker had much to sustain his interest and there was something in his occupation of the joy of the creator. In shoemaking, for instance, which the author cites as an example, the individual workman made the entire shoe, thus following every step in the operation. To-day, in the great factories, the shoes are made wholly by machinery and each process is directed by a specialist workman who performs at high speed only one or very few of the total number of operations required in the production of a single shoe; he knows only this one task and the satisfaction of sharing in all the steps necessary for the turning out of the finished product is denied him. He becomes himself a part of the machinery, turning and turning forever in one single monotonous round, and like the rest of the machinery he wears out. Then there are the other injurious influences of the great industrial hive—the bad air, the poor light, the noise of the machinery, the high temperature of the work shop and the sudden change to cold and damp in the return to the home, the vitality being lowered by the long hours of confinement.

The following are the suggestions which Dr. Dublin offers for the diminution of mortality at the middle ages: "(1) We must place even greater emphasis on the municipal control of the communicable diseases of early life in order to reduce the instances of heart and kidney impairments which often result therefrom. (2) We must encourage the movements directed against the spread of venereal diseases as well as the intemperate use of alcoholic beverages. (3) We must further all efforts for the improvement of adequate labor legislation and promote a better understanding between employers and employees. This program will include the improvement of factory sanitation, the medical examination of employees, and the instruction of both employers and employees in industrial hygiene. (4) It will be necessary to supplement labor legislation with the careful examination of death certificates to see that in every instance those who are responsible for preventable deaths are properly prosecuted. (5) Finally, we must heartily encourage the movement for public education on all topics connected with personal hygiene that there may be better cooperation between physicians and their patients and that there may be no unnecessary losses through neglect of symptoms pointing to serious organic diseases."

CHRONIC ADHESIVE PERICARDITIS IN CHILDHOOD.

Chronic inflammation of the pericardium is not an exceedingly rare occurrence in childhood, although Potain recognized the period of most frequent incidence between the fifteenth and twentieth years of life. In most of the cases occurring in adolescents the disease has had its beginnings in early childhood. This stage of the disease is particularly apt to be latent, a fact which emphasizes the importance of keeping a sharp lookout for pericarditis in all rheumatic and tuberculous children. The two most common causes of chronic adhesive pericarditis are rheumatism and tuberculosis. Syphilis is an occasional factor. In almost all instances of the rheumatic type chronic adhesive pericarditis is associated with chronic endocarditis. This accounts for the fact that the lesions of the former are usually overlooked. Pericarditis may be only a part of a general mediastinitis. In children subject to chorea the possibility of the existence of a latent pericarditis should be borne in mind.

In a lucid discussion of this subject in the *Journal de Médecine de Paris*, September 13, 1913, P. Nobécourt alludes to a distinctive characteristic of all chronic inflammations of the pericardium, namely, the persistence of the clinical phenomena as soon as the disease has passed the latent stage. A dyspnea on exertion is succeeded by a dyspnea that is constant. Crises of precordial distress and of palpitation become more and more frequent. There arise sooner or later localized edemas, oliguria, ascites, and enlargement of the liver. All of these phenomena point to a persistent asystole.

Without enumerating the well-known physical signs of chronic adhesive pericarditis, it may suffice to state that Nobécourt, in agreement with other clinicians, does not regard any of these signs as distinctive. The evidence in favor of chronic pericarditis is not more than strongly presumptive. For instance, in an individual presenting a rebellious asystole, with a greatly enlarged heart and an unvarying area of cardiac dullness, and with a persistently enlarged liver, one is justified in making a presumptive diagnosis of chronic pericarditis. Immobility of the apex is not a pathognomic sign. A year ago Pezzi described what he regarded as a characteristic phenomenon in this condition, namely, an absence of the presystolic auricular wave in the cardiogram. Nobécourt, however, discounts the value of this sign, which at any rate is not a constant one.

Chronic tuberculous pericarditis differs in certain notable respects from the rheumatic type. There is always an associated mediastinitis with enlargement of the peribronchial lymphnodes. The pericardium forms a fibrous, infiltrated shield around the heart, which is not greatly enlarged. The liver is always hypertrophied. Tuberculous peritonitis is frequently present. The pericardial affection is chronic from the outset, developing insidiously and without manifest cause. The child shows emaciation, pallor, and fever, and becomes easily dyspneic and cyanotic. In time there develop ascites and enlargement of the liver, which draw the attention to this organ. Examination of the heart shows a normal or only a slightly increased area of dullness. Immobility of the apex is constant, and in association with the other manifestations is pathognomonic. Auscultation reveals no orificial murmurs, but discloses a fetal rhythm. The pulse is frequent, small, but regular. The individual affected with tuberculous pericarditis usually presents infantile characteristics and a gradually increasing cachexia and dies from asystole or from some intercurrent disease.

CLINICAL SIGNIFICANCE OF THE PULSE-RATE DURING SLEEP.

Many observations have been made of the frequency of the pulse of normal individuals during sleep, and with few exceptions a distinct showing of the pulse during this condition has been recorded. Apparently no attempt was made to study systematically the pulse-rate during sleep in various morbid conditions, and to derive from this knowledge data of clinical value. Felix Klewitz (*Deutsches Archiv für klinische Medizin*, October 2, 1913) undertook the investigation of this subject, employing a method that marked a vast improvement over the crude methods that have been used hitherto in noting the pulse-rate of the sleeping individual. In order to eliminate any possible disturbing factor resulting from the presence of the experimenter in the room of the sleeping subject, Klewitz arranged an apparatus with which by means of suitable tubing connected with the stethoscope chest-piece attached to the patient's chest, it was possible for the experimenter to record his observation in an adjoining room. In this manner he studied the pulse-rate during sleep of normal individuals, of those suffering from heart disease in the state either of compensation or of decompensation, of patients with tachycardia of organic origin, and of patients affected with nervous tachycardia. The results obtained in this investigation are of eminent interest from both the theoretical and the practical viewpoints.

In twenty normal individuals the average pulse-rate during sleep was 59.3, and during waking was 74.1. The average diminution was therefore 19.9 per cent. The variations of the pulse during sleep are less than those during waking, the pulse curve in the former condition approximating a straight line. The irregularities occasionally noticed in the pulse during the waking hours do not disappear during sleep. Absolute repose of the body at night without sleep may at times be accompanied by a reduction of the pulse-rate as marked as when sleep is present. In sleep during the daytime the pulse frequency is diminished only slightly or not at all.

Patients with compensated valvular lesions behave with respect to their pulse in sleep exactly as do normal individuals. In cases of decompensated heart disease there is mostly a less marked diminution of the pulse frequency during sleep. In very bad instances of decompensation the pulse during sleep may even be more rapid than during waking. This observation is therefore of some prognostic value. Irregularities, such as extrasystoles, the pulsus bigeminus, the pulsus trigeminus, etc., do

not disappear during sleep. In a series of cases of tachycardia in which subsequent observation revealed an underlying organic affection of the heart, the tachycardia continued during sleep. In cases of purely neurotic tachycardia, however, the acceleration of the pulse disappeared during sleep. The determination of the condition of the pulse during sleep possesses, therefore, a distinct value in the differentiation of organic from functional tachycardia.

Oxytocic Properties of Internal Secretions.

It was long ago surmised that the various internal secretions were complexes made up of groupings of certain primitive bodies. Thus a hypothetical vasoconstriction is redundantly present in adrenalin and pituitrin and also to a greater or lesser extent in other—practically all—of the glands of internal secretion. This is proved for the thyroid, pancreas, ovary, corpus luteum, and especially for the intestinal mucosa. At the recent annual session of the German Naturalists and Physicians (*Berliner klinische Wochenschrift*, October 13) Lindemann reported his results in the study of the oxytocic power of the various internal secretions. The hypophysis is naturally left out of consideration as its position here is assured and it may serve as a standard. It was learned that extract of intestine had oxytocic powers marked enough for use in obstetrics. Next in order in efficiency were thyroid extract, pancreatic extract and adrenalin. Thus far the results obtained show much variation, with which digestion and diet seem to be concerned. The oxytocic principle supposed to be common to all is believed to be kin to proteinogenic amines.

The Pathogenesis of Scarlet Fever.

The phenomenon of anaphylaxis has provided a good working hypothesis in explanation of the clinical picture of certain exanthemata, as measles and scarlet fever. Martin Kretschmer, in the *Jahrbuch für Kinderheilkunde*, September 1, 1913, contributes a logical thesis in favor of the anaphylactic nature of scarlet fever. He notes that this disease occurs in individuals who have a hypersusceptibility to streptococcus infection. He also cites a number of facts which speak against the existence of a specific microbic factor in this disease. Thus, the incubation period is a varying one. Sporadic cases may occur in the household or in the hospital, even though strictest hygienic conditions prevail. Attempts to reproduce the disease experimentally have failed. A close analogy exists between scarlet fever and serum sickness. In the latter there are an exanthem, a varying period of incubation, vomiting, fever, glandular enlargement, swellings and pains in the joints, and renal symptoms varying from a mild albuminuria to a severe hemorrhagic nephritis. The streptococcus is such a common morbid factor in many of the minor ailments of childhood, that it is not difficult to conceive of the individual acquiring a hypersusceptibility to this microorganism. Czerny has pointed out that fat, "pasty" children are an easy prey to scarlet fever and suffer from a severer type of this disease than other children. Moro notes that the former group of children are also more subject to serum sickness. The analogy between scarlet fever and serum sickness is indeed a close one, but it is only an analogy and should not misguide one in the effort to frame definite scientific conceptions.

News of the Week.

Health of the Canal Zone.—The report of the Department of Sanitation for the month of September, 1913, gives the total number of deaths from all causes among employees in the Canal Zone as 44, of which 36 were due to disease and 8 to violence, making an annual average death rate per thousand for the month of 8.92. For the total population of Panama, Colon, and the Canal Zone, the death rate per thousand for the month was 27.39, which is high as compared with the figures of previous Septembers. Of the deaths among employees, 7 were due to pneumonia, 4 to tuberculosis, 1 to dysentery, and 1 to hemoglobinuric fever. As usual, there were no cases of yellow fever, smallpox, or plague.

The Sale of Poisons.—Following the reports in the newspapers lately of several cases of death from the accidental or intentional ingestion of tablets of bichloride of mercury, Congress has taken up the consideration of a bill requiring that such preparations shall be colored in order to distinguish them from other non-poisonous tablets, and is also considering placing limitations upon the sale of this and other poisons.

Cornerstone Laid.—With appropriate ceremonies the cornerstone of the new dispensary of the Hospital for Deformities and Joint Diseases, New York, was laid on November 4. The building will be situated at 41 and 43 East 123d Street, or just around the corner from the hospital building proper. Addresses were made by Dr. Abraham Jacobi, Dr. Reginal Sayre, and Judge Julius Mayer of the United States District Court, who outlined the history of the institution since its establishment in 1904 as a clinic under the control of Dr. H. C. Frauenthal.

Fire at College.—The Leonard Medical College of Raleigh, N. C., the best known Negro medical college of the South, was badly damaged by fire on November 8, the chemical and biological laboratory being entirely destroyed. The blaze began among the explosives in the laboratory, and at one time threatened the entire school buildings.

Medical School Consolidation.—The new Medical College of Virginia, the product of the consolidation of the University College of Medicine and the old Medical College of Virginia, was formally opened on October 30, and dedicated to medical education in the South. It was predicted, during the ceremonies that a further consolidation with the medical department of the University of Virginia was to be expected and hoped for, since by this means Virginia would secure a single medical institution of the highest rank.

Asylum Dedicated. — The Schuylkill County Hospital for the Insane at Schuylkill Haven, Penn., which was recently completed at a cost of $600,000, was formally dedicated on October 30. The new institution has accommodations for 600 patients.

Surgery and Reform.—In Chicago recently four patients were operated upon in the hope that the result would be the elimination of criminal tendencies and moral deficiencies in them all. The operations were done at the instance of Judge Bridgeman of the Circuit Court of St. Joseph, Mich., who has announced that hereafter he will not sentence any one convicted of moral crimes in his court, until by the use of the knife, an opportunity for regeneration has been given the affected mind.

The Plague.—Serious alarm as to the health condition of Ecuador is excited by the reports re-

ceived from Guayaquil. A large number of cases of bubonic plague have been discovered there, and yellow fever also is prevalent.

In Seattle, Wash., vigorous efforts are being made to destroy all the rats, especially along the water front, because of the finding recently of six which were infected with bubonic plague.

Patent Medicine Achievements.—The appraisal of the estate of the late J. M. Kilmer of Binghamton, N. Y., exploiter of a patent medicine known as Swamp Root, puts a valuation of $2,600,000 upon it. This is the result of twenty years' exploitation of the preparation.

Fire Near Hospital.—Patients in the Williamsburgh and Eastern District Hospitals, Brooklyn, were alarmed in the early morning one day last week by a fire which destroyed a large tent in a lot only a few yards from both institutions.

Gifts to Charities.—By the will of the late Edward Sallinger of New York, bequests of $500 each are made to Mount Sinai Hospital, the Montefiore Home, and Beth Israel Hospital.

St. Luke's Hospital, New York, receives a bequest of $50,000, and the House of Rest for Consumptives one of $10,000, by the will of the late Herman C. von Post of this city.

By the will of the late Miss Elizabeth P. Cresswell of Philadelphia the sum of $5,000 is bequeathed to the Philadelphia Home for Incurables.

By the will of the late Rebecca L. Bringhurst of Philadelphia the sum of $15,000 is bequeathed to the Trustees of the University of Pennsylvania for the endowment of three beds in the Children's Orthopedic Ward; and the sum of $5,000 to the Philadelphia Home for Incurables.

The Mountainside Hospital of Montclair, N. J., receives a bequest of $2,500 under the will of the late Mr. Alfred C. Toxbury of that city.

The Woman's Hospital and the Presbyterian Hospital, New York, receive each one-tenth of the residuary estate of the late Mrs. M. A. Murray, estimated at over $50,000.

By the will of the late Mrs. Ellen Phillips Samuel of Philadelphia, the sum of $20,000 is bequeathed in equal parts to the Jewish Hospital, Jefferson Hospital, St. Christopher's Hospital, and the Woman's Hospital of that city.

College of Physicians and Surgeons.—At a meeting of the trustees of Columbia University, New York, on November 3, Dr. James W. Jobling, formerly of Chicago, was appointed assistant professor of pathology, in succession to the late Dr. Hugh A. Stewart. Dr. Frederic S. Lee was elected delegate to the University Council from the Medical Faculty to serve until June 30, 1916, in succession to Dr. George S. Huntington. Several gifts were also announced, including $7,500 from Dr. C. W. McMurtry for alterations in the dermatological department of the Vanderbilt Clinic, and $905 from Prof. E. B. Cragin for alterations in the gynecological department, and an anonymous gift of $1,500 to be added to the income of the Crocker Special Research Fund and expended for the investigation of the effect of radium on cancer.

A recent census of the graduates of Columbia University gave some interesting results. Of the class of 1840 of the College of Physicians and Surgeons, the medical department of the university, five members are thought to be still living, although their addresses are unknown. Of the class of 1844, two graduates are known to be alive; of 1845, four are living; of 1846, seven; of 1847, two; of 1848, four; of 1849, three; of 1850, three; of 1851, twenty-two; of 1852, twenty-six; of 1853, twenty, and of 1854, ten. The oldest living graduate of the University, so far as is known, is Robert M. Olyphant of New York, who received his B.A. degree in 1842.

Personals.—Dr. John L. Bower of Reading, Pa., medical examiner for the Reading District of the Schuylkill Valley Division of the Pennsylvania Railroad, has been promoted to be medical examiner in chief of the Philadelphia district.

Dr. James E. Murphy of Philadelphia has been appointed resident physician at the Wildwood Sanatorium at Hartford, Conn.

Dr. Charles E. Woodruff, lieutenant-colonel in the United States Army Medical Corps, retired, has recently become a co-editor of *American Medicine*.

Conference of Health Officers.—The Thirteenth Annual Conference of the Sanitary Officers of the State of New York will be held in Utica, November 19-21, 1913. The week beginning November 16 will be "Public Health Week" in Utica, during which popular lectures on various subjects addressed to various classes of the community will be delivered daily.

Medical Society Elections.—Virginia Public Health Association: Annual meeting in Lynchburg on October 23. Officers elected: *President,* Dr. Mosby G. Perrow, Lynchburg; *Vice-Presidents,* Dr. Robert C. Bagby, Westpoint, and Dr. C. B. Boyer, Stonega; *Secretary-Treasurer,* Dr. Lucien Lofton, Emporia.

Medical Society of Virginia: Annual meeting in Lynchburg on October 21-23. Officers elected: *President,* Stephen Harnsberger, Catlett; *Vice-Presidents,* Dr. Robert C. Bryan, Richmond; Dr. J. S. Davis, and Dr. Benjamin R. Gary, Newport News; *Treasurer,* Dr. Mark W. Peyser; *Secretary,* Dr. Paulus A. Irving, Farmville. The next meeting of the society will be held in Washington, D. C.

San Bernardino County (Cal.) Medical Society: Annual meeting in Redlands on October 15. Officers elected: *President,* Dr. Benjamin Franklin Church, Redlands; *Vice-Presidents,* Dr. Henry William Mills, San Bernardino, and Dr. L. J. LaMotte, Colton; *Secretary,* Dr. Carlos G. Hilliard, Redlands; *Treasurer,* Dr. William Taltavall, Redlands.

San Joaquin Valley (Cal.) Medical Association.—Annual meeting in Fresno on October 14. Officers elected: *President,* Dr. C. P. Kjaerbye, Fresno; *Vice-President,* Dr. L. R. Willson, Fresno, and Dr. Warden T. Barr, Fresno; *Secretary,* Dr. R. O. Ross, Fresno; *Treasurer,* Dr. Thomas M. Hayden, Fresno.

Eighth District (Tex.) Medical Society.—Annual meeting in Wharton on October 16. Officers elected: *President,* Dr. Stephen A. Foote, Bay City; *Secretary,* Dr. Phillip E. Parker, Bay City.

Somerset County (Penn.) Medical Society.—Annual meeting in Rockwood on October 21. Officers elected: *President,* Dr. George C. Berkheimer, Windber; *Vice-President,* Dr. Herbert P. Myers, Confluence; *Secretary,* Dr. Henry Clay McKinley, Myersdale; *Treasurer,* Dr. Walter S. Mountain, Confluence.

Princess Anne County (Va.) Medical Society was organized on October 18 with the election of the following officers: *President,* Dr. Thomas B. Luxford, Princess Anne; *Vice-Presidents,* Dr. Thomas L. Brooks, Oceana, and Dr. Nathaniel A.

Nicholson, Creeds; *Secretary-Treasurer,* Dr. A. D. Tyree.

Sixth District (Tex.) Medical Association.—The following officers were elected at the annual meeting in Corpus Christi on October 14 and 15: *President,* Dr. F. G. Painter, Corpus Christi; *Vice-President,* Dr. T. J. Turpin, Corpus Christi; *Secretary-Treasurer,* Dr. L. S. Monfolf, Aransas Pass.

Second District (Ia.) Medical Society.—At the annual meeting held at Davenport on October 15 officers for the ensuing year were elected, as follows: *President,* Dr. F. H. Little, Muscatine; *Vice-Presidents,* Dr. C. F. Howard, Iowa City, and Dr. L. B. Carson, Maquoketa; *Secretary-Treasurer,* Dr. J. V. Littig, Davenport. The 1914 meeting will be held in Davenport.

Northwestern Ohio Medical Association.—The annual meeting of this association was held in Findlay on October 16 and 17, when the following officers were elected: *President,* Dr. J. D. Tritch, Findlay; *Vice-Presidents,* Dr. G. P. Willard, Tiffin, and Dr. W. A. Dickey, Toledo; *Secretary,* Dr. S. D. Foster, Toledo; *Treasurer,* Dr. E. H. Porter, Tiffin.

Coast Line Surgeons.—At the annual meeting of the Association of Surgeons of the Atlantic Coast Line Railroad on October 14 the following officers were elected: *President,* Dr. J. N. Baker, Montgomery, Ala.; *Vice-Presidents,* Dr. A. M. Brailsford, Mullins, S. C., and Dr. P. P. Lane, Waycross, Ga.; *Secretary-Treasurer,* Dr. C. P. Aimar, Charleston, S. C.

Wabash County (Ill.) Medical Society.—Annual meeting at Mount Carmel on October 28. Officers elected: *President,* Dr. John Jerome McIntosh, Allendale; *Vice-President,* Dr. E. R. Lescher, Mount Carmel; *Treasurer,* Dr. W. B. Baird, Friendsville; *Secretary,* Dr. J. B. Maxwell, Mount Carmel.

Montgomery County (Ill.) Medical Society.—Annual meeting at Litchfield on October 28. Officers elected: *President,* Dr. Zeb V. Kimball, Hillsboro; *Vice-President,* Dr. Geo. G. Allen, Litchfield; *Secretary,* Dr. H. F. Bennett, Litchfield; *Treasurer,* Dr. M. W. Snell, Litchfield.

Louisa County (Va.) Medical Society was organized at a meeting held recently, when the following officers were elected: *President,* Dr. Eugene Pendleton, Cuckoo; *Secretary-Treasurer,* Dr. Thomas M. Taylor, Louisa.

Hospital Cornerstone Laying.—The cornerstone of the new Children's Hospital of Philadelphia, to be erected at Eighteenth and Bainbridge Streets, was laid with appropriate ceremonies on October 22. The actual placing of the stone in position was done by Miss Charlotte Rush, a lineal descendant of Dr. Benjamin Rush. Addresses were made, among others, by Dr. Joseph S. Neff, Director of Public Health and Charities, and Dr. J. Claxton Gittings, secretary of the medical staff of the hospital.

Memorial to Dr. Fitz.—In the amphitheater of the Harvard Medical School, Boston, on Monday evening, November 17, there will be held a memorial meeting to the late Reginald Heber Fitz, professor emeritus of the theory and practice of physic. Addresses will be made by W. W. Keen, professor emeritus of surgery in the Jefferson Medical College, Philadelphia; Charles W. Eliot, president emeritus of Harvard University; Henry P. Walcott, chairman of the board of trustees of the Massachusetts General Hospital; William Sydney Thayer, professor of clinical medicine, Johns Hopkins University, Baltimore, and William T. Councilman, Shattuck professor of pathological anatomy, Harvard University.

Obituary Notes.—Dr. Jesse S. Myer of St. Louis, Mo., died at his home, from leukemia, on October 30, aged 40 years. Dr. Myer was graduated from the University of Missouri in 1893, and from the Marion-Sims College of Medicine, St. Louis, in 1896, and following his graduation from the latter continued his studies at the Charité Hospital, Berlin. From 1902 until 1912 he was instructor and lecturer on clinical chemistry and microscopy at Washington University, and until his death served as chief visiting physican to the Jewish Hospital. Dr. Myer was a member of the American Medical Association, the Missouri State and St. Louis Medical Societies, and the American Gastro enterological Association, and of the last named a member of the council, and editor of its official publication. He had also attained literary recognition, particularly through his "Life and Letters of William Beaumont."

Dr. August Schumacher of Hamilton, Ohio, a graduate of the Medical College of Ohio, Cincinnati, in 1897, a member of the Ohio State and Butler County Medical Societies, former coroner of Butler County and former health officer of Hamilton, died at his home on October 12, aged 39 years.

Dr. Thomas Alexander Elder of Wooster, Ohio, a graduate of the Rush Medical College, Chicago, in 1868, and of the Bellevue Hospital Medical College, New York, in 1872, and a member of the Ohio State and Wayne County Medical Societies, died at the Presbyterian Hospital, Chicago, on October 19, aged 70 years.

Dr. Ellsworth Henry Ward of Riverside, Cal., a graduate of the Cleveland, O., University of Medicine and Surgery in 1874, and one of the founders of the Riverside Hospital, died at his home on October 23, aged 62 years.

Dr. James Thomas Harris of San Jose, Cal., a graduate of the College of Physicians and Surgeons of Keokuk, Ia., in 1877, at one time coroner of Santa Clara County, and city physician of San Jose, and a member of the California State and Santa Clara County Medical Societies, died at his home from paralysis, on October 21, aged 74 years.

Dr. Samuel B. Mills of Louisville, Ky., a graduate of the Medical Department of the University of Louisville, in 1852, and a former member of the Louisville Board of Health, died at his home on October 25, aged 85 years.

Dr. Philip T. O'Brien of Clinton, Ia., a graduate of the Albany Medical College, N. Y., in 1872, died suddenly at his home on October 31, aged 63 years.

Dr. John M. Rader of St. Louis, Mo., a graduate of the St. Louis College of Physicians and Surgeons in 1893, formerly a deputy coroner of St. Louis, died suddenly at his home on October 21, aged 54 years.

Dr. Edith E. Keisker of Philadelphia, Pa., died on October 23, at the age of 35 years, as the result of scarlet fever contracted at the Municipal Hospital for Contagious Diseases in the course of her work as school medical examiner.

Dr. John A. Bush of Greenville, Tex., a graduate of the Louisville Medical College, Ky., in 1890, died at his home after a short illness on October 23, aged 48 years.

Dr. Clarence G. Clark of New York, a graduate of the University of Michigan, Department of Medi-

cine and Surgery, Ann Arbor, in 1899, and a member of the Physicians' Mutual Aid Association, died at his home on November 5, aged 36 years.

Dr. Daniel A. Arter of Canton, O., a graduate of the Cincinnati College of Medicine and Surgery in 1850, died recently at his home, aged 84 years.

Dr. Thomas C. Finnell of New York, a graduate of the New York University Medical College in 1880, and a member of the medical staff of the Department of Education, died suddenly in the street on November 6, aged 48 years.

Dr. Elizabeth G. Pyrum-Perry of Fryeburg Center, Me., and formerly of New York, a graduate of the Eclectic Medical College of the City of New York in 1882, died at her home, from pneumonia, on November 7, aged 93 years.

Obituary.

CHARLES McBURNEY, M.D.,

NEW YORK.

Dr. Charles McBurney of New York died suddenly at the home of his sister in Brookline, Mass., on November 7, from heart failure, following a hunting trip in Maine, on which it is feared he may have overtaxed his strength.

Dr. McBurney was born in Roxbury, Mass., on February 17, 1845, and was educated at the Roxbury Latin School until his entrance into Harvard University from which he was graduated with the degree of B.A. in 1866. He then entered the College of Physicians and Surgeons, New York, and received his medical degree in 1870, having also in the meantime received an M.A. from his alma mater. After serving for a year and a half as interne at Bellevue Hospital and spending two years in study abroad, Dr. McBurney began the practice of his profession in New York. In 1873 he was appointed demonstrator of anatomy at the College of Physicians and Surgeons, and in 1882 lecturer on operative surgery; in 1889 he became professor of surgery, and head of the department, a position which he resigned some years later because of the increasing demands of his private practice, though he retained the chair of clinical surgery until he was made emeritus professor. He was connected with many of the large hospitals of New York, but his most notable work was done in connection with the Roosevelt Hospital, where in 1888 he was placed in full charge of the surgical service. During the twelve years of his work there the hospital attained an international reputation, and many noteworthy additions were made to therapeutics and surgical methods. At the time of his death Dr. McBurney was consulting surgeon to St. Luke's Hospital, the Presbyterian Hospital, the Orthopedic Hospital, St. Mark's Hospital, and the Hospital for Ruptured and Crippled, and was a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, of which he was vice-president from 1892 to 1895, the Practitioners' Society of New York, and the Roman Medical Society, and a corresponding member of the Société de Chirurgie of Paris. His contributions to the literature of surgery were many and important, the most notable being those on the subject of appendicitis.

Of late years he had made his home at Stockbridge, Mass., and funeral services were held there on November 9.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HARVEIAN ORATION—NOGUCHI'S DEMONSTRATION AT ROYAL SOCIETY OF MEDICINE—SECTION OF HISTORY OF MEDICINE, PROFESSOR JASTROW—MEDICAL SOCIETY OF LONDON, CEREBROSPINAL FLUID—MISTAKES IN PROGNOSIS—COMMITTEE ON AFRICAN DISEASES—ROYAL COLLEGE OF SURGEONS—MEDICAL MUSEUM—ACTION AGAINST BRITISH MEDICAL ASSOCIATION—CHARITABLE BEQUEST—OBITUARY.

London, October 24, 1913.

The Harveian Oration was delivered at the Royal College of Physicians according to custom on St. Luke's day (Saturday). This year the orator was Dr. Mitchell Bruce who took for his subject the Treatment of Fever. For the 150 years from the death of Harvey to the first decade of the nineteenth century he pronounced the social conditions of this country revolting. Sanitation did not exist; ventilation was hindered by the window tax and overcrowding excessive. Yet in those days the foundations of sanitation were laid by such men as Mead, Pringle, Lorid, and Blane. In 1831 came the first epidemic of cholera for which the country was altogether unprepared. In 1847 typhus killed above 30,000 persons in England and Wales. From 1871 to 1880 typhoid fatalities were 78,000. It was humiliating to see the time that Parliament let pass before attempting legislation. Medical representations backed by advances in chemistry, physiology, and pathology had no effect except on some grave emergency which aroused a spasmodic effort. The terrible tale of deaths from fever and the destitution following raised the poor rate to such a height that the Commissioners in 1838 reported that "prevention would be more economical than mitigation," and this consideration of economy had more influence in promoting public health legislation.

The period after 1859 was all important in the history of the pathology of fever and, in fact, of infection generally. Pasteur, Lister, and Koch traced the contagion of certain febrile diseases to vegetable organisms; Lewis, Obermeier, and Lavaran traced others to animal organisms. The greatest modern triumph of preventive treatment was Lister's demonstration of his antiseptic method. This was followed by the discoveries of Roux, Buchner, and Metchnikoff. The history of the pathogeny of fever showed that men, as well as facts, had to be waited for. Pasteur, Lister, Metchnikoff, and Behring had to come and to share with Harvey the honor of their great discoveries. It was surprising to see how Harvey forecasted modern advances, but he was also distinguished by his restraint from speculation. Revealing his conception of the workings of nature, he repressed himself and resumed the position of a simple, patient observer content to record facts for his successors. After the oration the Baly Medal was awarded to Dr. John Haldane, Reader in Physiology at Oxford.

Dr. Noguchi's demonstration at the Royal Society of Medicine which was unfortunately postponed by his indisposition came off on Monday and I need scarcely remark was a great success. His researches are well enough known on this side to secure the respect and admiration of all concerned in the advancement of our art. He showed pure cultures of various spirochetes—pathogenic and saprophytic—illustrating his investigations and dis-

coveries in regard to the transfer of disease and propagating the virus outside the body. Then there were slides showing the *Treponema pallidum* in the brain in cases of general paralysis of the insane and locomotor ataxia. By inoculating rabbits he had produced the various symptoms and lesions of paralysis thus proving the organism to be the cause of the disease. A good deal of interest was excited by the description of his method of cultivation of organisms in liquid and solid bodies from which he had excluded oxygen more or less completely. It was by this method that he had cultivated the virus of rabies and of poliomyelitis. The series of cultural studies of rabies, illustrating his important researches on this disease naturally received special attention.

He classifies spirochetes according to their habitat: (1) Those which grow only in the tissues of the host; *e.g.* the organisms of syphilis and of African tick fever; (2) which only grow in the blood of the host, *e.g. Sp. Obermeieri;* (3) those growing on mucous surfaces, such as are constantly found in the mouth. These last are nonpathogenic, but both the other two classes are pathogenic.

The Section on the History of Medicine began with a most interesting lecture on the "Medicine of the Babylonians and Assyrians" by Prof. Morris Jastrow, Jr., of the University of Pennsylvania. He outlined as fully as time allowed the course of Babylonian and Assyrian medicine and thought it a noble achievement that the physicians passed across the barren wastes of incantation rites and divination practices and reached at least up to the borders of the promised land of genuine medical science—indeed, perhaps, beyond the frontier and took possession of some of the outposts.

The session of the Medical Society of London was opened on the 13th by the president, Sir David Ferrier, with an address on the "Cerebrospinal Fluid in Health and Disease." Of course he had to consider the differences between the lesions of syphilis and parasyphilis. As the blood and cerebrospinal fluid yielded the same reaction it was supposed by many that the spirochete must remain in the body, but he and Emery had sought it in vain and other theories were advanced. Now, however, Noguchi and Moore had found it and their discovery was confirmed by others and this would seem to have obliterated the distinction.

Dr. David Ross, the new president of the Aesculapian Society opened its session with an address on "Mistakes in Prognosis" and offered some useful hints as to the care to be exercised in replying to the anxious inquiries often made. He gave illustrations of errors that had been made, some of the cases resulting in recovery after a hopeless view had been expressed. He doubted if the date of death could be foreseen by anyone and some instances of the attempt to do so being proved unwise by the patient recovering soon after the time for death had been forecasted.

Surgeon-General Sir David Bruce was first witness at Earl Desarts' Committee on African Diseases, appointed to inquire into and report on the parts played by animals and flies in the spread of trypanosome infection; the question of game destruction in a localized area or on a wider scale; or an attempt to exterminate wild animals; or whether any other means could be found to control these diseases. Sir David Bruce has been in charge of the Commission of the Royal Society on Sleeping Sickness in Nyassaland.

The new calendar of the Royal College of Surgeons, just issued, shows 375 members and 66 fellows admitted during the year. Diplomas in public health issued were 41 in number, in tropical medicine 4. As to the short title of the last D. T. M. Eng. it has been decided to add a reference to hygiene, so we are told the title will now be "D. T. M. and H. Eng.," which I hope will be enough for the gentlemen who pass an additional examination to secure a lengthier tail to their names.

The Council has forwarded congratulations to their oldest member, Surgeon-Major Hinton of Adelaide, on attaining his 100th birthday.

The Historical Medical Museum is to be closed with the month. It has been a great success—a natural result of the organizing skill of Mr. Welcome, at whose sole cost it was brought together. It is probable that when the loaned specimens have been returned the others may form the nucleus of a permanent museum.

Dr. Slowman's action against the B. M. A. was ended on Saturday. By advice of the judge the parties conferred with the result that defendants agreed to expunge the resolution objected to and admitted irregularities. Also to pay plaintiff £500 and his costs.

By the will of Miss A. J. J. Arden hospitals and charities benefit to the amount of £67,000.

Major James Moir died yesterday. Born in 1860 he entered the Royal Arms Medical Corps twenty-six years later, served in South Africa in 1900 and received the Queen's Medal with three clasps. Retired in 1905.

Dr. William Watts Thetford, probably the oldest medical practitioner in Ulster, having practised in County Down for about fifty years, has died in his 91st year. He qualified in 1849. Had been surgeon to the Coast Guard and the Royal Irish Constabulary.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

THE ACADEMY OF MEDICINE AND THE NOTIFICATION OF TUBERCULOSIS—PRACTICAL DIFFICULTIES OF THE LATTER—THE SURGICAL TREATMENT OF ACUTE APPENDICITIS — ARTIFICIAL PNEUMOTHORAX—COMPENSATORY RENAL HYPERPLASIA—A MONUMENT TO GUINARD.

PARIS, October 1, 1913.

At the close of a long discussion the Academy of Medicine on July 1, 1913, voted on the report of the permanent commission on tuberculosis. By a vote of 55 to 21, with eight votes not cast, the Academy adopted the following recommendation of Roux, Vaillard, Landouzy, and Charles Richet: (1) It is in the public interest that all open cases of tuberculosis should be reported. (2) The notification should be made to a health officer, who should be bound by the professional secret, and who should carry out the necessary prophylactic measures, provided these are not looked after by the attending physician. (3) The public authorities should extend aid to indigent consumptives and to their families. The Academy also passed a resolution declaring that in all hospitals that shall be built in the future a ward should be set apart for open cases of tuberculosis. The necessity of a national campaign against tuberculosis in France, more effective than has been the case in the past, is quite apparent to almost everyone, for in this respect our neighbors, particularly England and

Germany, have surpassed us. In Paris, out of every 10,000 inhabitants, there died from pulmonary tuberculosis in 1875, 41 individuals; in 1910, 35 individuals; a diminution of 14 per cent. in the mortality from this disease is thus apparent. On the other hand, during the same period, the reduction in mortality in England was 56 per cent., and in Prussia 52 per cent.

But the vote of the Academy does not decide this question. There are financial limitations involved in rendering aid to the needy consumptives. Nor is notification alone sufficient in coping with the spread of the infection, for it is necessary to disinfect the premises of the patients, to improve the dwellings of the poor, and to instruct the consumptives as to the dangers of carelessness. The rank and file of the profession know better than do the members of the Academy, the thousand difficulties that are involved in the practical application of a measure requiring the reporting of all cases of tuberculosis.

The treatment of acute appendicitis came up for discussion at the recent meetings of the Surgical Society. The majority of surgeons now prefer early operation. Potherat operates at the beginning of the attack, or as soon as he is called in. Témoin does likewise, and cites the good results he has obtained with this method in 3,000 cases. On the other hand, Reynier favors operation in the interval, even in cases in which there is a diffuse peritoneal reaction presenting the syndrome described by Dieulafoy under the name "vomito negro appendiculaire."

In only one type of appendicular disease does he favor operation at the outset, namely, in gangrenous appendicitis. In this condition there is at first a slight peritoneal reaction; the abdomen is not very much distended, and there is very little vomiting. On the other hand, the general infection dominates the clinical picture; there is a subicteric tinge of the conjunctivæ; the temperature rises to from 102.2° to 104° F.; the pulse is full and frequent, and, finally, the temperature does not fall upon the application of ice. The last is a pathognomonic sign. Jacob operates early when there is only a slight reaction generalized in the entire abdomen with the defensive muscular reaction extending to the left abdominal wall. Lenormant operates immediately if he is called within the first forty-eight hours. He operates without delay in cases of diffuse peritonitis; in those in which there is a purulent collection; and also in toxic cases with a slight local reaction but severe general manifestations. With the exception of these cases he advocates temporizing, and the resort to surgery when in spite of the application of ice the general condition gets worse, or when the local process seems to be spreading.

Delbet believes that in one hundred cases of acute appendicitis there are only a dozen in which operation is necessary. The latter are cases of peritonitis with or without perforation. As the most important sign of general peritonitis, he considers immobilization of the diaphragm, which is also an early sign. Among one hundred cases of appendicitis there are eighty-five in which it is best to resort to the application of ice. Errors of diagnosis are not rare. There are two or three cases in every hundred in which one should not operate; these are the cases of hematogenous appendicitis with complications in the biliary passages. In these cases operative interference is most frequently disastrous.

"Artificial Pneumothorax in the Treatment of Pulmonary Tuberculosis" was the subject of a paper read before the Society of Internes by Léon Bernard. In the technique the latter employs only the apparatus of Russ. The principle of the method consists in the introduction into the pleural cavity of a certain amount of gas, which compressing the diseased parts of the lung favor their sclerosis. In general it is better to employ a general compression. Repeated examinations by means of the *x*-rays are necessary in order that one may determine the degree of compression produced. With a well-ordered technique accidents such as convulsions, embolism, and sudden death are not to be feared. Remote by-effects, as subcutaneous emphysema are negligible. Pleurisy may complicate the course of the treatment, but does not aggravate the prognosis.

The conditions that indicate this method of treatment are deep, old, and circumscribed lesions (acute tuberculosis, pneumonia, or bronchopneumonia). The method of Forlanini should be employed if the lesions extend in spite of the orthodox methods of treatment. In most cases the bilaterality of lesions constitutes a contraindication. Other contraindications are the fibrous forms of disease with sclerosis and extensive pleural adhesions. The method is one to be rarely employed. In only 1 to 3 per cent. of cases of pulmonary tuberculosis should it be applied, and of these it is successful in about one-third. The good results in these few cases justify this procedure.

"Compensatory Hyperplasia of the Kidney, Following Unilateral Nephrectomy," was the subject of a paper presented before the Society of Biology by Paul Carnot. In a first series of experiments he killed the animals ten to twenty days after having removed one kidney, without employing any treatment to stimulate the compensatory hyperplasia. The latter almost always developed to an extent of 16 to 50 per cent. of the spared kidney. The average increase was 33 per cent. in fifteen days.

Carnot next showed the effects of certain therapeutic agents in favoring compensatory renal hypertrophy. Most toxic substances retard this process; likewise does urine. On the other hand, urea, and above all, the extracts of the kidney, notably the extracts of hyperplastic kidneys, activate proliferation and may cause an increase in weight of 60 per cent. in fifteen days. The same effect is observed after the use of pituitary extract. The best results are obtained with the use of *x*-rays in small doses. These, Carnot said, have produced an increment in weight of from 60 to 88 per cent. in fifteen days.

A monument to commemorate Dr. Guinard, who was recently slain, was unveiled June 24. Mesureur, Landouzy, and Delorme referred to the high qualities that Guinard had displayed, to his devotion to duty, to his surgical honesty, and to his professional loyalty. He met death with stoical courage. His life and his death provided an example for many generations to come. It was most fitting that the monument should stand in the Hôtel Dieux, where Guinard was one of the leading teachers.

6. On the Treatment of Delirium Tremens by the Subdural Injection of Sodium Bromide. S. P. Kramer.

1. **Treatment of Scoliosis.**—R. W. Lovett in reviewing the methods of correcting scoliosis states that Wullstein and Shanz have shown that the suspension position can produce remarkable results. Sever and Lovett have demonstrated that the prone lying position can bring about satisfactory results. Abbott has shown that the flexed back lying position is attended by apparently effective correction. It is probable that the particular technique employed is of less importance, as to the final result, than the skill and experience of the surgeon, the amount of force used, and the efficiency of the after-treatment. But after a trial of all methods the author believes that the method of Abbott offers on the whole distinct anatomical advantages and the greatest ease of correction, but the method must be regarded as being to a certain extent still *sub judice*.

2. **Observations on Gastric Disease.**—C. L. Scudder presents an analysis of two hundred cases of gastric disease that have been under his care. He is impressed by the part which syphilis plays in the etiology of chronic stomach disease. Syphilis of the stomach is more common than generally has been supposed. It is a tertiary manifestation. A multiplicity of lesions are possible. These lesions may be a gummatous tumor, or ulcerations in the stomach wall involving the mucosa, or adhesions extending from the stomach to neighboring organs. Syphilis of the central nervous system with symptoms of gastric crises may confuse the picture, when only the spinal fluid will show evidences of the infection. The symptoms of syphilis of the stomach may resemble chronic ulcer—or even cancer—differing from ordinary ulcer in their lack of regularity and persistence. In all of the author's suspected syphilitic cases there have been many peritoneal adhesions. He has made mistakes in diagnosis in the following cases: The diagnosis of gastric ulcer in twelve cases proved to be adhesions in one case; no pathology in three cases; syphilis, but not of the stomach, in one case; leioma in one case; and appendicitis in six cases. A diagnosis of duodenal ulcer in three cases proved to be Lane's kink and appendicitis in one case, sarcoma of the stomach in another, and appendicitis in the third. A diagnosis of carcinoma of the stomach in two cases proved to be gastric ulcer in one case and duodenal ulcer in the other case. In one doubtful case a diagnosis of stomach, gall-bladder, or appendix disturbance proved to have no visible pathology. The author has been most assisted to a diagnosis of chronic ulcer by a carefully elicited story of the onset and course of the symptoms. Definite pain in the stomach region has been the most constant symptom. The hunger pain, so-called by Moynihan, has been found to be associated so frequently with ulcer on the gastric side of the pylorus that the author is inclined to think that it is not diagnostic of duodenal ulcer. As regards the surgical treatment of cancer of the stomach it is pointed out that gastroenterostomy is a poor palliative measure. The length of life secured is but about four months. It is better, if practicable, to resect as a palliative measure, and rid the patient of a sloughing mass of cancer, not being content simply with a posterior or anterior gastroenterostomy. The length of life is longer after resection than after gastroenterostomy.

5. **Alcohol in the Treatment of Furunculosis of External Auditory Canal.**—O. A. Lothrop describes the technique of this method of treatment as follows: The canal is cleaned of cerumen, desquamation, discharge, foreign bodies, or polyps. A wick is then inserted into the canal, nearly to the drum membrane, completely filling the lumen. If there is no discharge cotton is used. If there is a discharge a gauze wick is used. If the canal lumen is partly closed by one or more distinct "ripe" furuncles, these should first be incised and the pus evacuated. Any incision should be carefully made into the center of the furuncle, for, if this is not done, the pus does not escape and the patient is not relieved. In addition, there is danger of infecting a new area, and a perichondritis sometimes results from trauma to the cartilage. A probe point will often help to locate the center of a furuncle. After being inserted snugly into the canal, the wick is saturated with alcohol, plain or with boric acid, and the patient is instructed to keep the wick wet by dropping alcohol upon it at frequent intervals. The wick should be removed daily by the physician and a fresh one inserted. Whenever a pocket of pus can be located it should be incised. After incision, the alcohol should be applied before the patient recovers from the anesthesia. The alcohol smarts on freshly cut or abraded surfaces with the first application, but gives very little discomfort at later applications.

6. **Subdural Injections of Sodium Bromide in Treatment of Delirium Tremens.**—S. P. Kramer has used this method of treatment in a series of twenty cases and vouches for its safety and efficacy. The technique of the treatment consists in the withdrawal of 50 to 60 c.c. of cerebrospinal fluid by lumbar puncture. The same amount of a sterile one per cent. solution of sodium bromide is injected with a syringe. There is absolutely no danger from increased subdural pressure. This amount and even as much as 80 cubic centimeters of fluid have been injected into the subdural cavity in an interval of one minute without the least sign of increased intracranial pressure. Sodium bromide is not toxic to the nervous system. The potassium salt must not be used, since it is slightly irritating. The patients as a rule show a lessened delirium within a few minutes after the injection. This immediate improvement, however, disappears after a short time, but is followed in from 12 to 15 hours by a permanent disappearance of the delirium.

10. The Intravenous Treatment of Rheumatic Fever. P. M. Patterson.

1. **Errors in Diagnosis and Prognosis of Gallstone Disease.**—B. T. Tilton points out that jaundice occurs only exceptionally in gallstone disease. A common belief held is that the symptoms caused by gallstones are always directly referable to the liver and biliary ducts. This mistaken idea has probably been the cause of most errors in diagnosis. The classical symptoms that have long been ascribed to cholelithiasis are unfortunately the exception. Other organs, particularly the stomach, give the first evidence of gallstones, and that it may not be until months or years later that the symptoms point directly to the liver and bile ducts. Patients with epigastric pain and stomach symptoms are constantly being treated for indigestion, while the real trouble, gallstones, is entirely overlooked. Stomach clinics are visited by patients with

gallstones who are religiously treated by gastric lavage, antacids, sedatives, etc., without relief. It is evident that a failure to recognize the real nature of these cases, over a long period of time, may lead to serious changes in the gall bladder, bile ducts, pancreas, and other organs. As a consequence a simple lesion becomes a complicated one and the patient runs the risk of a sudden attack of acute cholecystitis, obstruction of the common duct, infectious cholangitis, or the gradual development of painful adhesions about the gall bladder and ducts, pyloric obstruction, chronic pancreatitis, cancer of the gall bladder, and other lesions resulting from the continued presence of stones.

2. Special Technique in Palpation.—L. Napoleon Boston, has employed a special technique for the purpose of determining the degree of tension over various portions of the abdominal surface. In normal subjects, when the patient is resting upon his back with the thighs flexed, there is a slight increase in tension immediately below the right costal margin (hepatic tension). This area when compared with the same area in the left superior abdominal quadrant, offers slightly more resistance to the palpating finger. Comparing the two sides of the abdomen, one or two inches above the level of the umbilicus, the same degree of resistance is offered to the palpating fingers. There is no appreciable difference in the resistance of the two sides of the abdomen below the umbilicus during health. This method for palpating the two halves of the abdomen simultaneously is to begin immediately above Poupart's ligaments, ascending in lines drawn from the center of Poupart's ligaments to the costal border. One should continue by comparing the two halves of the abdomen at equal levels ascending to the margin of the ribs. One may also palpate the abdomen, employing the same scheme and ascending from the inferior abdominal region to the costal margin, following lines approximately two inches to the right and the same distance to the left of the line previously mentioned. Through this method of palpation it is possible to elicit one of the most delicate signs of new growths of the abdomen. Enlargement of the liver, spleen, and kidneys; uterine, ovarian, and cystic growths and fecal impaction are all mapped out by a localized increase in tension of the abdominal wall over the site of the lesion. Prolapse of any viscus causes a lessened resistance to the finger when palpating over its normal position; and increased tension is detected immediately over the present position of such migrating viscus. Localized inflammatory processes involving the abdomen are accompanied by undue tension over a limited portion of the abdomen, and this is exemplified in acute appendicitis, pyosalpinx, gastric cancer, and conditions accompanied by localized peritonitis. Posture may materially alter the degree of abdominal tension, therefore it is preferable to perform palpation while the patient is resting upon his back, on his right side, on his left side, and when standing.

5. Teaching of Sex Hygiene.—Mary Sutton Macy calls attention to a few very potent dangers in the teaching of sex hygiene. First there is the danger of introducing pathological data—not only morbid and detailed information about masturbation, sex anomalies, and kindred diseased conditions, but also statistics on the prevalence of sexual diseases, and of prostitution. The pendulum has swung so far from the old-fashioned silence on all sex topics that one is in serious danger of saying too much and talking too often, without making plain the facts that (1) the reproductive function is only one function of the body, (2) that it is physiologically no more vital than any other, and (3) that it is closely associated with and interdependent upon all other mechanisms of the human machine. The author emphasizes the danger of too detailed information, and in this relation quotes from the report of the special committee of the American Federation of Sex Hygiene as follows: "Sex instruction has a purely practical aim and should be strictly limited by this aim. Its purpose is to impart such knowledge of sex at each period of the child's life as may be necessary to preserve health, develop right thinking, and control conduct. Its aim is both hygienic and ethical; and whatever knowledge of sex and of sex relations in human life is not necessary at any particular period of the child's life for these ends should not be imparted at that period."

5. Salvarsan Relapses.—M. L. Heidingsfeld alludes to the difficulty of establishing fixed rules for the treatment of syphilis. A few fundamental principles are generally accepted. The intravenous administration of salvarsan is conceded to be the most efficient method of its administration. With proper technical precautions it can be performed in ambulatory practice but painstaking surgical asepsis is essential. In his early use of the drug the author was inclined to give large doses frequently repeated, but experience has made him more conservative. He insists on the value of the Wassermann test as essential in the treatment of syphilis as even salvarsan. Of his 651 cases 23 per cent. failed to produce a negative reaction with salvarsan and when salvarsan was aided by other measures the Wassermann reaction failed in about 12 per cent. of the patients. From an objective clinical point of view the latter were free from visible manifestations, but the persistent strong Wassermann reaction showed that they were uncured. For the past year or more the author has been using various methods as adjuncts to the salvarsan treatment. In the beginning he employed massive intravenous administration of mercury oxycyanide and mercury bichloride but gastrointestinal disturbances caused him to abandon these drugs. Since then he has employed a 10 per cent. solution of sodium cacodylate and atoxyl with better results, the former proving the more reliable and efficient. Some cases were not favorably influenced, however. The injections were made twice weekly for thirty to sixty days and if the Was-

sermann was negative in thirty days they were given once weekly, but for never more than a total of sixty days. They were always well tolerated. Only five cases have relapsed to a positive Wassermann after a negative one for one full year. Salvarsan is not unfailing. It effects an apparent clinical and laboratory cure in about 77 per cent. and the remainder give every promise in the majority of cases of an ultimate clinical cure with the aid of sodium cacodylate and other measures.

7. **The Pseudodiphtheria Organism in the Urinary Tract.**—W. W. Townsend is convinced that under the proper conditions a pseudodiphtheria bacillus in the genitourinary tract can become a pathogenic organism; that it is more common as an etiological factor than is appreciated in the textbooks, as evidenced in the numerous cases of chronic urethritis in which it is found, in the cases reported by Rosenow and in the one studied by the author. The latter's findings endorse fully Brown's statement that it is not at all uncommon as a sequence of gonorrhea to find a condition in which the urine shows large numbers of organisms of different forms, which undoubtedly tend to keep up the inflammation. The subject of symbiosis is one for further study by the bacteriologists and of vast clinical interest in the treatment of rebellious conditions of the genitourinary tract.

11. **Acidosis as a Postoperative Complication.**—W. B. Russ notes that because of a marked reduction in the normal alkalinity of the blood, the result of some perversion of metabolism, many of the patients requiring surgical operations are unfit subjects for general anesthesia and the ordeal of an operation. The warning signs in such cases are: (1) A history of unaccountable headaches, vertigo, attacks of dyspnea, occasional nausea or vomiting, an unreasonable dread of the operation, tachycardia, and other nervous symptoms. (2) A peculiar sweetish odor to the breath, suggesting the odor of decayed apples. In some cases this is marked and unmistakable. (3) The presence in the urine of the acetone bodies. To disregard these warning signs is to subject the patient at best to an anesthesia requiring large amounts of ether or chloroform, and attended with struggling and great rigidity of the muscles, difficult breathing, a rapid pulse and nausea, followed by a prolonged and nerve-racking convalescence with persistent vomiting, restlessness, dyspnea, a rise in temperature and much suffering, or, if less fortunate; to subject the patient to the certainty of a fatal termination, preceded by nausea, air-hunger, persistent vomiting, a rise in temperature, great nervousness, followed by coma and death in from ten hours to two or three days. A recognition of acidosis in time followed by the institution of such measures as a carbohydrate diet of from 6 to 8 ounces of oatmeal and cream with lactose, large quantities of carbonated alkaline water, colon flushings with an alkaline solution and the internal administration daily of 3 or 4 drams of sodium bicarbonate or sodium citrate by mouth will be followed by a rapid disappearance of all or most of the unfavorable symptoms, and the patient will be rendered for the time being at least a safe subject for the anesthetic and the operation.

6. The Experimental Transmission of Disseminated Sclerosis to Rabbits. W. E. Bullock.

1. **Impaired Retinal Activity.**—G. A. Berry concludes that, physiologically, when the intensity of a light stimulus, acting only on a few end organs of the retina, is diminished in any way—that is, when either the brightness of the test object or the contrast between it and its background is diminished—then the visual acuteness, the power of recognizing detail, is lowered. For diminished intensity of stimulus in the case of the normal eye one may assume diminished excitability, conductivity, or receptivity in that of the diseased eye. *A priori* the result must be the same in both cases. That the assumption is justifiable is shown by the fact that in every case of acquired visual defect, with obvious exceptions, the light sense for small visual angles is diminished. As this is not necessarily the case for larger visual angles, it follows that a summation of feebler individual impressions must have the effect of causing a stronger total impression. Both the light and color senses are greatly dependent upon the size of the angle under which any object is seen. The eye is unable to detect anything like as small differences in the intensities of contiguous retinal stimuli under a small, as it does under a greater, visual angle. And this circumstance, when taken along with the physiological imperfection of the retinal images of external points, is the reason why visual acuteness is greater in what we call a good light than it is in a sufficiently bad light. Thus is explained the drop in acuteness which takes place, physiologically, in the dark—a drop which is, however, greatly modified by retinal adaptation. Thus also is explained the drop which takes place, pathologically, when the excitability or conductivity of the nervous mechanism is lowered. It is obvious that, given normal optical conditions of the eye, a diminution in visual acuteness must depend upon some change in the retina, or its direct connections. The author leaves out of consideration those visual defects which come from optical errors alone. The explanation of visual defects that come from optical errors alone is simpler. The diffusion circles of the images of objective points are of quite another nature than those which are due to aberration. As a rule, the visual acuteness of an ametrope is relatively better when compared with that of an emmetrope when the light is insufficient to permit of full vision in the case of the latter. This is due to the absence, generally speaking, in the ametrope, *quâ* his ametropia, of any light sense defect. As regards the methods of examination for foveal vision it is easier and, for clinical purposes, sufficient to test the acuteness for Snellen's types under ordinary and reduced illumination and contrast, than to determine the limits of invisibility with the photometer and Masson's disc. Similar tests are not suitable for the examination of eccentric vision, and an estimate of visual acuteness at other parts of the retina than the fovea must be made with objects which subtend a very small visual angle.

2. **Symmetrical Necrosis of the Cortex of the Kidneys.**—H. D. Rolleston states that this condition is rare, being seen almost only in women directly after childbirth. Eleven cases have already been reported and the author now adds a twelfth case. Symmetrical necrosis of the renal cortex is almost invariably related to recent delivery, and the child is almost always stillborn. The symptoms resemble those of obstructive anuria, but uremic manifestations are not entirely absent. The kidneys may have been previously either healthy or diseased. The necrosis of the cortex is a characteristic lesion, and is intimately connected with thrombosis of the interlobular renal vessels, but the exact relation between these two events is open to discussion.

4. **Veronal Poisoning.**—W. H. Willcox points out that toxic symptoms may occur after the administration

of veronal, and these may be the result of: (1) a special idiosyncrasy causing a susceptibility to a small or moderate dose; (2) an excessive dose having been taken; and (3) repeated small doses as in the veronal habit. The toxic symptoms which occur after a single large dose are drowsiness, headache, and sometimes ataxia, accompanied by a reeling gait. The patient falls into a deep sleep from which he can be roused only with difficulty. In severe cases the sleep deepens into coma, and the patient becomes cyanosed with rapid and often stertorous breathing. In this stage it is very common for a marked rise of temperature, even to 103° F. or more, to occur, and a physical examination of the lungs will probably show all the clinical signs of pneumonia. These signs will be accompanied or followed by those of a general edema of the lungs, such as moist bubbling râles all over. It is quite easy for a severe case of veronal poisoning to be mistaken for pneumonia. When the condition of deep coma and pulmonary symptoms develops after the taking of a large dose of the drug it is uncommon for recovery to occur. Sometimes a condition of coma and high temperature will last for as long as four days before death supervenes, but after a very large dose death may occur in less than 24 hours. Cases of death have been recorded after even such small doses as 10 grains. In these cases probably other factors were present, and death was not entirely due to the drug. In a healthy adult it may be considered that a dose of about 50 grains is dangerous, and might be regarded as an average minimum fatal dose. It is well known that much larger doses have been taken without death resulting, but in these cases serious symptoms such as deep coma have occurred, and there has been grave danger. In the recorded cases of veronal poisoning the patients have often been the subject of some other disease, or of some other form of poisoning, such as alcohol, morphine, etc., and the veronal may not have been entirely responsible for the fatal issue. In fatal cases of veronal poisoning it is usually almost impossible to say what was the exact dose taken, since the early onset of coma usually prevents any information being obtained from the patient.

6. Transmission of Disseminated Sclerosis to Rabbits.—W. E. Bullock has been able to produce paralysis of the limbs in four rabbits out of five by injecting cerebrospinal fluid, withdrawn under rigidly aseptic conditions from a case of disseminated sclerosis, subcutaneously into the rabbits. The fluid was found to be potent after exposure to a temperature of 0° C. for 14 days, and after being filtered through unglazed porcelain. Histological examination of the spinal cord revealed a complete reproduction of the appearances found in the human subject—viz., (1) vascular engorgement and fragmentation of the myelin sheath in the early stages; and (2) areas of degeneration throughout the cord, demonstrable by the Marchi and Weigert-Pal methods, in the later stages of the disease. Whether the cerebrospinal fluid obtained from a second case of the disease would have produced paralysis in two wild rabbits or not could not be determined owing to the premature death; in the case of the other two animals the fluid was not potent in producing paralysis. A cat which was inoculated with fluid obtained from the first case remained active and healthy for nine weeks.

Deutsche medizinische Wochenschrift.

October 16, 1913.

Present Status of Hydrophobia Research.—Professor Josef Koch of the hydrophobia department of the Koch Institute refers to the opening of the latter in July, 1898. To-day, after fifteen years, there is a special building, an offshoot of the temporary institution. During the fifteen years some 5,000 individuals have received prophylactic inoculation, and thousands of suspicious animal brains have been studied for rabies. Thanks to the work of the institute rabies has become of very rare occurrence, and it is only in rural districts that cases occur with sufficient frequency for the general practitioner to be able to state that he has seen or treated one. Hydrophobia is now the only affection with 100 per cent. mortality. The commonest symptoms in the dog are alterations in character; shy and suppressed behavior; refusal of food; emaciation and paraplegia of the posterior extremities. The latter may last but a few days. The paralysis is unusually marked in fowls, and the disease is therefore chronic here with some chance of recovery. Some of the experimental and natural rabies cases in animals recover spontaneously. The question as to the hope of recovery in human cases from this example must be answered negatively. Rarely in a human case we see a spinal paraplegia develop violently. Such cases might naturally hold out some hope for recovery. Before the appearance of the paraplegia patients have slight fever, malaise, headache, pains in sacrum and loins, weakness in the lower extremities. Further among psychic phenomena, great restlessness, and depression of spirits led up to complete paralysis of an intention type. We naturally assume the existence of a myelitis, whether from the presence of a microorganism or of its toxins. Babes years ago ascribed the paralytic component to the inoculated virus. If weakened virus from the rabbit be injected near the spinal cord such a conclusion might be drawn from a few cases, but as such inoculations have been made by the thousand without the development of paralysis Babes' view cannot hold water. The alternative means a spinal type of rabies of rare occurrence which may of course indicate an abortive central type. But speaking of abortive types we come now to a most interesting question: since in infectious diseases as a class we have certain mild and abortive forms, why should not these occur in rabies? This query has already been answered by the discussion of the so-called spinal or paraplegic type.

Example of Freudian Analysis.—Enderlen expresses his belief that psychoanalysis is a joke and states that neurologists look upon it with a pitying smile. It is, therefore, astounding to see such an enormous literature spring up about it, giving a false idea of its worth. A counter propaganda should at once be instituted against it. He relates the following case: A young woman who had been subject to attacks of aphonia had consulted many physicians, whose diagnoses, however differently stated, all pointed to a neurogenic source. In despair at the successive failures the girl turned to a psychoanalyst who claimed that the condition was purely mental. After months of supervision the patient was pronounced cured and a fee of 1,300 marks cheerfully paid. Although her "mental state had become normal," there were much more than vestiges of the old trouble in existence. In fact to outsiders the girl appeared to be worse. It was merely a case of inventing a morbid state, in fact of calling the patient mentally unsound and then after months of treatment pronouncing her mentally sound. The parents rejoicing over their daughter's returning sanity gave little attention to the intermittent aphonia.

The Use of Salvarsan in Puerperal Infection.—G. Bleynie reports four cases of puerperal infection in which after all the usual measures had been resorted to apparently without avail there were injected intravenously 30 centigrams of salvarsan. Two of the patients recovered. In the two fatal cases the injection of salvarsan was followed by a temporary improvement.—*Journal des Sages-Femmes.*

Insurance Medicine.

Prognosis of Heart Affections from the Life Insurance Aspect.—Dr. James Mackenzie says that among the several circumstances which directed his attention to the subject of prognosis in heart conditions was the fact that in the examination of individuals for life insurance he was the means of rejecting a number because of some heart affection who have been able to follow their ordinary occupations for many years and who have never suffered from any form of heart failure. This experience led him to seek the reasons why some individuals with certain characteristic phenomena drifted and died, while others seemed little the worse. Books were vague on the subject, so he was forced to seek out lines of observation for himself. These lines were simply to differentiate clearly the various phenomena, to watch individuals possessing them as the years passed by, and to take every opportunity of seeing how the heart responded under the ordinary strain of life. It was always necessary to seek associated phenomena and to note the state of health of the individual. We first consider what bearing has the cause of the abnormal sign upon the efficiency of the heart; does it indicate heart failure or foreshadow the occurrence?

A clear idea of the term heart failure is necessary. Heart failure is the inability of the heart to maintain a circulation so efficient that it can meet the strain that a healthy, vigorous life demands. In the physiology of the heart its forces may be considered composed of two kinds—a rest force strong enough to maintain an efficient circulation when the body is at rest, and a reserve force, brought into action when the body or any part of it is called into activity. The amount of reserve force varies in different individuals, making the standard peculiar to the individual. Notwithstanding this, the knowledge of what a healthy individual can do is well known, the individual himself recognizing his limitation.

Heart failure sets in by a limitation of the cardiac response to effort in the first instance, and as it progresses, the limitation becomes more and more restricted until the rest force is encroached upon and dropsy or dyspnea appear. At first the evidence of heart failure is entirely subjective and gradually increases until physical signs are present. A normal circulation is dependent upon a healthy heart muscle, which has its limitation of power. Heart failure is an expression of an exhausted heart muscle. As an outcome of this expression, the presence of any sign revealed by physical examination, however abnormal it may seem, is of no serious significance so long as it is the only sign present, or so long as there is no limitation of the reserve force of the heart. Mackenzie considers this statement of very great importance in the prognosis of heart affections, especially with regard to life insurance. The most common manifestations of the heart regarded as abnormal are the irregularities. A normal heart is supposed to be perfectly regular in its action, whereas, from birth to death, normal hearts may be frequently irregular in rhythm. The clinical teaching of the past dealing with irregularities has been due to a mistaken idea, according to Mackenzie, and only in recent years has there been any attempt to differentiate the various forms of irregular heart action. The inability to distinguish the grave forms from those which are normal and not serious has led to the assumption that all irregularities were of evil import.

There are certain irregularities, such as the youthful irregularity and the extra-systole, present so frequently in healthy people and occasioning no signs of heart failure, that under no circumstances should be considered as impairing the prospect of the individual, when they are the only manifestation. If present with other signs, then the prognosis should be based on the other signs, not on the irregularity. Other irregularities, such as auricular fibrillation, heart-block, pulsus alternans, etc., should arouse an inquiry as to how far their cause has embarrassed the heart muscle, as they are always the outcome of an actual heart lesion, and are accompanied by other evidences of cardiac disease, or impairment of the heart muscle. It is therefore upon the associated evidences that the decision must be made.

Murmurs are the second important group of heart affections. As far as life insurance is concerned, MacKenzie divides them into two great groups: those of no significance, and those whose significance has to be considered and weighed. The first group embraces all those which are termed functional and those in which there is a doubt whether they are functional or not. They are supposed to originate according to their mechanism, as mitral, tricuspid, etc. From the life insurance aspect, so long as these murmurs are the only phenomena present they are not to be regarded. Many murmurs associated with a harmless type of irregularity, as the extra-systole, do not become grave; but associated with a limitation of the reserve force, as a weakened heart muscle, then the decision should be based on the cause of this inefficiency, which is either a lesion of the muscle itself or an affection which has impaired the muscle. In the second group are placed all the organic murmurs, and here a variety of conditions is to be found. These should be studied as to whether the process causing them is stationary and if it is embarrassing the heart muscle, or if progressive, and the rate of progress. Murmurs indicate that the valves have been invaded by a disease process and the danger is that the mischief is not quiescent. In cases of heart failure with murmurs it is the muscle lesion which is the causative agent, and not the regurgitation, as supposed by the upholders of the back pressure theory. The prospect of the patient's future can be estimated fairly well by considering the state of the heart's powers and the physical signs of the condition of the muscle.

It will be seen, therefore, that however instructive the evidence revealed by physical examination may be, the essential information for prognosis is the appreciation of the condition of the heart muscle, which can only be learned by a full knowledge of how the heart responds to effort. Speaking generally, exhaustion of the reserve force in a healthy or diseased heart is always accompanied by sensations of distress, and the premature occurrence of these signs indicates the limitation of the heart muscle. Breathlessness is the most common sign and the one least considered on the ordinary insurance blank. The knowledge obtained in recent years on the irregularity of the heart's action constitutes a revolution, not only with regard to the accurate differentiation of the irregularities, but of their diagnostic and prognostic significance.—Life Assurance Medical Officers' Association, March 15, 1913.

Book Reviews.

Orthopedics in Medical Practice. By Prof. Adolf Lorenz, Regierungsrat, Director of the Imperial University Ambulatorium for Orthopedic Surgery in Vienna, and Dr. Alfred Saxl, Assistant Surgeon in the Imperial University Ambulatorium for Orthopedic Surgery in Vienna. Authorized Translation from the German by L. C. Peel Ritchie, Ch.M., M.D., F.R.C.S. Edin., Late Volontär-Arzt in the Imperial University Ambulatorium for Orthopedic Surgery in Vienna; Tutor in Clinical Surgery, University and Royal Infirmary, Edinburgh. With thirty-nine Illustrations. Price $3.00 net. New York: William Wood and Company, 1913.

This book supplies a distinct want in medical literature. It discusses the close interrelation between orthopedics and general medical science. It shows how a number of skeletal and muscular developments play an etiological rôle in the production of internal diseases, and similarty it points out the effects of various so-called medical diseases upon the skeletal system. The book is divided into six chapters which deal in order with the respiratory, circulatory, digestive, urinary, nervous, and locomotory systems, respectively. Among some of the important points touched upon in the first chapter is the relation of scoliosis to displacement of the thoracic organs. It is pointed out that any condition in the osseous chest wall which may restrict the movements of the pulmonary apices, may play a rôle in the evolution of tuberculous involvement at these sites. There is reviewed the work of Freund, Mendelsohn and Schmorl who pointed out the connection between pulmonary tuberculosis and rigidity of the spinal column, and particularly the presence in the former of shrinking of the first rib and ankylosis of the sternoclavicular joint. Freund's operation consists in division of the shortened and ossified cartilage. Nickol has perceived a close relationship between cervical rib and apical tuberculosis, the latter having been discovered in many cases of the former condition. Poncet has recently alluded to a possible tuberculous origin of scoliosis. The deforming effects of emphysema, bronchitis, and pleurisy are fully described. Fat embolism as the result of operative manipulation of the bones or joints is a subject that concerns both the internist and the surgeon. In a similarly complete manner the authors discuss the many orthopedic aspects of the diseases in other parts of the body. Of particular interest is the full and ample description of the orthopedic treatment of the paralyses and paraplegias. One can have no hesitation in recommending this volume to the general practitioner as a complete survey of the latest developments of orthopedic science in its manifold bearings on internal medicine. The book is well written and the translator has brought to his task a sympathetic knowledge of the subject-matter which gives a peculiar individuality to this English edition. The printing, paper, and binding are in keeping with the excellent character of this work.

Syphilis and the Nervous System. For Practitioners, Neurologists, and Syphilologists. By Dr. Max Nonne, Chief of the Nervous Department in the General Hospital, Hamburg, Eppendorf. Authorized Translation from the Second Revised and Englarged German Edition. By Charles R. Ball, B.A., M.D., Chief of the Nervous and Mental Department, St. Paul Free Dispensary; Neurologist, St. Joseph's Hospital, Bethesda Hospital, Mounds Park Hospital, Minnesota Soldiers' Home, and State Home for Crippled and Deformed Children. 98 illustrations in text. Price $4.00. Philadelphia and London: J. B. Lippincott Company, 1913.

There are few subjects in medical science that have undergone such revolutionary changes within the past few years as has that which deals with syphilis of the nervous system. The most recent of these changes is the discovery by Noguchi of the presence of the microorganism of syphilis in the brains of paretics. Unfortunately, this, the second edition of Nonne's well known work was printed before the announcement of Noguchi's discovery, for it is quite probable that this announcement would have changed some of Nonne's opinions regarding the relationship of syphilis and paresis. He states that general paresis is not a specific syphilitic disease of the brain, but that the relationship between it and syphilis is manifold and intimate. He holds that syphilis weakens the already more or less predisposed brain in its resistance, so that later injurious factors are able to influence it toward the development of paresis. In the light of Noguchi's discovery the relationship between syphilis and paresis is to be regarded as not merely an intimate one, but one of direct causal nature. One of the opinions of Nonne has attracted considerably attention, namely, that paresis is curable. This opinion was based upon the observation of ten cases in the course of nineteen years, in which cases Nonne thought that recovery had occurred. Further observation has reduced this number of cases of recovery to four, and Nonne still believes that an absolute cure in paresis is possible. This opinion is supported by that of many neurologists in different parts of the world. The broad scope of the subject of syphilis of the nervous system is simply mirrored in its wonderfully complete exposition in the pages of this book. The titles of the chapters convey a fair idea of its scope. They are as follows: introduction; pathology; etiology of nervous lues and specific endarteritis; syphilitic cerebral meningitis; specific basilar meningitis; symptomatology of syphilis of the base of the brain; symptomatology and prognosis of specific basilar meningitis; neuroses and psychoses in syphilitics and in cerebral syphilis; dementia paralytica and syphilis; syphilis of the spinal cord; meningomyelitis; tabes and syphilis; cerebrospinal form of syphilis; syphilitic disease of the peripheral nerves; hereditary syphilis and the nervous system; concerning the behavior of the Wassermann reaction in the blood and spinal fluid, also pleocytosis and the increase of globulin (phase 1) in syphilogenetic diseases of the nervous system; prophylaxis, and salvarsan therapy. As regards the last the opinion of Nonne deserves careful attention. He states that in cerebrospinal syphilis "the cases in which salvarsan has had an entirely favorable effect are in the minority. In by far the greater number of cases the superiority of salvarsan over mercury and iodide is not apparent. In cases of gummatous disease of the central nervous system immediate salvarsan therapy may be said to be specially indicated. In specific diseases where the vital centers are involved it is especially contraindicated." A complete bibliography completes this volume. In making a final appraisal of this work one may state that it belong to the category of those medical works that record individual experience and original research. It completely covers the entire field of syphilis of the nervous system. It is well written, and translated into clear and idiomatic English. It should prove of distinct use to the general practitioner no less than to the neurologist and syphilologist.

Aids to Practical Pharmacy for Medical Students. Adapted for the Examinations in "Practical Pharmacy" and Materia Medica of the Conjoint and other Examining Boards, and for General Use, by A. Campbell Stark, M.B., B.S. (Lond.), L.S.A. (Eng.), Ph.C., University Medallist and Exhibitioner in Materia Medica; Late Demonstrator on Materia Medica, St. George's Hospital Medical School; Late Lecturer on Biology, Westminster Hospital Medical School. Second edition. Price $1.00 net. New York: William Wood & Company. 1913.

This little book is intended as an aid to students preparing for the examination in Practical Pharmacy of the Conjoint Examining Board of Physicians and Surgeons in England. Naturally, the British Pharmacopoeia is the basis of the present work; and, while the book seems to be well prepared, it is not likely to be of much service to students in American Schools.

Old Age: Its Care and Treatment in Health and Disease. By Robert Saundby, M.D., Edinburgh; Hon. LL.D., St. Andrews and McGill; Hon. M.Sc., Birmingham; Fellow of the Royal College of Physicians, London; Hon. Fellow of the Royal College of Physicians, Ireland; Professor of Medicine in the University of Birmingham; Consulting Physician to the General Hospital (Birmingham), to the Birmingham and Midland Counties Eye Hospital, and to the West Bromwich Hospital; ex-President, formerly President of Council, of the British Medical Association; Emeritus Senior President of the Royal Medical Society. Price $2.10. New York: Longmans, Green & Co.; London: Edward Arnold, 1913.

This is one of the most practical of the many books on old age that have appeared in the last quarter of a century. That it is most readable need not be said to those familiar with Dr. Saundby's writings, and that it contains wise counsel simply expressed will also be taken for granted. In the opening chapter on The Duration of Life, Dr. Saundby gives many well-authenticated examples of men and women who have lived to the age of a hundred and over with mental faculties well preserved and free from the sorrows and distress laid by the psalmist upon the backs of those living beyond the fatal limit of threescore years and ten. In the second chapter normal old age, or senile physiology, is discussed, while the rest of the book is devoted to the diseases of the aged. A number of appendices contain dietary tables and recipes, a list of exercises suitable for elderly people, and formulæ of the prescriptions mentioned in the text.

Clinical Surgical Diagnosis. For Students and Practitioners. By F. de Quervain, Professor of Surgery and Director of the Surgical Clinic at the University of Basle. With 510 Illustrations and 4 Plates. Translated from the Fourth Edition by J. Snowman, M.D. Price $7.00 net. New York: William Wood and Company, 1913.

The casual turning of the pages of this book, with a glance at the many illustrations, convinces one at the outset that one is in the presence of a volume that mirrors original experience. A varied and abundant clinical material, and a sympathy with the diagnostic needs of students and practitioners, bred of long experience in teaching, has enabled the author to produce a work of eminently practical value. Each surgical condition is discussed from the viewpoint of the symptom for which the patient presents himself to the surgeon for relief. The completeness with which the author surveys every diagnostic possibility is well exemplified in the section on lockjaw. In turn there are briefly described the numerous conditions of which inability to open the mouth in the striking symptom: neurosis, apoplexy in the lower frontal convolution, tumors of the pons, tetanus, periostitis, actinomycosis, tuberculosis, or osteomyelitis of the jaw, gangrenous stomatitis, acute arthritis of the articulation of the jaw, discitis (a slight looseness of the capsule of the articular condyle), arthritis deformans of the articulation of the jaw, suppuration in the tympanic cavity, injuries with bony proliferation in the neighborhood of the articulation of the jaw, retrotonsillar abscess, cicatricial bands in or under the mucous membrane, and malignant neoplasm near the tonsil. Only one who has had to deal with an obscure case of partial lockjaw can appreciate the exhaustive manner in which the author discusses this condition. The brief case reports that elucidate the important points bring these before the reader in a most vivid manner. The illustrations are particularly helpful. There are 509 of these, and all are reproductions of photographs of the author's own cases. It is difficult to pick out any one portion of this work for special commendation, for the entire field of surgical diagnosis is thoroughly gone over. An interesting chapter is that in which the author discusses acute inflammation within the abdominal cavity. The various regions of the abdomen are discussed with reference to the surgical conditions localized in these regions. A separate chapter is devoted to acute appendicitis. An important distinction is made between two groups of cases of so-called chronic appendicitis. The author points out that logically this term should be applied only to that form of appendicitis in which the appendix does not recover from its inflamed condition. The other group of cases has nothing to do with the appendix, including cases of localized ulcerative colitis, localized functional disturbance of the large intestine in their various forms, such as cecal distention, etc. Without yielding to the temptatoin to point out some of the other seasoned views of the author, the reviewer must be content to place an estimate upon this work as one that the general practitioner no less than the surgeon will read and reread with pleasure and profit. The beauty and clearness of its illustrations, and the excellent typography, paper, and binding, all serve to make this work a model of the printer's art.

A Manual of Venereal Diseases. Introduction by Sir Alfred Keogh, K.C.B., late Director-General of the Army Medical Service. History, Statistics, Invaliding, etc., Brevet Colonel C. H. Melville, R.A.M.C., late Professor of Hygiene, Royal Army Medical College. Clinical Pathology, and Bacteriology, Brevet Colonel Sir William Leishman, K.H.P., F.R.S., R.A.M.C., Professor of Pathology, Royal Army Medical College. Clinical Course and Treatment, Major C. E. Pollock, R.A.M.C. Second Edition, Revised and Largely Rewritten. With New Matter by Major L. W. Harrison, R.A.M.C., Clinical Pathologist, Military Hospital Rochester Row. Price $3.75. London: Henry Frowde, Hodder & Stoughton; New York: Oxford University Press, 1913.

The volume is based upon a study of the methods of treatment of venereal diseases in the British army. That the military service provides ample opportunity for the investigation of these diseases, with the patients under close control and scrutiny, there can be no question. In addition to the excellent delineation of the well-known clinical features of the venereal diseases the authors have had ample opportunity to test the various methods of treatment, and these are given in full, together with an estimate of their relative merit. We know of no single textbook on venereal diseases which presents such a full exposition of the latest diagnostic and therapeutic methods in syphilis. The search for differentiation of the *Treponema pallidum;* the serum diagnosis of syphilis, with the details in its technique; the various modes of administering salvarsan and neosalvarsan, all come in for careful consideration. The orthodox methods of treatment are, however, not neglected. The sections devoted to gonorrhea are also strikingly complete and detailed. In fact the reader may be confused by the profusion of methods in seeking some routine, definite plan of treatment. The sociological aspects of venereal disease are not overlooked. Prophylaxis is discussed, but in its moral and disciplinary aspects, rather than in its latest "army-packet" phase, so loudly extolled on this side of the Atlantic. This volume is provided with a number of excellent colored photogravures, and other illustrations. It is well written and should prove a boon to the student of the latest developments in the diagnosis and treatment of venereal diseases. The printing, paper, and binding leave nothing to be desired.

Headache. Its Varieties, Their Nature, Recognition and Treatment. A Theoretical and Practical Treatise for Students and Practitioners. By Dr. Siegmund Auerbach, Chief of the Polyclinic for Nervous Diseases, in Frankfurt, a.M. Translated by Ernest Playfair, M.B., M.R.C.P. Price $1.50. London: Henry Frowde, Hodder & Stoughton; New York: Oxford University Press, 1913.

Headache is one of the common though by no means one of the minor maladies. The interpretation of this symptom demands a profound knowledge of medicine. This small volume of 208 pages, written by a neurologist presents a comprehensive survey of the many varieties of headache and delineates the different modes of treating them. The classification is particularly helpful. First the author recognizes the more independent forms of headache as migraine, neurasthenic headache, and the nodular (rheumatic) or induration headache. Next he discusses the headaches associated with diseases of individual organs. In the following section the author deals with headaches in general diseases. The combinations of different forms of headache are described in the final section. A most ingenious theory is advanced to explain the origin of migraine. The author assumes that the predisposition to this disease depends upon a disproportion between cranial capacity and brain volume, and that the attacks are brought on by exciting causes which, through the action of the vasomotor mechanism, are calculated to exaggerate this disproportion. This work constitutes an original and most instructive contribution to the literature of neurology and cannot fail to be of distinct service to the general practitioner.

Practical Bacteriology, Microbiology, and Serum Therapy (Medical and Veterinary). A textbook for laboratory use by Dr. A. Besson, formerly director of Bacteriological Laboratories of the Military Hospitals of France and of the Péan Hospital; Laureate of the French Institute. Translated and adapted from the fifth French edition by H. J. Hutchens, D.S.O., M.A., M.R.C.S., L.R.C.P., D.P.H. (Oxford), Heath Professor of Comparative Pathology and Bacteriology of the University of Durham; formerly an Assistant Scientific Investigator, Royal Commission on Tuberculosis. With 416 illustrations, 149 of which are colored; price $10.50 net. London, New York, Bombay, and Calcutta: Longmans, Green & Co., 1913.

Besson's monumental treatise on microorganisms has long enjoyed a high repute in France, and among bacteriologists of other nations, but is little known to the profession in general in other than French-speaking countries. We are glad, therefore, to welcome an English translation, especially one so well made as this. Mr. Hutchens has discharged his difficult task with great skill, avoiding an awkward literalness of version while preserving admirably the meaning and even the style of the original. He has not given us, however, a mere translation, but has enriched the original with many notes and additions which the rapid advances in microparasitology in the interval between the publication of the fifth French edition and that of the English translation have made necessary. The work is divided into seven parts, of which the following are the titles: I, General Technique; II, The Pathogenic Bacteria; III, The Parasitic Fungi; IV, The Pathogenic Spirochætæ; V, The Protozoan Parasites; VI, The Filtrable Viruses; VII, The Application of Bacteriological Methods to the Examination of Water, Sewage, and Air. The illustrations are good and the book is beautifully printed on thin but opaque paper. The general practitioner will find much of interest and exceeding value in this book, and for the bacteriologist it is well-nigh indispensable.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 17, 1913.

DR. HENRY D. CHAPIN, CHAIRMAN.

Atypical Infantile Paralysis.—Dr. F. L. WACHENHEIM read this paper. He stated that one of the striking features of the present epidemic of infantile paralysis, which had prevailed since 1907, was the large proportion of atypical cases. The following course was run by the typical and classical form of the disease. The patient suddenly fell ill with moderately high temperature, more or less gastrointestinal disturbance, and general weakness of the extremities. In a few days the temperature would abate, leaving the child paralyzed in one or more limbs. This paralysis gradually passed off, except for one group of muscles, in usually one of the lower extremities, which remained atrophied and disabled for life. Infantile paralysis was considered a disease of the anterior cornua, usually of the lower spinal cord, rarely involving other portions of the gray matter. During the epidemic of last fall Dr. Wachenheim observed seven cases, of which only one was typical; the other six cases were so atypical that he thought them worth reporting in full. Attention was called to a series of cases reported by Dr. Henry Koplik in which symptoms recalling both cerebrospinal and tuberculous meningitis dominated the clinical picture throughout the course of the disease. It seemed that the Fehling test was of doubtful value in severe cases of meningoencephilitis; this seemed to vary, according to the intensity of the infection, rather than the etiology of the disease. A characteristic feature of these cases was the sudden onset. The high leucocyte count seemed to be a constant feature. The cerebrospinal fluid at first was cloudy, but differed from that of cerebrospinal meningitis in that the sediment consisted largely of leucocytes; in a few days the fluid cleared up, leaving only a delicate fibrin on standing. The germ of poliomyelitis, which had recently been found, might turn up in the spinal fluid of this group. The intraspinal pressure was usually not high. The temperature was apt to run the course usually observed in poliomyelitis, possibly rather high at first, but falling to normal before the remission of the grave cerebral symptoms. After all was said the most striking feature was the disproportion between the cerebral symptoms and the general condition of the patient; this was the chief guide in the diagnosis of his case. After the first few days one infant held its own and even gained in weight, in spite of the presence of an apparently serious intracranial condition. This clinical discrepitancy was so remarkable that it could not fail to attract the notice of the attending physician, and clear up speedily all remaining doubts as to the type of the disease. The prognosis in this type of the disease was fairly good as to life; unfortunate after effects, as a paralysis of some muscular group, mental impairment, and amaurosis, might remain. The resulting paralyses were apt to be of the flaccid type distinctive of poliomyelitis, not spastic as after ordinary meningitis. The remarkable variations displayed by so small a clinical material were sufficient to convince them that infantile paralysis was one of the most protean affections of the central nervous system.

The Year's Progress in Poliomyelitis Research.—Dr. GEORGE DRAPER had no paper because the subject assigned to him really called for a review of the literature on the subject of poliomyelitis; consequently anything he might say had already been published. However, there were three points worthy of special emphasis. The first was in reference to the visceral pathology of the disease. Poliomyelitis had hitherto been classified as a disease of the nervous system, but now it had been discovered that there were general lesions. The lesions in the liver, similar to those noted in leukemia, were specially worthy of mention. The second point had reference to the epidemiology. In Sweden washings from the rectum of patients suffering from poliomyelitis had been injected into monkeys and the disease reproduced, though it did not follow the typical course pursued in man. It had been found that the virus existed in the nose and mouth of healthy persons who had been thrown in contact with those suffering from the disease. Thus these secretions, long suspected as being the carriers of poliomyelitis, had proved to be such. The third point was the identification of the organism itself. This organism was extremely small, just on the limits of visibility, was anaerobic and cultivated only with the greatest difficulty. It took the Giesma stain best, was variable to the Gram stain, but tended to be Gram positive, varying, however, with the constituents of the media. It fulfilled Koch's laws. The discovery of this organism was not only of moment because of its relation to poliomyelitis, but because it opened up a new field of bacteriology.

Dr. HENRY HEIMAN said that when one considered that there were at least nine varieties of poliomyelitis it was not surprising that so many atypical cases were found. Dr. Wachenheim's cases would serve as a nucleus for many other types to be observed in the future. Hardly any part of the cerebrospinal nervous system was exempt from attack, and this might account for the many types of this disease. Because of spasticity the cerebrospinal and meningeal types were sometimes confused with meningitis. After the subsidence of the spastic signs paralysis appeared and the diagnosis became clear. In the severe cerebral forms it was almost impossible to give a definite prognosis. Dr. Heiman asked, since the germ was anaerobic, how it was able to live in the nasal secretions or in the rectum.

Dr. H. L. AMOSS said that Dr. Draper had described the organism of poliomyelitis very accurately. It was only with the greatest difficulty that they had succeeded in cultivating the organism at all and according to Noguchi's method. They tried out about twenty-five samples of ascitic fluid before they at last succeeded in cultivating the organism from the nervous tissues of the monkey dead of the disease. The organism had been found in the spinal fluid of a monkey, but never, so far as he knew, in that of the human being. They had concentrated fluids from several human cases of acute poliomyelitis under diminished pressure at 33° C. and injected it into the brain of monkeys, resulting in suggestive symptoms only. With regard to the viability of the organism, one of their strains had been kept in 50 per cent. sterile glycerine in the ice-box for twenty-four months and was still capable of producing the disease when inoculated into the brain of monkeys.

Dr. F. L. WACHENHEIM said that the points he wished to emphasize were the difficulty of diagnosis in the meningeal cases in the early stages, and that in a few days one could size up these cases as not typical meningitis. The subject of insects as carriers of poliomyelitis had not been discussed during this meeting and it was to be hoped that it would be brought up later.

Results of the Investigations of Summer Diarrhea at the Boston Floating Hospital, 1910-1913.—Dr. HENRY I. BOWDITCH of Boston said that his remarks would be only an accumulation of facts and would illustrate the fact that by intensive work they could accomplish more than by extensive work. The Boston Floating Hospital had accommodations for 120 ward patients and 160 day patients. Children were taken at all ages. There was a post-graduate staff of about 16 internes, 2 bacteriologists and 1 pathologist connected with the hospital. The scientific work was started in 1909, when Dr. Lucas and one of his confrères were working on agglutinins in the blood of dysenteric cases. In 1910 Dr. Arthur I. Kendall made, with the assistance of the staff, an extensive bacterio-clinical study of diarrheas, especially dysenteries. They established a shorter method by twenty-four hours of making the bacteriological diagnosis of the dysenteries produced by the Flexner and Shiga bacilli. They found the gas bacillus was in many cases the predominating organism and then they demonstrated a clinical test for its presence in the stools. This test consisted in taking a tube one-quarter full of milk and inoculating it with mucus from a movement. The whole was boiled over a Bunsen flame for one minute and then kept at blood heat for from six to nine hours. A positive gas bacillus infection peptonized the milk, squeezed out the whey, riddled the curds with gas and produced a strong odor of butyric acid. This same year they shortened the former long period of starvation in dysenteries from three, five or seven days to twenty-four hours. Boiled water was given as temporary starvation. This was followed by barley, lactose and buttermilk, according to the infection. They used for the first time (1910) a solution of dextrose (2½ per cent. in normal saline) for stimulation in cases of dysentery of the Flexner type with marked loss of water and depletion. The idea underlying the procedure was that the normal amount of circulating dextrose in the system had been partially used up and by supplying the infecting organism with the food it could be prevented from living on the body proteins and producing toxins. In 1911 they isolated for the first time the Shiga bacillus from the blood. This year they made investigations along the line of rectal

irrigations, trying various solutions; most of them did little good. They now gave saline irrigations immediately on admission and but few during the course of the disease. Where the infection was low they used silver nitrate (3 per cent.) Other solutions, like tannic acid, were of little effect. They found that pyelitis was rather frequent in their cases, the majority of them occurring in cases of streptococcus infection. In 1912 there was an increase in the number of cases infected with the gas bacillus. They carried out the theory of feeding high proteins, giving buttermilk, fat free milk and Eiweiss milk without any trouble. After the first week they felt perfectly safe in giving these without making bacteriological examinations. Almost all the children improved under this treatment. The year 1913 was as yet an incomplete story. During this year there was a predominance of the "slime" bacillus. This bacillus first appeared in August, 1912. The bacterial study of these cases during these years seemed to show that the predominating bacillus in the month of August would be the predominating one in the following July. This carried out the cyclic phenomenon of epidemic diseases. They used this year high protein feedings during July because of the presence of the gas bacillus. In August the Flexner bacillus appeared and because of the danger of giving high proteins in such cases they quickly changed to other methods of feeding, five or seven per cent. lactose solutions with or without barley starch.

Dr. Richard M. Smith of Boston, Mass., said that they had seen primarily three large groups of patients on the Floating Hospital, the first presenting simple digestive disturbances caused by errors in diet, due either to a single constituent of the food or a combination. The diseases in this group were not primarily associated with the summer months. The second group included patients who had more than a simple digestive disturbance. The etiology of this group was not well understood. The third group included cases which were true infections and were to be sharply differentiated from the other groups. The organisms responsible for the individual cases varied, but the cases as a whole could be satisfactorily grouped together under the term infectious diarrhea. The type of organism showed a marked seasonal tendency, one type usually predominating in a single summer. The particular organism could not be absolutely determined by clinical study alone but must be determined by bacteriological investigation. The pathological findings from different bacteria varied strikingly, as also did the response of individual infants to various kinds of treatment, whether fed upon carbohydrate or protein high diet. Many of the types of organisms and the corresponding clinical condition were only partially understood, but they recognized several distinct groups, the Shiga, Flexner bacilli and the gas bacillus. The work was undertaken with no preconceived ideas, but they were trying to draw logical conclusions from the combined clinical, pathological and bacteriological study of the material as it had presented itself at the Floating Hospital.

Dr. Rowland G. Freeman said that if Dr. Bowditch could teach them some simple way of identifying the different sorts of bowel infections and a successful treatment for each sort they would be indefinitely indebted to him. His first experience in pediatrics having been in the autopsy room he said he had always used an anatomical classification. Clinical cases were readily classified in this manner. The lesion was in most cases an ileocolitis and only the lower twelve inches of the ileum and each end of the colon being infected, the transverse colon being distended with gas. These cases might be acute or chronic. There might be simply a congestion or an enlargement of the follicles, or an erosion giving rise to blood in the stools. Dr. Freeman had always loked forward to a bacteriological classification, but so far their information had not been sufficient for this. Some years ago great efforts were made to isolate the Flexner bacillus from the stools, this organism then being known as the Shiga bacillus and he then had two large services in institutions and in studying the results of the bacteriological examinations he felt convinced that the Flexner bacillus was simply a terminal infection and had no significance as regards prognosis and treatment. They were not, however, looking for the Flexner bacillus as a predominating organism.

Dr. Godfrey R. Pisek said that the combined work of the clinician, the laboratory worker and the chemist had told them something practical and given them a clew to the results obtained in selected cases. The men in Boston were on the right track in stating that certain types of bacilli were predominant in certain localities and not in others. It was well known that in New York sociological agencies, educational propaganda and rational methods of management had effected marked results.

Dr. Herman Schwarz said that they had examined a large number of stools at Mount Sinai Hospital and the Flexner and Shiga bacilli were found in all cases in which blood and pus were present in the stools. It seemed possible that these bacilli might be the normal terminal infection in practically all these diarrheas.

Dr. Alfred F. Hess said that Dr. Bowditch had not mentioned the reaction of the stools. Dr. Kendall originally emphasized the importance of this reaction, stating that where an acid reaction was present one should use proteids, and where the reaction was alkaline a carbohydrate diet should be used. They had found that in spite of an alkaline reaction children frequently got well with proteid food. Dr. Hess said that he did not quite understand what was meant by starvation of from five to seven days. It was stated that sugar was suggested because sugar had partially disappeared from the blood. Was that a demonstrated fact or a supposition? It was most important in these cases to give water. This could be given by the drip method by way of the mouth, as was done by the rectum, using a nipple. A quart could thus be given in a day and this method had the further advantage of keeping the baby quiet.

Dr. Henry Heiman said that in thinking over Dr. Bowditch's work it seemed to him that he had proved his cases to have been infectious diarrheas. They were all acquainted with the fact that the Flexner, Shiga, and other bacilli caused specific infections, but these must be distinguished from the so-called summer diarrheas in which there was no specific infection, in which hundreds of saprophytes might be found, but in which these bacteria played only a secondary rôle. At the Mount Sinai Hospital, in the so-called summer diarrheas, the examinations for the Shiga bacilli were almost always negative; out of forty cases examined there was only one in which cocci were found, though Gram negative bacilli were always present. Dr. Heiman believed that most cases ordinarily called summer diarrheas were not caused by specific organisms, but were mostly due to nutritional disturbances with gastrointestinal symptom in which the bacteria played only a secondary rôle.

Dr. J. Finley Bell of Englewood said that the work done at the Floating Hospital was most interesting, but it entailed elaborate laboratory apparatus which was not practical in private practice; probably a simpler method of determining the type of diarrhea with which one was dealing would be evolved. He referred to one case in which blood and mucus were present and in which diplococci were found in the stools, and asked if that was a distinct organism or a streptococcus infection.

Dr. Roger Dennett said that he was interested in the therapeutic test of determining the variety of diarrhea with which they were dealing by feeding sugar solution. In New York many of them had been using just the opposite test, that of giving high protein mixtures as a routine in all cases except the acute febrile dysenteries, in which gruels seemed to be indicated. With the exception of this last variety of cases Eiweiss milch and the strong milk and water mixtures seemed less liable to do damage and appeared more logical on account of Finkelstein's work in which he attributed so many cases of "injury" and "intoxication" to sugars. What about using barley gruel mixtures or cooked starches instead of the sugar solution? Would starches take the place of sugar solution? Therapeutically there must be some place for the time-honored barley gruel which had been used for so many years in the treatment of diarrhea.

Dr. Henry I. Bowditch of Boston said he had not intended to evade the question of mortality, and that while he did not have the figures with him the mortality for 1910 and 1911 was high when the Flexner, Shiga and streptococcus bacilli were predominant. The mortality in the presence of the gas bacilli was fifty or sixty per cent. less until the last month of the summer, when it suddenly jumped up, due to a wave of the Flexner bacilli. Dr. Hess was right in saying that he considered that acid movements were those in which it was wise to give proteid food; as to the advisability of giving sugars the reaction must be taken into consideration with other symptoms. By starvation he meant starvation as regarded food, but water was pressed. As to the treatment of those cases grouped as summer diarrhea to which Dr. Herman had referred, there was no sharp rule for procedure. They had not used Eiweiss milch so much, partially on account of the difficulty of preparing it, but were rather inclined to the milk mixtures. Dr. Dennett had asked in regard to the lactose; they had usually used lactose, though barley water might be administered in the early stages. One advantage of giving starch was that there was less fermentation with it, but it did not provide much nourishment.

There was one more point to be mentioned and that was the great opportunity for them to get results from groups of cases by cooperative study. They would like such a group of cases studied in Philadelphia, in New York, Boston, etc., and then they could come together and get something definite from the results of their observations.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Ohio State Medical Board.

June 2-5, 1913.

(*Concluded from page* 827.)

PATHOLOGY.

1. By what agencies does the body protect itself against the entrance and harmful effects of pathogenic bacteria?
2. Describe morbid anatomy of bronchopneumonia.
3. What changes take place in extravasated blood? Name them.
4. What changes take place in an inflamed part, causing redness and swelling?
5. Describe the process of primary healing—of secondary healing.

DIAGNOSIS.

1. State the difference between organic and functional murmurs.
2. Describe method of examining the size of the spleen.
3. What is the diagnostic significance of edema of one arm and hand?
4. Describe râles, mention varieties and state diagnostic significance.
5. What are friction sounds and what do they signify?
6. What pathological significance has an increased vocal fremitus?
7. What is dyspnea and what does it signify?
8. Describe diagnostic indications from the character of cough.
9. Describe aphasia; name varieties in reference to localized lesions.
10. In what pathological conditions is ocular paralysis present?

PRACTICE.

1. Name the different forms of non-malignant stricture of the rectum. How far above the anus is a simple stricture usually found?
2. Describe your procedure in making a physical examination of the abdomen.
3. Describe the urinary findings in diabetes mellitus and chronic interstitial nephritis.
4. Make a differential diagnosis of pleuritic and pericardial effusion.
5. Define and give etiology of neuritis.
6. Give pathology of typhoid fever. Name some of its complications.
7. Give symptoms and management of paranoia.
8. Differentiate between renal and hepatic colic.
9. Give the differential diagnosis of variola.
10. Give the differential diagnosis between paralysis agitans and tabes dorsalis.

OBSTETRICS.

1. State your views with reference to examinations and what you would expect to learn by them.
2. Name some of the causes and give treatment of hemorrhage after labor.
3. How would you distinguish one shoulder from the other, when the hand and arm cannot be reached?
4. Outline general scheme of treatment for persistent and pernicious vomiting of pregnancy.
5. Give diagnosis and management of the third position of the vertex.

SURGERY.

1. Discuss acute osteomyelitis.
2. Describe complete inguinal hernia—give symptoms of strangulation and treatment.
3. Name varieties of goiter and mention the indications for surgical interference.
4. What lesions would you consider in a severe injury about the ankle joint?
5. In an oblique fracture of the lower third of the femur, state the usual position and give the muscular control of the fragments.

DERMATOLOGY, SYPHILOLOGY, AND DISEASES OF THE EYE, EAR, NOSE, AND THROAT.

1. Describe infantile eczema—outline its treatment.
2. Differentiate scabies from prurigo.
3. How do you recognize and treat scabies?
4. Describe the initial lesion of syphilis.
5. Briefly outline treatment of syphilis.
6. What faulty anatomical conditions of the eye constitute myopia, and how can it be corrected by lenses?
7. Describe simple chronic rhinitis.
8. Describe otitis media purulenta and mention possible complications.
9. Describe iritis; give causes and treatment.
10. Describe laryngeal tuberculosis.

ANSWERS.

PATHOLOGY.

1. *Agencies by which the body protects itself against the entrance and harmful effects of pathogenic bacteria*:—The acidity of the gastric juice, urine, and vaginal secretion; the alkalinity of the blood; the general bactericidal action of the blood and lymph; the action of the leucocytes and phagocytes; the agglutination action of the blood; and the general antitoxic action of the organism.

2. *Morbid anatomy of bronchopneumania*:—"The disease affects both lungs, and begins in the terminal bronchioles, spreading thence to the infundibula and alveoli. The consolidated patches have therefore a lobular arrangement, but if many adjacent lobules are affected the consolidation may be almost lobar. The bronchioles are inflamed and frequently plugged with mucus, and their walls and the surrounding interstitial tissue are infiltrated with small cells. The walls of the air vesicles in the consolidated area are congested, their epithelium is swollen, and their lumen is filled with proliferated epithelial cells, leucocytes, and a mucous or mucopurulent (not fibrinous) exudate. Many lobules are collapsed, but not inflamed, from plugging of the bronchioles. When cut into, the small consolidated areas are seen to be conical in shape, with their bases towards the pleura, reddish in color, with indefinite margins, and separated from each other by crepitant lung tissue. Adjacent lobules may be emphysematous (compensatory emphysema). The bluish-gray collapsed areas are most numerous in the lower lobes." (Wheeler and Jack's *Handbook of Medicine.)*

3. *Changes which occur in extravasated blood*:—"Blood extravasated in the tissues soon coagulates and subsequently undergoes disorganization, the red corpuscles breaking down into pigment-matter, which may be carried away or deposited at the seat of hemorrhage. The fluid elements may be completely absorbed, or, stained with coloring-matter, may remain as a cyst. A focus of hemorrhage may set up reactive inflammation and lead to encapsulation by new connective tissue. Sometimes hemorrhagic accumulations become inspissated and undergo calcification. Blood in the serous sacs does not readily coagulate, but mingles with the normal liquid secretion. It may be gradually absorbed or may undergo degenerative changes, especially when infected by microorganisms." (Stengel's *Pathology.)*

4. "The phenomena of inflammation are dilatation of the arterioles, capillaries, and small veins. At first the blood current is quickened, then retardation occurs, and may progress to stasis and thrombosis. During this time exudation of plasma and white corpuscles from the small veins and perhaps the capillaries, is going on. . . . Red corpuscles may be exuded and broken up, setting free their coloring matter. . . . *Redness* is due to the hyperemia, and disappears on pressure, unless stasis has occurred. *Swelling* is due to the hyperemia and exudation. If the inflammation is under tense structures, like the palmar fascia, the swelling may appear in another part, as on the back of the hand." (*Aids to Surgery*).

5. *Healing by first intention:* "Exudation of plasma from the neighboring blood-vessels occurs, and its fibrinogen is converted into fibrin, so gluing the edges of the wound together. Leucocytes are poured out and infiltrate the wound, absorbing any blood clot present. These are followed by fibroblasts (connective-tissue cells), which take their place. New capillaries form by budding out from adjacent ones, and vascularize the new tissue. Fibrous tissue is formed by intercellular exudation from the fibroblasts and so the fibrocicatrical union is complete, for at the same time epithelium is spreading over the narrow surface line."

Healing by granulation or second intention occurs when the edges of the wound have not been brought together. "Exudation of plasma and leucocytes occurs, followed by

fibroblasts and budding from the capillaries, thus forming granulation tissue. The dead tissues or sloughs are separated, and a red area of granulation is then exposed. The deeper layer of granulation tissue is converted into fibrocicatricial tissue, which contracts, and so the wound gradually lessens in size. In the meantime epithelium spreads in from the edge over the surface, and so the scar is completed. (*Aids to Surgery.*)

DIAGNOSIS.

1. *Organic murmurs* are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease.

Organic murmurs may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

2. An enlarged spleen is diagnosed by palpation. "The position of the patient should be right lateral if minor enlargements are to be noted, as in typhoid fever or other acute infections, and the right hand should make pressure posteriorly while the left makes palpation. Abdominal distention defeats palpation save in great enlargement and the normal spleen is not palpable. If greatly enlarged the dorsal position is to be preferred and the condition can hardly be overlooked, unless with a tense wall the careless or hurried examiner fails to get below the actual border or to distinguish between muscular resistance on the one side and the splenic mass on the other. In these cases the chief notch in the anterior border is sharply defined and quite distinctive. In all cases where doubt arises as to the nature of a large tumor in the splenic area it should be remembered that a splenic growth or tumor is superficial, that its dullness is marked and can be carried directly back to its normal area behind the ninth, tenth, and eleventh ribs, that it ordinarily moves directly with respiration, and that if the colon be inflated splenic tumor dullness is not impaired. On the contrary, large renal tumors extend more deeply, are relatively fixed or immovable, are likely to be reniform or nodular, and are crossed by an area of resonance if the colon be distended with air. As in the case of the liver, a downward displacement of the diaphragm may produce an apparent increase in the lower splenic area just as an emphysematous lung or a pneumothorax may cause an apparent diminution in its upper percussion area."—(Greene's *Medical Diagnosis.*)

3. *Edema of the arm and hand* "may be the result of a tumor of the mediastinum or lung, aneurysm of arch of the aorta, innominate (right arm) or axillary artery, thrombosis of the axillary vein, enlargement of the axillary glands, or trichiniasis." (Butler's *Diagnosis of Internal Medicine*).

4. *Rales* are adventitious sounds heard during respiration; they originate either in the air passages or the pleura. Rales are classified as dry rales and most rales. *Dry rales* are sibilant or sonorous, and are heard in bronchitis, bronchial asthma, and pulmonary phthisis. *Moist rales* are crepitant, subcrepitant, mucous, and metallic rales. *Crepitant rales* are heard in lobar pneumonia, pulmonary edema, hemorrhagic infarction, and atelectasis. *Subcrepitant rales* are heard in bronchitis, pulmonary edema, atelectasis, phthisis, and edema of the lungs. *Mucous rales* are heard in phthisis, bronchitis, and bronchiectasis. *Metallic rales* are heard in cavities, consolidation around large bronchi, and compressed lung.

5. *Friction sounds* are rubbing or creaking sounds due to friction of opposed pleural surfaces when inflamed and coated with fibrin; they are similarly produced in like conditions of the pleura and peritoneum.

6. *Increased vocal fremitus* is found in:—Consolidation or infiltration of the lung, pneumonia, pulmonary tuberculosis; also when there is a tumor between the chest wall and a large bronchus; sometimes, too, in the presence of cavities in the lungs.

7. *Dyspnea* is difficult, painful, or laborious breathing; shortness of breath.

"*Dyspnea may be due* to obstruction of the air passages, pressure upon the respiratory system from without by tumors, and distention of abdomen, diseases of the lungs and pleura, heart disease, asthma, anemia, or paralysis of muscles of respiration as the result of hemorrhage, tumors, or degeneration of the respiratory center in the medulla or toxic agents in the blood. It may be *inspiratory* when it results from obstruction, as in foreign bodies in the larynx or trachea, or it may be *expiratory*, as in emphysema or bronchial asthma. A combination is the more frequent condition. In all forms of dyspnea it is important to determine whether the shortness of breath bears any relation to exertion. Dyspnea *independent of exertion* is a serious condition and is symptomatic of severe cardiac and pulmonary disease. Dyspnea *dependent upon exertion* is less serious and is observed in health, simply debility, anemia, obesity, and somewhat moderate cardiac debility."—(Hughes' *Practice of Medicine*).

8. "DIAGNOSTIC INDICATIONS FROM THE CHARACTER OF COUGH.—(*a*) *Dry cough* is found in the first stage of acute bronchitis, pulmonary phthisis, bronchial asthma, pertussis, epidemic influenza, and acute pneumonia; pleurisy, and diseases of the nasopharynx and larynx. It is also caused by:—Inhalation of irritating fumes or dust, elongated uvula or enlarged lingual tonsil, foreign bodies, and 'reflex' or extra-respiratory conditions. A single, slight, dry cough, frequently repeated, is the 'hacking' cough premonitory of pulmonary phthisis. (*b*) *Loose cough* occurs in the later stage of acute bronchitis, pertussis, pneumonia, pulmonary phthisis, bronchial asthma, bronchiectasis, and pulmonary gangrene. (*c*) *Paroxysmal cough* is most characteristically seen in pertussis. It also occurs in the second stage of acute bronchitis and the softening stage of pulmonary phthisis. It may be due to abscess of the lung, bronchiectasis, and phthisical or gangrenous cavities; also to enlargement of the bronchial glands, mediastinal tumor, and other extra-respiratory lesions. (*d*) *Laryngeal cough* may be due to spasm of the larynx, largynitis, tuberculous or syphilitic ulceration of the larynx, inhalation of dust particles in certain occupations, impacted foreign body in larynx, food particles entering the larynx in pharyngeal paralysis, elongated uvula, or enlarged tonsils; it may also be due to irritation of the recurrent laryngeal branch of the pneumogastric nerve by the pressure of thoracic aneurysm, cancer of the esophagus, enlarged bronchial glands, and mediastinal tumor. (*e*) *Suppressed cough* may be due to:—Pleural inflammations (especially diaphragmatic pleurisy), pneumonia, pleurodynia, acute peritonitis, and abdominal rheumatism; also pertussis, or acute coryza and bronchitis." (From Butler's *Diagnosis of Internal Medicine*).

9. "The speech areas, four in number and in kind, are in the left hemisphere in righthanded persons and in the right in lefthanded persons. There are two types of aphasia, which is the loss of the power of speech, known as motor and sensory aphasia. The motor speech center lies in the posterior part of the third frontal convolution (Broca's convolution), just in front of the center of the muscles of speech (hypoglossal and facial nerve centers). A lesion of the motor speech center causes motor aphasia, in which there is a loss of the word-forming power, although the tongue is movable and the patient may understand spoken and written language and knows what he wants to say. It is as if memory of the motor combinations essential to produce speech were lost.

"The power of writing is usually lost with motor speech. The probable location of its cortical center is in the posterior two-thirds of the first, and perhaps in the second, temporal convolution. A lesion here causes 'word deafness,' a sensory aphasia in which the memory of the sounds of words is lost so that they are not understood, though hearing may be normal.

"The visual speech center lies in the posterior part of the angular gyrus in the outskirts of the higher visual or the visuopsychic field. Word-blindness (alexia), or the loss of memory of printed or written language, is caused by a lesion here, though sight itself may be normal." (Woolsey's *Surgical Applied Anatomy*).

10. *Ocular paralysis may be present in:*—Syphilis, tumor of the brain, cerebral hemorrhage, locomotor ataxia, meningitis, toxemia or injury or inflammation (in the sphenoidal fissure).

PRACTICE.

1. *Non-malignant stricture of the rectum* may be due to:—Syphilis, inflammation, pressure, tuberculosis, ulceration, gonorrhea, scar-tissue, and adhesions. It is usually found about an inch to an inch and a half above the anus.

2. *Physical examination of the abdomen:* "All clinical methods are applicable to this region. The customary prior cathartic removes misleading fecal masses, but accomplishes little more, and may produce a flatulent distention and troublesome peristaltic activity.

"The head and shoulders, particularly the former, should be high, the feet firmly placed and the patient in an easy

and unconstrained dorsal posture. To relax the walls the knees may be drawn up, but often better relaxation may be had with the legs extended or but slightly flexed. The breathing should be easy and natural, with the mouth open, and the patient's attention should be diverted by conversation and inquiry. The hands should be warm, the light should be adequate, its source behind the patient, and no clothing or other covering embarrass the examiner. The flat of the palm and fingers, not the tips, should be used, tender areas should not be immediately approached, nor does the discovery of one justify repeated and purposeless punching and poking. In palpating movable organs or growths respiratory movement should be met directly by the tips of the fingers at right angles to the free margin, the hand being firmly but gradually depressed in deep expiration and allowed to rise laggingly and shift slightly upward to meet the descending border in inspiration. If the hand moves the organ or growth under examination, the opposite palpating hand should be almost motionless as the other brings the organ or tumor to it. After tolerance is established, the finger tips may be used to determine consistence and outline. The deep or superficial character of any pain or tenderness developed by examination and its precise localization or extent of diffusion should be accurately determined. Malingering or hysterical patients can often be misled or diverted by conversation, by attracting their attention to some special region which is being explored by one hand while the supposed tender point is palpated by the other or by misleading and positive statements as to the effect of pressure, forced respiration, etc., upon the spurious symptoms. In some cases nothing less than general anesthesia suffices. The dorsal posture is the best for general purposes, but the lateral is of value in palpation of the spleen or kidneys or for the purpose of 'spilling' the intestinal contents of a large-bellied person to render more accessible the lateral region under examination. The patient may with advantage be placed upon the hands and knees or in the knee-chest position to bring a growth forward against a thin and relaxed abdominal wall. Finally, all portions of the abdomen should be thoroughly examined, not forgetting the hernial openings. The full hot bath is a most useful adjunct." (Greene's *Medical Diagnosis*).

3. In *diabetes mellitus,* the urine is enormously increased in amount, the specific gravity is high (about 1.025 to 1.040), and sugar is present.

In *chronic interstitial nephritis,* the urine is pale in color, has a low specific gravity (about 1.005 to 1.010), traces of albumin may sometimes be found, a few hyaline casts are sometimes present, the solids are generally slightly diminished.

4. *Pleuritic and pericardial effusion:*—"In pericardial effusion dyspnea is a more prominent symptom than in pleural effusion. In the former the heart is not displaced to the right, as in pleural effusion. In pericardial effusion percussion shows the area of flatness to be circumscribed, and to be most marked in the axillary region. Along the posterior margin of the left pleura normal pulmonary resonance is obtained, whereas in pleural effusion a flat note is elicited over this region. In pericardial effusion the heart-sounds are distant, feeble, or muffled, while in pleural effusion the quality of the heart-sounds is unaltered." (Anders and Boston's *Medical Diagnosis*).

5. *Neuritis* is inflammation of a nerve or of a bundle of nerve fibers. It is said to be caused by:—Exposure to cold, traumatism, extension of inflammation from surrounding parts, certain infectious diseases, poisons, and cancerous or anemic conditions.

6. Typhoid fever. *Pathology:*—"Principally inflammation of the lymphoid tissue of the lower portion of the ileum, with more or less catarrh throughout the bowel. *Peyer's patches*—(1st week)—are swollen through infiltration of leucocytes, the surfaces raised and fawn-colored. The infiltration involves the submucous coat, and may extend to the muscular layer. The lesions are most numerous at the lower end of the ileum. (2nd week).—The surface becomes abraded; sloughs form, which are often bile-stained. (3rd week).—Sloughs come away, leaving ulcerating surfaces. Typical typhoid ulcers, with undetermined edges, are thus formed. A few solitary glands undergo the same process. At the end of the week the ulcers begin to granulate, but healing is usually slow. The mesenteric glands may undergo the same changes, but more often become swollen, red, and tender only, or break down into cheesy masses. The spleen and liver are enlarged; the heart is soft and flabby. The voluntary muscles undergo granular degeneration; in fact, the changes are those found after death from high temperature, etc."

Complications.—"Hemorrhage; from bowel, nose, or mucous surfaces. Perforation, which may occur even in mild cases. It is commonest in the third and fourth weeks. Peritonitis, with or without perforation. Meteorism or tympanites. Thrombosis, usually of the femoral vein, and embolism. Neuritis, and later 'typhoid spine.' Bronchitis, and pneumonia, lobar in the early stages, later catarrhal. Early 'typhoid state,' or early cardiac failure. Bed-sores." (From Jack's *Handbook of Medicine*).

7. *Paranoia* "is essentially chronic, the delusions becoming fixed upon one particular subject, or set of subjects, which in turn dominate the life of the individual. The most common characters of these systematized delusions are delusions of persecution or suspicion, delusions of exaltation or grandeur, or of pride, and delusions of unseen agents or influences. The range which these delusions assume is most wide and varied, but always associated with the *ego.* The patient is being persecuted not because, as in melancholia, he has committed some sin, or thinks he has, and deserves punishment, but because the persecutors wish to deprive him of his rights, titles, or estate, or degrade him, or in some way injure him. In the diagnosis there are three points to keep in mind: First, the duration—the fixed, systematized delusions must have existed over one year; second, the absence of symptoms of mania or melancholia; and third, the presence of systematized delusions affecting the personnel of the individual." (Hughes' *Practice of Medicine*).

The disease is incurable. The patient should be placed under the best hygienic conditions; as much out-of-door life as possible, and the minimum of drug therapy. Nutritious food (sometimes stimulants are necessary), plenty of sleep, and moral treatment are indicated.

8. In *renal colic:* The pain is in the region of the affected kidney; it radiates down the thigh; there are intense rigors; retraction of the testicle may be present; also history of previous attacks or of calculi; the urine may be scanty, suppressed, or bloody.

In *hepatic calic:* The pain is in the region of the liver; it radiates to the right scapula and toward the umbilicus; chills and sweats are common; also vomiting, and sometimes symptoms of collapse and jaundice; calculi are found, if at all, in the feces.

9. *Variala:* The eruption usually appears first on the forehead and wrists, and on the third or fourth day; it is first macular, then papular, then vesicular, and, finally, pustular; it does not appear in successive crops; the spots are multilocular, and do not collapse on being punctured; the papule is hard and shotty, and does not disappear on stretching the skin. *Varicella:* The eruption usually appears first on the trunk, is evident on the first day, comes in successive crops, is not shotty, and disappears on stretching the skin; the spots are unilocular, and collapse on being punctured. *Scarlet fever:* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the tongue is of the "strawberry" type; the lymphatics in the neck may be swollen, and there is sore throat. *Measles:* Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small, dark red papules with crescentic borders, beginning on face and rapidly spreading over the entire body; desquamation is branny. The eruption is dark, not uniform, and is shotty; coryza, coughing, and sneezing may be present; Koplik's spots are present. *German measles:* Period of incubation, ten to seventeen days. Stage of invasion, one day. Eruption appears on first day, is most intense on second day, consists of red papules, often fades from face before it is seen on the limbs. The pulse is not much accelerated, all the symptoms are slight. Desquamation is very slight. There may be slight sore throat and swollen cervical glands. Koplik's spots are absent.

10. *Tabes dorsalis* is characterized by the absence of the patellar reflex, swaying of the body and inability to maintain the erect position when the eyes are closed, the Argyll-Robertson pupil, general ataxia, and various crises.

Paralysis agitans is characterized by the presence of various tremors, and the peculiar "propulsion gait."

OBSTETRICS.

1. *Examinations.* "A general examination should be made as early in pregnancy as possible, especially of the heart and lungs, because pregnancy has an important relation to diseases of these organs. Obstetric examination is usually unnecessary until the seventh month, when the

fetus is viable and of sufficient size to be readily palpated. At this time both an abdominal and vaginal examination is required. Abdominal examination should include inspection, palpation, and auscultation. The discovery of any abnormality will permit at this time of proper consideration of both mother and child. Practice in palpating the fetal head will often aid the attendant in confirming or denying the patient's history as to the duration of the pregnancy. The position of the fetus, however, is not yet sufficiently fixed, and, therefore, a second abdominal examination should be made in the middle of the last month. It is inadvisable to conduct a patient through pregnancy without at least one vaginal examination, which is best done at the first abdominal examination. A second examination in the last month is not always essential, but often the relations of the fetal head to the pelvis may better be determined in this way, and thus enable the attendant to more confidently begin the conduct of labor.

"An internal exploration is advisable in all cases as a part of the preliminary examination; in women pregnant for the first time and in others whose obstetric history leads to suspicion of pelvic deformity, it is imperative. The objects are to learn the condition of the soft parts—vulva, vagina, cervix, especially in multigravidæ—to confirm the diagnosis of presentation and position, to detect a possible vicious insertion of the placenta, and to determine the capacity of the bony pelvis.

"*During labor.* Before examining internally the hands must be disinfected. This part of the examination aims to determine the condition of the vulva, the vagina, the cervix, and the bony pelvis, and to verify the diagnosis of fetal presentation and position as made out by the abdominal examination. Possible anomalies of the fetus, too, that may complicate the labor should be recognized. The resistance likely to be offered at the vulva as the head descends, the lubrication of the vagina, the degree of dilatation of the cervix, the thickness and consistence of the cervical border, the presence or absence of injuries sustained in former labors are to be noted.

"A surgically clean internal examination entails little or no risk of infection. Yet abundant statistics have shown that the best puerperal results are obtained when it is possible to refrain wholly from internal interference. All unnecessary manipulations within the passages should be avoided. If a thorough antepartal examination has been made, a single vaginal examination during the first stage of labor will usually suffice. This is generally advisable to make sure that the cord or an arm has not prolapsed and that no other complication has developed. Should any irregularity be detected repeated examinations may be required.

"It should be a routine practice to make a bimanual examination of the pelvic organs in the third or fourth week of the *puerperium*. The object is to determine the presence or absence of injuries of the vagina or cervix, the degree of uterine involution, and the possible existence of retrodisplacement of the uterus or other abnormal conditions." (Jewett's *Practice of Obstetrics*).

2. POST-PARTUM HEMORRHAGE. *Causes:* Anything interfering with the firm contraction of the uterus after the expulsion of the child; retained placenta, or membrane, or clots; weakness of the uterine muscle; rapid labor; delayed labor; poorly developed uterine muscle; inflammation or disease of uterus.

Treatment: Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging with gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

3. When the hand and arm cannot be reached, the physician should find the axilla; this points toward the child's feet.

4. *Pernicious vomiting of pregnancy.* "The treatment consists in rest in bed in a quiet, darkened room and the administration of easily digested foods, such as milk, broths, eggs, etc. A careful search must be made for some local exciting cause, and if any such condition is found, it should receive appropriate treatment. Sexual intercourse should be interdicted. The bowels should be kept freely open. Sodium bromide, camphor, cocaine, silver nitrate, cerium oxalate, hyoscine hydrobromide, antipyrine, etc., are among the drugs used internally. Rectal alimentation may be necessary, and, as a last resort, dilatation of the cervix and internal os, or abortion may be performed. (*Pocket Cyclopedia.*)

5. The third position of the vertex is the right occipito-posterior.

Diagnosis:—"On abdominal examination the striking features are the ease with which the small parts of the fetus can be felt in front, and the fact that the back can either not be made out, or is made out well to the right flank. Auscultation is apt to be very unsatisfactory. Usually the heart is heard round toward the right flank, but owing to the damping down of the sound by the thick muscles, it is but poorly heard. Occasionally it is heard also in front and to the left owing to the throwing forward of the child's thorax. On vaginal examination one is frequently struck by the ease with which the anterior fontanelle can be felt. The sagittal suture is found in the right oblique, but the posterior fontanelle is high up behind the head if the flexion is imperfect.

Management.—"(*a*) *When diagnosed while the head is at the brim.* (1) Leave it alone. The occiput will probably rotate to the front all right if it is given plenty of time. (2) If flexion appears to be deficient, try to increase it by pushing up the sinciput with the fingers in the vagina during a pain, at the same time pressing down upon the fundus with the other hand. (3) The head may be rotated by passing the hand into the vagina and grasping it between the fingers and thumb. At the same time the shoulders must be rotated by abdominal palpation, or else the head will at once go back to its original position. This maneuver generally requires an anesthetic.

"(*b*) *When diagnosed after the head has entered the pelvis.* (1) Leave it alone. After exercising the patience of all concerned, it will probably rotate spontaneously. Only about one case out of twenty fails to do so. (2) An attempt may be made to increase flexion as before. (3) Manual rotation may be attempted as before, but the head must first be flexed and gently pushed back out of the pelvis. (4) If the pains are weak, forceps should be applied well back on the head, so that when traction is applied, flexion will be promoted. The head should then be pulled well down on to the pelvic floor. If it begins to rotate, take off the forceps and leave the rotation to nature, merely keeping the head on the pelvic floor by pressure on the fundus. After rotation the forceps may, if necessary, be reapplied and delivery completed.

"(*c*) When the occiput has definitely rotated into the hollow of the sacrum, and the case has become a persistent occipitoposterior, forceps should be applied and the head delivered with the occiput posterior. The perineum should be guarded as much as possible, and any tears stitched up at once. In extreme cases craniotomy and pubiotomy may require to be considered." (Johnstone.)

SURGERY.

1. *Osteomyelitis* is inflammation of the bone and marrow; the term is often used now for inflammation of bone. It is *caused* by infection, the bacteria gaining entrance either through a wound, or by extension from neighboring tissues, or they may be brought by the blood.

Symptoms: Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present.

Treatment consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails amputation may be necessary.

2. *Symptoms of strangulated hernia: General.*—"Severe pain comes on suddenly after some effort, at first referred to the umbilicus, and subsequently to the site of the hernia. This is accompanied by some shock. The pulse is weak, and, though slow at first, becomes rapid; the skin is cold and clammy; vomiting occurs, and soon becomes frequent and fecal-smelling. Constipation is complete, though both feces and flatus may be passed at first from the lower bowel. The patient generally becomes exhausted from the vomiting and inability to take food. When gangrene occurs the temperature becomes subnormal, the pulse very rapid and weak, and the patient dies of toxemia from the general peritonitis which follows gangrene. *Local.*—A tumor forms at one of the hernial sites; or more often the patient has been the subject of a hernia, which he now finds to be irreducible, tense, tender, and without impulse on coughing. If allowed to persist the sac and coverings become gangrenous."

Treatment is taxis or operation. "Operative treatment should be undertaken at once when gentle taxis has failed. An incision is made over the sac, which is then opened. There is usually fluid in the sac, so there is no danger of wounding the gut. The fluid is washed away, then the cause of strangulation is made out, and a hernia knife guided up to it by a finger or broad hernia director. The constriction is nicked in one or two places and the gut is drawn down so that the site of strangulation may be examined. Omentum is ligatured and removed. According to the condition of the intestine the further treatment differs. (1) If the gut, though black, has not lost its polish, it is reduced by gently compressing it to remove the edema. (2) If gangrene is suspected, the strangulated portion must be resected, and end-to-end union established. (3) If the gut is undoubtedly gangrenous, one of two methods must be adopted: (*a*) If the patient is profoundly collapsed and will not bear a prolonged operation, an artificial anus is established by dividing the constriction outside the sac, so as not to open the peritoneal cavity. The loop of bowel is then opened to give free exit to the feces. Most of the cases which have to be treated in this way are so bad before treatment is commenced that a fatal termination must be expected. (*b*) If the patient can possibly stand it, immediate resection gives the best chance, and with Murphy's button or a bobbin much time can be saved. A radical cure is advisable after the strangulation has been relieved, unless the patient's condition contraindicates it. Liquid food is given at the end of twenty-four hours, and the bowels need not be disturbed for five or six days, when castor oil may be given." (*Aids to Surgery.*)

3. *Varieties of goiter:* Parenchymatous, cystic, adenomatous, exophthalmic, fibrous, and malignant. *Indications for surgical interference:* Dyspnea, cysts, adenomata, malignant disease (if possible), and in simple cases when medicinal treatment fails.

4. *A severe injury about the ankle joint might suggest:* Fracture of the lower end of tibia, or fibula, or of both bones; Potts' fracture, dislocation at or near the ankle, fracture of one of the tarsal bones, sprained ankle, rupture of the tendo Achillis.

5. *In oblique fracture of the lower third of the femur:* The lower fragment is drawn backward by the Gastrocnemius and Plantaris muscles, and upward by the Rectus, Biceps, Semimembranosus and Semitendinosus muscles. The upper fragment is drawn inward by the Pectineus and Adductors, and forward by the Psoas and Iliacus.

DERMATOLOGY, SYPHILOLOGY, AND DISEASES OF THE EYE, EAR, NOSE, AND THROAT.

1. *Infantile eczema* is generally pustular, and when occurring on the scalp is known as "milk crust." It is said to be due to general weakness, malnutrition, susceptibility of the tender skin to wounds, and the tendency to scratch an itching skin. In the management of this condition special attention must be given to the infant's food; the child should wear a mask or skullcap (whenever possible) smeared with a suitable ointment. Unna's paste is also serviceable. Scratching must be prevented. Calomel, rhubarb and soda, and cod liver oil are all beneficial.

2 and 3. *Scabies* is a contagious, animal, parasitic disease, due to the *Sarcoptes scabiei*, characterized by burrows and a multiform eruption, and attended by severe itching. The eruption usually occupies certain areas where the skin is thin; these are the interdigital spaces, the flexor surface of the wrist and arm, the anterior and posterior axillary folds, the mammæ and nipples (in women), the umbilicus, the buttocks, the penis, the inner side of the thighs and legs, and the toes. The face is exempt except occasionally in infants. The itching is intense and worse at night. The affection is curable, but dermatitis may result from overtreatment.

Treatment consists in a thorough scrubbing with soap and warm water, followed by friction to dry the skin, and the application of sulphur ointment; the latter to be repeated morning and night for three days. The whole process may need to be repeated one or more times.

Prurigo occurs on the extensor surfaces, and is accompanied by enlarged glands.

4. The *initial lesion of syphilis* is called the chancre. It usually appears in from two to six weeks after inoculation, and may show itself as a papule, erosion, or ulcer. It is sharply defined, has a cartilaginous feel, and has an indurated base. The secretion, if any, is thin and serous. It is generally single, and is accompanied by enlarged lymphatic glands.

5. "The *treatment of syphilis* in all cases should be directed toward the general health; and tonics, stimulants, nutritious food, and fresh air should be freely allowed. Mercury is used for its direct effect upon the disorder, and potassium iodide in the late stage for its general alterative and absorbent effect. In the early stage the protiodide, the bichloride, or the biniodide of mercury may be administered by the mouth. In the intermediate stages this may be continued alone or combined with potassium iodide. Often in the late stages potassium iodide is administered alone. In children and pregnant women mercurial inunctions are preferred. There are other methods of introducing mercury into the system, such as by intravenous or hypodermic injections, but the above-mentioned methods are most generally used. Involvement of the special organs requires appropriate local treatment in addition to the administration of the iodides and mercurials. The latest addition to specific therapy is Ehrlich's synthetic arsenic compound, arsenobenzol, or salvarsan. A single injection of a proper dose is reported to be as destructive to the *Spirochæta pallida* as quinine is to the *Plasmodium malariæ*." (*Pocket Cyclopedia.*)

6. *Myopia* is a condition in which the anteroposterior axis of the eye is abnormally long, and parallel rays are focused in front of the retina. The condition can be corrected by means of a concave lens.

7. *Chronic rhinitis* generally results from successive attacks of acute rhinitis, and is apt to cause atrophy or hypertrophy of the nasal mucous membrane. Crust formation occurs in the latter condition. The patient becomes very liable to take cold. Treatment is general as well as local.

8. *Acute purulent otitis media:* Acute catarrhal otitis media, instead of undergoing resolution, may pass into acute purulent otitis media (especially in exanthemata) from the passage of pathogenic germs from the nasopharynx into the middle ear. The pain will become more intense, the hearing dull, tinnitus will become louder and more distressing, and fever usually sets in.

Chronic purulent otitis media is due to the permanent lodgment of staphylococci in the acutely inflamed middle ear. This unfortunate result is usually brought about by improper—*i.e.* excessive—treatment of acute otitis media, generally by the patient, but sometimes, regrettably, by the physician.

Complications of middle ear disease are inflammation of the mastoid cells, caries, and necrosis, phlebitis, meningitis, and brain abscess. (From *Cyclopedia of Medicine and Surgery.*)

9. IRITIS is inflammati[on] iris. *Causes:* Syphilis, rheumatism, gonor[rhea] es, leprosy, scrofula, tuberculosis, injury [to] the eye. *Symptoms:* Pain, photophobi[a] [con]iary congestion, discoloration of iris, exud[ate] [num]ber. *Treatment:* Causal abstraction of [the] s, atropine, diaphoresis, shielding the eye fr[om]

10. *Tuberculous laryngitis* "ma[y] [occ]ur it is usually secondary to phthisis. Tu[bercles] break down, and become ulcers, which coalesc[e] [in] great destruction of tissue. The most co[mmon] for these ulcers is about the arytenoid cartila[ges] cords, and the under surface of the epiglottis. [The] granulations on the posterior wall of the larynx [are] strongly suggestive of tuberculosis. The subjective s[ymp]toms are those of syphilis of the larynx. Tubercle bac[illi] may be found in the expectoration. The treatment is that of tuberculosis elsewhere, with applications of lactic acid and insufflations of iodoform or thymol iodide. Tracheotomy may be needed for the same conditions as in syphilis of the larynx." (Stewart's *Surgery.*)

Strangulated Hernia in Young Infants.—R. N. H. Anglin Whitelocke reports two instances of successful operation for strangulated hernia in female infants aged 22 and 17 days respectively. Several points of interest to the surgeon are gathered from the experience of these cases, as follows: (1) The early stages at which strangulation occurred, and with apparently no definite cause. (2) The unusual nature of the hernial contents: in the one case an ovary and tube as well as small intestine; in the other, an unduly mobile cecum with large appendix measuring 3½ in. (3) The successful issue in each case even after the obstruction and symptoms of strangulation had lasted for over three days. (4) The absence of postoperative shock after a general anesthetic and herniotomy, and in the younger infant after appendicectomy in addition. Herniotomy in such young infants must be exceptional, and a successful appendicectomy at the age of seventeen days is certainly so.—*British Journal of Children's Diseases.*

Miscellany.

The Collection of Disputed Claims.—Thomas F. Reilly in his book "Building a Profitable Practice" tersely discusses the principles that should guide one in the collection of a professional bill. In most States claims for services must be filed within two years. The physician must prove that he has been employed and that his services have been accepted. He must show in court the date of visits and the amount charged up each day after the visit made. This, however, is not always insisted on. If a visiting list is used, nothing should be written concerning the disease that the patient suffered from on the page where the charge is entered. In a card index one cannot legally use one side for the patient's history and the other side for his accounts, as this card index can not be presented in court. If the patient has died and left an estate the bill should be filed with his executors, or if there are no relatives or executors, the bill should be filed with the public administrator. In physicians' records of accounts arbitrary signs are of little value in courts of law. To be collectible the exact charge should be put down as "visit," "office-call," "operation," etc., and should be entered on the day of the service. Except with big bills and with people owning property it is not advisable to sue. A parent is bound to pay for medical services rendered to a minor child, and if the child is over 21 years of age the parent is not liable unless some special order is given. The husband is liable for the medical bills of his wife even though not living with her at the time. The master is not responsible for the medical attention given to his servant. If the wife calls the physician to attend the servant the master is not responsible even though the wife promises to pay the bill. A sea-captain is responsible for medical services rendered to a seaman during the voyage or until the latter is discharged. If the physician is called by anyone to attend a patient, the one calling the physician (excepting in the instances mentioned above) is not bound to pay for the services unless he states specifically that he will pay the bill. When a physician employs another physician to assist him he is entitled to recover the value of the services of the assistant. The Statute of Limitations as to the validity of an account varies in different States. In many States each new payment makes the whole account date from that time. Books of account are of variable value. In New York the physician's account book is admissible if he can show that it is his regular account book, and that no one except himself and wife made any entries. The fact that there are entries showing that patients paid bills is sufficient proof that the account book is properly kept. The books shown as evidence should be of original entry. Each item must be charged separately and a specific sum should be charged for each visit. If an operation has been performed the charge for this should be entered separately. If the account books contain any information as to the physical condition of the patient, they are in most States inadmissible as evidence, owing to the Statute of Privileged Communications. In most States a judgment secured against a patient acts as a bar against subsequent suit on the latter's part for malpractice. In collecting claims from estates the account, properly sworn to, should be presented to the administrator or executor usually within six months. If the claim is rejected an action should be brought against the administrator within three months, otherwise there is great danger that the claim will be barred. The order of collection in most States is as follows: (1) funeral expenses; (2) expenses of administration; (3) expenses of past illness; (4) judgments; (5) public debts, and (6) simple contract liabilities. In some States the physician's claim falls in the sixth class.

CLINICS, DEPARTMENT OF PUBLIC CHARITIES

CALENDAR, NOVEMBER, 1913

	MONDAYS		
City Hospital	Ophthalmology	Dr. Stronse	2:00 P.M.
	Surgery	Dr. Dawbarn	2:00 P.M.
	Dermatology and Syphilis	Dr. Gottheil	3:00 P.M.
Cumberland St. Hospital	Surgery	Dr. Walmsey	3:00 P.M.
	Laryngology and Rhinology	Dr. Stewart	4:00 P.M.
	Surgery, Oral	Dr. Shea	4:30 P.M.
	TUESDAYS		
Neurological Hospital	Neurology	Dr. Byrne	9:00 A.M.
Randall's Island Hospitol	Orthopedics	Dr. Ogilvy	10:00 A.M.
	Ophthalmology	Dr. Mulcahy	2:30 P.M.

INDICATIONS FROM THE URINE IN THE TREATMENT OF CERTAIN DISEASES OF THE SKIN.*

By L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK,

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

THE urine is a very complex fluid and reflects the condition of the system from day to day to a surprising degree, and in a manner which is not realized as fully as it should be. If subjected to an absolutely critical analysis of every possible ingredient it is probable that no two specimens of urine passed by the same individual at intervals of some hours would be exactly alike, as has been shown by many observers, since the publication of the remarkable lectures of Dr. Bence Jones nearly fifty years ago.[1] It was this book which first seriously directed my attention to the intimate relations between the condition of the urine and various systemic changes.

It is not difficult to appreciate how or why the urine may furnish valuable indications in regard to the treatment of certain diseases of the skin when we recall the anatomical and physiological relations of the kidneys to the system. As I have remarked on another occasion,[2] "After the blood has received the elements of nutrition from the stomach and intestines, and has been prepared and modified by the various organs, including the internal secretions, it also receives excrementious substances from the tissues, largely through the lymphatic system. Then, after it has been aërated and purified by the lungs, and is on its way through the aorta to nourish the body, a small artery takes, as it were, a sample of this arterial blood to each kidney for final judgment as to its quality and for the removal from it of injurious substances, as far as possible. This relatively small portion of purified blood is then returned to the vena cava and thus again to the lungs, for further oxidation. It is to be remembered that only a relatively small portion of the blood flows at one time through the kidney (even under forced diuresis it is estimated that only one-twentieth of the blood passes through the kidneys in a minute), while the great bulk of it passes unchanged directly to nourish the brain and the rest of the body, waiting for its further purification by the kidneys. These organs might, therefore, be spoken of as the final judges of what perfect blood should be, as their function is to eliminate substances injurious to the body."

The urine, therefore, is the most perfect exponent of the catabolism and anabolism of the system, and too much stress cannot be laid upon the importance of its repeated and complete volumetric analysis in connection with the treatment of very many cases of diseases of the skin; for by it we may learn, daily if we will, much which cannot be otherwise ascertained in regard to the manner in which the nutritive processes are carried out, and the character of the blood which induces the cutaneous disorder.

It is understood, of course, that our study relates to the results of functional derangements of the urinary secretion, and not to evidences of organic disease of the kidneys; for albumen and casts, and even glycosuria, play but little part in the urinary changes which we are considering. On the contrary, very many of the abnormal conditions of the urine to be considered later have very little if anything to do with the integrity of the kidneys, but rather represent a failure in some portion of the system to elaborate perfect blood; so they would rather indicate a proper and faithful performance of kidney functions, in attempting to remedy a faulty blood state, and remove injurious elements.

These abnormal conditions, then, relate to volumetric derangements in the many constituents of urine which might ordinarily be considered normal, but which under minute analysis is often found to be, in one way or another, quite different from the standard of that belonging to perfect health. This is so constantly found to be the case among the thousands of analyses which have long been made in my laboratory in connection with private patients, exhibiting many different cutaneous ailments, that for years I have leaned very heavily on my repeated quantitative urinary analyses, in different cases, for guidance in regard to the proper internal measures required. In this brief paper I cannot attempt to analyze the mass of data collected, but I would like to so strongly impress the practical teaching that I have had from them that others will be inclined both to study the subject and also to reap the benefit which I have obtained in practice, from a close consideration of the urine in its relation to certain diseases of the skin. For this purpose I have had collected the data from some three thousand (2,952) analyses made in my laboratory since 1909, and will utilize them as best I may in the brief time at my disposal. The analyses have been made according to Purdy,[3] and his percentages have been used.

It is recognized, of course, that the condition or composition of the urine may be influenced greatly at any time by the character and quantity of the food and drink consumed, also by the amount of oxygen inhaled, by physical and mental exercise, and by the action of various organs, etc.; therefore, in estimating the importance of any particular change found in its composition, much thought and care must be exercised in order to interpret cor-

*Read at the Seventeenth International Medical Congress, London, August 7, 1913.

rectly the significance or bearings of the same upon the conditions present, whether it be on the skin or any portion of the body, and to apply the proper remedies, whether dietetic, hygienic, or medicinal.

In general medicine the relation between the skin and the excretion from the kidneys is a matter of every-day observation and consideration. Thus, all are familiar with the temporary changes which may take place in the urine from a chilling of the surface, in fever, before and after an attack of gout, etc., as also with the dry, parched skin in chronic Bright's disease and glycosuria, likewise with the relief afforded to congested kidneys by a free diaphoresis, etc. But we have been slow to recognize the relation of deficient or deranged kidney excretion to the integrity of the skin and its functions, although occasionally very strong evidence of this has been adduced by individual observers, which we cannot here dwell upon.

Unquestionably much of the failure to utilize the indications from the urine in the treatment of certain diseases of the skin has been due to the too prevalent inclination to regard all cutaneous affections as purely local conditions, or idiopathic diseases, in which the skin is alone concerned, and as due to external causes or of parasitic origin.

While I recognize fully the influence of microbic agencies in connection with very many diseases of the skin and of other organs, I also claim that it is very short-sighted to disregard, as is often done, the soil, or physical condition of the individual tissue in which the microorganism lodges and finds its nourishment. Certainly in many lines the pendulum of medical thought, if not practice, is swinging away from a purely local etiology to a recognition and study of the constitutional relations of disease: thus, in tuberculosis we are slowly coming back to recognize the truth of the teaching of Sir Andrew Clark, who many years ago used to say, "Gentlemen, do not pay so much attention to the lungs, take care of the stomach and the lungs will take care of themselves," and even in cancer there is a strong tendency to regard the perversion of cell growth as due to faulty metabolism, principally of protein elements.

It is high time, therefore, for the dermatological world to review its basis of thought, and, if necessary, to revise its method of procedure in regard to the care of many of the lesions on the skin which may require treatment. Sir William Osler has rendered great service by his careful and intelligent work along certain dermatological lines, in regard to the connection of skin lesions with internal disorders, thus showing the direction along which studies should be made if we are to arrive at a true conception of many cutaneous affections and their cause.

In the clinical study of the urine, observers of late years have commonly dwelt on the importance of making only tests of the entire urinary output of the day, insisting that percentages signify nothing unless they relate to the whole amount of urine passed in the twenty-four hours. While I grant that this is often very important, and while in many cases I have the entire daily urine saved and measured frequently, even over long periods of time, and samples of the same analyzed, in the majority of cases I find greater benefit from the older method of analyzing that passed at bedtime, or at 10 o'clock and that passed in the morning, or at 7 o'clock; in this way we get a separate estimate of the result of the work and food of the day, the *urinum cibi*, of older writers, and that passed after rest and fasting, the *urinum haustus*. The contrast between the two is often surprising, and by adding the figures from each and dividing the result, we can get a very fair idea of the character of the total output.

Bouchard, who remarks:[1] "We are only on the threshold of discoveries which remain yet to be made in the chemical analysis of the urine," has made some interesting experimental studies on the toxicity of the urine which are very instructive. He summarizes one part of his studies as follows: "What is certain is, that during the day the body forms a substance which, when accumulated, would induce sleep, and that during sleep it elaborates, instead of this narcotic substance, a convulsive substance which, when accumulated, could produce muscular twitchings and induce waking." He had previously shown experimentally that a concentration of the day urine when injected into animals, in sufficient quantity for their weight, caused death by coma, while a concentrated night urine caused death by convulsions. This subject is a most interesting one, which cannot be gone into now, but this much is given in order to support the view that the analysis of different portions of the urine, taken at various times a day, can often yield important and valuable data in regard to the functioning of different parts of the organism and the nutrition of the system, including the skin.

Quantity.—The actual quantity of the urine passed each twenty-four hours may, of course, vary greatly according to the action of the skin and lungs, and the quantity of fluid taken into the system; but we all know that there is a general average quantity which should be passed in health, about 45 ounces for a person of 150 pounds, while in diabetes and various forms of kidney disease the normal quantity may be enormously increased or diminished, as also in certain nervous states. Few realize, however, that with only functional derangement of the system the daily quantity may vary very greatly, as I have watched it in many patients with skin ailments. Thus, in a lady, weighing 160 pounds, with *lichen planus*, I have had the urine measured almost daily for many weeks, and in the weekly record it will sometimes run over 70 ounces, and perhaps the next day only 34 ounces. Another lady, weighing 163 pounds with severe *psoriasis*, passed but thirteen ounces on the day before her visit, and on other days had passed eleven and even as little as 7 ounces of urine in the twenty-four hours; and many, many instances could be given where there was very imperfect and deficient urinary secretion in those who supposed they were in good health, except for the eruption.

Specific Gravity.—While, as a rule, the specific gravity of urine is supposed to depend upon the quantity passed, and this again largely upon the amount of fluid taken into the system, this is by no means the universal rule, for it may vary at times very greatly according to the state of the system; thus, I have found it 1.041, with no sugar, and as low as 1.001, with no actual kidney disease. And it is just this variation in the quantity and specific gravity of the urine from time to time which, if quickly recognized and intelligently interpreted, will aid much in understanding the systemic and metabolic disturbances upon which many diseases of the skin depend. And as these wrong conditions of the urine are corrected by appropriate treatment, dietary and medicinal, an eruption which had previously

proved rebellious will yield favorably to local measures which had before seemed ineffective; this, of course, applies mainly to such dermatoses as *eczema, psoriasis, acne, lichen planus, urticaria*, some *bullous eruptions*, etc.

Volumetric Acidity.—Closely associated with the quantity and specific gravity of the urine, and of even greater importance as a guide in connection with the treatment of certain diseases of the skin, is the actual volumetric acidity frequently measured, which can be done quite easily by the oxalic acid and phenolphthalein test.

Bearing well in mind what was previously said in regard to the formation of the urine directly from the completed arterial blood, on its way to vitalize all the tissues of the body, it can readily be understood what an important indicator this excretion is in determining the exact state of the blood, both as to is excrementitious substances and its alkalinity. With a standard of about .300 for the average acidity of normal urine, it must certainly make a great difference in regard to the well-being of the individual, as well as in the condition of the skin, when the acidity is found to be .600 or .800, or even 1.386, as I found it recently in a very bad case of *indurated acne*, or when it is reduced to .126 or even .063, or when it is even strongly alkaline, and that without bladder complications.

Excessive urinary acidity is frequently observed in connection with many diseases of the skin, *eczema, lichen planus, psoriasis, acne*, and others, and eruptions will often be seen to be red and congested and the itching increased when there is high acidity of the urine, and to be relieved when this is reduced by appropriate treatment; for the abnormal acidity of the urine but reflects a lessened alkalinity of the blood circulating through the skin. On the other hand a greatly reduced acidity of the urine, or persistent alkalinity, not dependent on bladder trouble, may be quite as harmful; and I recall a case of *urticaria* which proved rebellious, until on analysis of the urine I found it to be .063, almost neutral, when the eruption was arrested promptly on the free administration of urotropin, bringing the acidity of the urine up to normal.

Urea.—As the principal end product of the metabolism of protein substances, urea, or its proper excretion, may be of great importance in connection with certain diseases of the skin. In perfect health, with a mixed diet, the urea should be pretty constant at 2 per cent. in the urine, and nearly an ounce should be passed each day. But careful analysis in many patients with certain skin affections shows the greatest variations, from two or three times the normal amount down to an almost total absence of urea, indicating extremes of deranged nitrogenous metabolism. In a case of *dermatitis herpetiformis* Hardouin[5] made a daily analysis of the urine of 24 hours, over a period of six months, and found that on eight occasions, at pretty regular intervals, there was a fresh eruption after a period of diminished excretion of urea; the outbreak began a few days after the lowest point of urea elimination was reached. In a second case the onset of the attack also coincided with the lowest point of urea excretion; this has been verified by others, and also in a case in the New York Skin and Cancer Hospital.

Uric Acid.—In spite of the professional discredit into which uric acid itself, as a factor in disease, has fallen, there is little question but that the work of Haig[6] has served a good purpose in directing attention to the harmful results of a faulty metabolism of nitrogenous products. While its accurate quantitative estimation in the urine is difficult, it happens that sometimes the indications from its excretion are very suggestive.

Thus, in my own personal case, as already reported,[7] the uric acid and urea in the urine were actually higher after a five days' experience with a non-protein diet of rice, bread, butter, and water than they were on the night and morning before this was undertaken; showing that without the introduction of any exogenous protein or nuclein the blood took up from the tissues effete nitrogenous elements, and made them to appear in the urine, even in a greater degree than before. With this relief to the system the extremely distressing *vesiculo-bullous eruption* on the hands, to which I had been subject for a good many years in the summer, often lasting many weeks, disappeared completely by the expiration of this five days' strenuous diet, without the use of any remedies, internal or external. The same experience has been repeated in myself with the recurrence of the eruption in summer three or four times.

Indican.—The etiological significance of an excess of indican in the urine has not as yet been clearly worked out, but it is being recognized more and more as a valuable indicator of putrefactive changes occurring in proteins, mainly in the large intestine. It is interesting to observe, however, how frequently it appears in the urine in connection with outbreaks of *eczema, urticaria, acne*, and some other skin affections, and how they will improve under the same local treatment when this urinary error is removed by appropriate measures, dietary and other. As far as I know, no satisfactory explanation has been given as to how the putrefactive changes in the intestine affect the skin, but intestinal auto-intoxication is a factor which has to be considered and overcome, in connection with many affections of the skin, and the variations in the amount of indican in the urine afford a most satisfactory means of determining the existence of this condition.

Sulphates.—These, like indican, may often prove a good indicator of the proper metabolism of proteid substances, and they may sometimes be present in excessive quantity even when no indican is found. While the normal standard here accepted is 1 per cent., we have frequently found it 2, 4, 6, and even as high as 22 per cent., especially in *psoriasis;* this would indicate an intake of nitrogenous matter far beyond the demands of the system or the power of its proper assimilation.

Chlorides.—The estimation of the chlorides in the urine sometimes affords suggestions of value in regard to the treatment of certain cutaneous affections; and while a moderate excess or diminution from the average has no great significance, being derived from the food, a great excess often indicates that the individual consumes more food than the system requires, while a great diminution may signify the need of increased nutritive matter. Among our analyses, in one case, that of a young lady of 20, with *psoriasis*, there was 50 per cent. of chlorides, and in a lady of 60 with *eczema* there was but 2 per cent. The immense importance of chloride of sodium in the economy, in its relation to the gastric secretion, blood, and tissues, would imply that a knowledge, through the urine, of its supply in the blood and its proper elimination must be of value in connection with disease, whether of the skin or other portions of the body; and our practical experience has demonstrated this to be the fact time and again in many skin affections.

Phosphates.—These being also largely derived from the food are subject to considerable fluctuations in the urine in normal persons, and some care is required in judging the results of analysis. But phosphates are known to be largely increased in the urine in certain chronic diseases, as of the bones, nervous tissue, etc., and diminished in many other conditions, and the greatest variations were continually found in our cutaneous cases, in a manner often quite inexplicable. With an accepted average normal standard of 10-12 per cent. there were many specimens in which only a trace was found, while the highest recorded was 26 per cent. Continued increased elimination will often indicate a waste of nervous tissue, which may be of the utmost importance in some dermatoses; while with a prolonged, greatly diminished excretion we have a failure of nutritive powers which is of equal importance in other skin affections.

There are other ingredients of the urine, normal and abnormal, which have not been so fully studied, but which may be of importance in some conditions of the skin; such as are the coloring matter, which has been shown by Bouchard to be poisonous, creatinin, skatol, acetone, β-oxybutyric acid, etc. The thought naturally arises that if derangement in some of the urinary elements which have been carefully observed is so important in connection with certain diseases of the skin, can it not be possible that some of these other ingredients of the urine may, by their derangement, act in the same or different manner, in inducing some of the skin lesions which are often so troublesome.

There are yet a few urinary changes observed microscopically which should be mentioned as affording indications for treatment in certain diseases of the skin.

Urates and Uric Acid.—Heretofore we have spoken of uric acid as determined by quantitative analyses, but in many cases it will be grossly represented, by masses of urates, or even uric acid crystals, soon after passing. These are always of some significance in connection with certain skin affections, but should be carefully interpreted; for like the uric acid showers after attacks of gout, they may represent the effort of nature to throw off accumulated, effete, nitrogenous matter. When such deposits persist they indicate perverted nitrogenous metabolism, which should be attended too quite as much as other urinary derangements, if the best results are to be obtained in *eczema, psoriasis, acne*, and other affections.

Oxalates.—Oxalate of lime was formerly regarded as of much more importance, as a urinary deposit, than it is at present, for it is now recognized that it may come from an excess of certain vegetables and fruits in the diet. But when excessive or persistent it signifies, a process or state of sub-oxidation which should not be neglected in connection with certain affections of the skin. Thus, in acute *lichen planus* and *pruritus ani* oxaluria is an indication for the free administration of nitric acid, which will often prove of the most signal value in these troubles.

It would be interesting and highly instructive and profitable if we could point more especially to changes in the urine which necessarily accompanied definite diseases of the skin. But unfortunately this is not possible in our present state of knowledge; we must have vastly more carefully recorded observations. Undoubtedly many have the alterations in the urine which we have mentioned, with no eruption, but the same may be said in regard to many diseases of other organs; no one doubts the connection between uratic deposits and true gout, and yet the former are continually found without the latter. *Xanthoma diabeticorum* is recognized as associated with and probably dependent upon glycosuria, and yet how exceedingly rare it is in diabetes. There are undoubtedly concurrent causes of disease, of which we as yet know but little, and it is quite possible that closer observation and analysis will show further changes in the urine, or combination of changes, which may throw light on the pathogeny of some affections of the skin. In the present communication I have only endeavored to contribute my mite to this most interesting, instructive, and profitable line of investigation, and urge its further elaboration; for, of the practical importance, along therapeutical lines, of the matters which I have presented my daily experience makes me continually more positive.

One more thought. Mention has been made of a number of more or less acute and some chronic cutaneous affections in regard to which functional disturbances in the kindey excretion have been observed to be of significance. It is not probable, therefore, that careful study will demonstrate the same to be more or less true of still other eruptions which have not thus far been investigated in this direction, and that possibly in most cases where the skin is in any way diseased there may be some metabolic errors, which may be evidenced in the urine, if sufficient time, patience, and skill are employed. The notorious rebelliousness and proneness to recur of many affections of the skin should lead dermatologists to look away from a purely local etiology, and, with a broader view of medicine, seek for the underlying causes, which, as in diseases of other organs, are often found to depend on a defective metabolism, which is commonly indicated by defective or deranged urinary secretion.

THE PUBLIC VALUE OF DIFFERENT MILKS.

By CHARLES E. NORTH, M.D.,

NEW YORK.

MUCH progress has been made in recent years toward the solution of the milk problem. The agitation on the milk question has spread rapidly throughout the United States and the meetings and discussions among medical men, scientific men, and the public are leading to a far better appreciation of the relation which milk bears to public health and infant mortality, as well as a better understanding of its food value. Following the ideals established by the Medical Milk Commissions in the pro-

duction and sale of certified milk, a campaign of cleanliness and for the adoption of sanitary methods has been set on foot throughout the length and breadth of the dairy industry. One of the most remarkable occurrences has been the advent and increase of the process of pasteurization and the conversion of the great majority of medical men and scientists to the belief that it has the highest value as a public health measure, and can be applied to milk without any serious damage to food value.

The net result of this agitation has been the appearance on the market of a number of grades and classes of milk bearing different names and labels, making different claims of excellence, and, above all, offered for sale at prices ranging from 7 cents to 25 cents per quart. It is not strange that in the public mind there should be considerable confusion as to just what quality and what price are the correct ones, and how to choose from the list a milk which represents the highest value at the most reasonable cost.

The public value of milk, assuming that the average chemical composition of the different grades and classes on the market is about the same, depends chiefly on three fundamental characteristics. These are safety, cleanliness and price. Safety comes first. As applied to milk safety refers to a guarantee against disease, and particularly against the bacteria causing infectious diseases, many of which are known to be transmissible by milk. That milk which contains no infectious bacteria, other things being equal, is the safest. Cleanliness is a characteristic which represents the sanitary care which has been taken of milk from the time it is extracted from the cow's udder until it reaches the consumer. Milk from healthy normal cows is excreted from the udder in a clean condition, free from foreign elements and filth. Cleanliness contributes largely, of course, to safety, but it is easy to conceive of milk which is safe but not clean, and of milk which is clean but not safe. Cleanliness is demanded by the consumer for its own sake, entirely apart from safety. Cleanliness is required for the sake of decency. The enjoyment of life includes the enjoyment of food and the enjoyment of drink, and cleanliness, therefore, contributes to a fundamental human instinct. Price, to a large extent determines the degree of usefulness of milk. High prices restrict the market, while low prices widen the market. The value to the public of the high priced milk, used only by a small percentage of the people, is not nearly so great as the value of the low priced milk used by the great majority of the people.

Safety is secured by medical inspection of dairy employees, veterinary inspection of dairy cattle, and sanitary control over milk production and milk handling, and by pasteurization. Each of these measures has its own special advocates, and each milk on the market has been subjected in some degree to some supervision and treatment which has safety as its object. The cleanliness of milk is shown most clearly by the numbers of bacteria as determined by the plate method, which gives the so-called bacterial count. Much dirt is dissolved in milk, so that the dirt test is only a very rough test for cleanliness. Furthermore, milk which has been filtered or clarified can be freed from sediment and suspended particles, although the milk itself may have absorbed much soluble dirt, but the bacteria which accompanied the dirt are not removed by these methods to a sufficient extent to prevent the detection of uncleanness by the bacterial count. Lack of refrigeration and age result in the multiplication of bacteria with damage to the compositon of milk, as well as the production of toxic products. The bacterial count is therefore recognized by the majority of sanitarians as the best index to the sanitary character of milk, which is summarized under the word cleanliness.

There is no question that the measures taken to prevent the infecton of milk and to destroy bacteria, as well as the measures taken to keep milk clean during the period of production and handling, involve expenses which more or less increase its cost. As a consequence the retail price depends largely on the safety and cleanliness of the milk. In Table 1 is a list of a number of milks showing their character with respect to safety, cleanliness and price.

TABLE 1.—CHARACTER OF DIFFERENT MILKS

Milk	Safety	Cleanliness, Bacteria	Price, Cents
Grade A	Pasteurized in bulk	200,000	10
Grade A	Pasteurized in bottle	200,000	11
Grade A, raw	Medical inspected		
	Veterinary inspected	100,000	12
	Sanitation		
Certified and	Medical inspection		
guaranteed	Veterinary inspection	10,000	15–25
	Sanitation		
Grade B	Pasteurized in bottle		
Grade B	Pasteurized in bulk	1,000,000	10
Grade B, raw	Veterinary inspection	1,000,000	9
	Daily score	500,000	9
Grade C	Pasteurized in bulk	Over 1,000,000	7

If, now, we agree that safety, ceanliness and price, by which I mean low price, are the primary characteristics by which the public value of milk can be measured, and that safety is of an importance twice as great as either of the other two, we can establish a system of measurement for milk based on a total public value of 100, of which safety counts 50 points, cleanliness 25 points, and low price 25 points. In arranging measurements for safety one can attach a different value to each of the various safeguards which are practised. For many years the medical profession has considered the medical inspection of dairy employees a sufficient safeguard against the transmission of infectious diseases from dairy employees to milk. The recent discovery of typhoid carriers, and carriers of other diseases among dairy employees, has to a great extent diminished the respect held for such medical inspection. A number of epidemics of typhoid fever have resulted in recent years from typhoid carriers, and it is now recognized that absolute protection against the infection of milk by human beings cannot be secured through medical inspection. The same general change of opinion has taken place with regard to veterinary inspection. This is particularly true in relation to inflammations of the udder. It is now certain that the udder of dairy cows is often inflamed in a manner which cannot be detected by external physical examination, and yet which produces a discharge of bacteria into the milk. On the other hand, the pasteurization of milk at temperatures which are known to destroy all of the bacteria of infectious diseases transmissible by milk gives a guarantee far greater than any we can secure by the above methods. Pasteurization by the holding method in bulk, which permits of an extension of time of heating to thirty minutes, or more, at a temperature of 145° F., has been found efficient for the destruction of infectious bacteria, and the majority of other forms,

without damage to the food value of milk. Pasteurization of milk after it is bottled is superior even to this, for the reason that chances for reinfection are reduced to a minimum. The bottling of milk often results in a considerable increase of the numbers of bacteria after the milk leaves the heaters. Pasteurization in the bottle, which is the final container, therefore, represents the maximum degree of safety now known. From our present knowledge of the degrees of safety belonging to these various measures, it is possible to construct a table, as follows:

TABLE II.—SAFETY RATINGS FOR MILK

Maximum	50
Pasteurized in bottle	50
Pasteurized by holding method in bulk	45
Pasteurized by flash method at 160° F	40
Medical inspected employees, veterinary inspected dairy cattle, rigid sanitation	30
Scoring dairy farms 68	25
Physical examination of cattle	
Health board inspection of dairy farms	20
No inspection	10

Cleanliness ratings can be arranged on the basis of the numbers of bacteria found in the raw material. It seems proper to judge of the sanitary character of milk by its condition in a raw state, whether it is to be pasteurizeed or not, for this truly represents the raw material which is handled by the milk dealer. The degrees of bacterial excellence in milk recognized by sanitarians range from 10,000 per c.c. to over 1,000,000 per c.c. I have accordingly arranged a table of values for these various bacterial standards, as follows:

TABLE III.—CLEANLINESS RATINGS BASED ON BACTERIAL TESTS OF RAW MATERIAL

Bacteria per c.c.	Ratings
10,000	25
100,000	20
200,000	19
500,000	10
1,000,000	5
Over 1,000,000	0

The market price of milk ranges in different cities in this country from 7 cents to 25 cents per quart. In most of the large cities the prevailing retail price for bottled milk is 9 cents per quart. Price does not depend entirely on quality. Volume of business and local conditions are factors of primary importance. Thus, a milk dealer with a great volume of business in a territory where local conditions make cost of doing business cheap may be able to sell milk for 8 cents, for which another dealer with a small volume of business and in a locality where conditions are unfavorable to business must charge 10 cents per quart. At the present time a better grade of milk is selling in Milwaukee for 7 cents per quart than can be bought in Baltimore or New York City for 9 cents per quart, or in Philadelphia

TABLE IV.—PRICE RATINGS FOR MILK

Lowest retail market price	25
9 cents per quart or less	25
10 cents per quart or less	20
11 cents per quart or less	15
12 cents per quart or less	10
15 cents per quart or over	0

for 8 cents per quart. The prevailing market price represents the widest use of milk and therefore, as far as price is concerned, the highest public value. Prices higher than 9 cents greatly restrict the usefulness of milk, and have correspondingly lower public values. With these things in mind it is possible to construct a table giving ratings for the various milk prices, as follows:

If we now refer to Table 1, where the various characteristics of safety, cleanliness, and price of different milks are shown, it is possible to substitute the values given in Tables 2, 3, and 4 for the characteristics shown in Table 1. Thus, taking Table 2, which gives the values for safety, we can set down opposite each milk its safety rating. In like manner taking Table 3, which shows the values for cleanliness based on bacterial counts, we can substitute these values for the bacterial counts attached to each milk in Table 1. In like manner the values shown for price in Table 4 can be substituted for prices given in Table 1. These substitutions bring out clearly the relative public values in the different milks, and are shown in Table 5.

TABLE V.—PUBLIC VALUE OF DIFFERENT MILKS

Milk	Safety	Cleanliness	Price Rating	Public Value
Maximum	50	25	25	100
Grade A, pasteurized in bulk	45	19	20	84
Grade A, pasteurized in bottle	50	19	15	84
Grade B, pasteurized in bottle	50	5	20	75
Grade B, pasteurized in bulk	45	5	25	75
Grade C, pasteurized	45	0	25	70
Certified raw or guaranteed	30	25	5	60
Grade B, raw	20	10	25	55
Grade A, raw	25	20	10	55

The pasteurization of milk in the bottle at the present time is carried out by methods which do not permit of the treatment of large volumes of milk in a short time, in the common forms of bottles and caps. The machines used are of limited capacity and many of them require special kinds of bottles and caps. These expenses add one cent per quart to the retail price. It is believed that in the near future machines will be placed on the market for the pasteurization of large volumes of milk in the ordinary bottles capped with ordinary caps. If this is true it may be possible to sell milk pasteurized in the bottle at a cost no greater than the cost of pasteurization in bulk. When this is accomplished it will increase the price rating for milk from 15 points, which is the rating assigned 11-cent milk, to 20 points, which is the rating assigned for 10-cent milk, and would give Grade A pasteurized in the bottle a rating of 89. At the present time Grade A milk pasteurized in bulk or in the bottle represents the maximum degree of safety and cleanliness with a corresponding minimum price, and therefore milk of the highest public value.

The Grade B milks, pasteurized either in the bottle or in bulk, come next in favor. They are marked down in cleanliness but are very high in safety and in price ratings. The price of 9 cents per quart is the popular price of milk. The only criticism which can be offered to Grade B milk is its deficiency in matters of cleanliness. The price is low and the safety is high.

Certified or guaranteed milks are given a rating in public value which is very low for two reasons. In the first place these raw milks are now known to be at times unsafe, and they must be marked low in safety compared with pasteurized milk. In the second place, the extremely high price of certified and guaranteed milk restricts the market, so that in the United States to-day they represent only one-half of one per cent. of the total milk supply. Prices from 15 cents to 25 cents per quart must be given a very low rating. The highest claim

possessed by these milks for public favor rests in the matter of cleanliness. Their cleanlines is extreme and must be marked at a very high rating. But this cleanliness does not offset their deficiencies in safety and in price, and consequently, they must be given a low public value.

The milk of the future will be reasonably clean and scientifically pasteurized, and will be sold at a moderate price. Such milk as Grade A pasteurized at 9 cents or 10 cents per quart is the milk toward which the industry and toward which the majority of sanitary authorities are now working.

COMMINUTED FRACTURE OF THE LARYNX—ACCIDENTAL TRACHEOTOMY—MULTIPLE TRAUMA—EXTENSIVE FROSTBITE—RECOVERY.

By D. BRYSON DELAVAN, M.D.,

NEW YORK.

The subject of this history was formerly a well-known figure in the leading throat clinics of Central Europe. While his case may have been referred to in the public press of the time it does not seem that it has ever appeared in the medical literature of this country. My own experience, both in general surgery and in that of the department of diseases of the throat, has not furnished a parallel to it. It seems well, therefore, to place it upon record. About twenty years ago the patient came to the United States with the intention of making a living by the exhibition of his throat at various medical schools and by any other means within his power. He presented himself at the College of Physicians and Surgeons, where opportunity was given us to examine him.

He was a poor Roumanian Jew of about thirty and with the help of two canes hobbled painfully into our lecture room one day, offering his throat for examination and presenting the story of his sufferings. The haggard expression of his scarred countenance and the peddler's tray with its meager outlay gave evidence of unusual hardship and poverty. He was wearing a tracheotomy tube, and came to us for the purpose of demonstrating the introduction into a stenosed larynx of the dilator of Professor Schrotter of Vienna. From Schrotter, as well as from Professor Stoerck and others of Vienna, from Professor Fraenkel of Berlin, Prof. Moritz Schmidt of Frankfurt, and several other eminent European laryngologists, he brought strong letters in which the writers said that he had been in the habit of exhibiting himself at their clinics and vouched for the truthfulness of his story. They bespoke for him the kind consideration and generosity of their colleagues in other parts of the world. As to these letters familiarity with the handwriting of many of their authors proved them beyond question genuine. Moreover, I have heard by word of mouth from several of the writers of them the details of this remarkable case. No further corroboration was necessary, however, than that presented by the scars resulting from the injuries claimed to have been received.

The history is one of unique interest, not only by reason of the extraordinary vitality shown in the face of a series of injuries any one of which might easily have proved fatal, but because of the almost miraculous sequence of incidents, each instantly essential to the immediate saving of the man's life. The patient had been a prosperous young citizen of a town in Eastern Roumania, which lay in the midst of a country, sections of which were wild and badly protected. It was New Year's time, and the tax gatherer of the district had completed his collections and, with the revenue money in his possession, attended a banquet and dance upon New Year's Eve at the fine residence of a wealthy land holder. At the close of the festivities, shortly after midnight, the tax gatherer with his treasure and a party of seven companions, including the subject of this history, departed for their town, about sixteen miles distant, in a large three-horse sleigh. The ground was thickly covered with snow, the sky brilliant with stars, and the temperature below zero. Some of the journey lay through a particularly wild and desolate region, but the party was in high spirits and apparently not suspicious of danger. The fact that they were conveying a considerable sum of money had become known, however, and in the loneliest part of the way they were attacked by a band of outlaws. The place chosen for the ambush was at the edge of a dense wood not far from the banks of a stream. The suddenness of the onslaught made effective resistance impossible and all the party were quickly massacred, except our patient, who succeeded in concealing himself for a time under the fur robes in the bottom of the sleigh. His hiding place was soon discovered and he was dragged out and stripped of his valuables and clothing. A rope was fastened around his neck and he was hanged from the limb of a neighboring tree.

The attention of the bandits was then diverted from him in their eagerness to complete the robbery of the other victims. Left to himself and thus suspended in the air, his struggles were so desperate that he not only created a multiple fracture of his larynx, but also succeeded in breaking the rope. He fell to the ground rapidly suffocating, but nevertheless able to crawl into the bushes nearby, where he hoped to find concealment. His loudly stertorous breathing, however, quickly revealed his retreat. Two of the enemy rushed upon him, one armed with a large knife, the other with a revolver. The one with the knife, evidently approaching in the direction of the victim's head and at the left side, inflicted upon him three vicious cuts. The first extended from the margin of the right jaw upward across the face and over the forehead, passing completely through the cheek, dividing Steno's duct and incising the upper eyelid, but fortunately escaping the eye itself. The second attack resulted in a transverse incision straight across the throat, passing directly between the thyroid and cricoid cartilages and dividing the cricothyroid membrane. It failed, however, to injure either the carotids or the jugulars. Through this opening, as the man's head fell backwards, air was instantly admitted to the lungs and the frightful dyspnea occasioned by the fracture and resulting collapse of the larynx was overcome. The third slash, diagonally across the abdomen upon the right side, completely opened the peritoneal cavity throughout nearly its entire extent. Through this wound the intestines at once protruded, although apparently they had not been incised. To make sure work of the murder, the revolver was then emptied into him. Meanwhile the bodies of the other victims had been carried to the bluff at the bank of the stream, there about twenty feet above its surface, and had been thrown

one by one down upon the snow covered ice below. Our patient, apparently dead, was among the last to be so disposed of. The band then departed with their rich booty.

Some time during the next morning several peasants happening to come that way saw evidences of the tragedy that had taken place and, following the bloody trail from the woods to the river, discovered the corpses of the men below. With all speed they summoned help. Examinations showed that all of the party save one were dead. In him there seemed to remain a faint spark of life, but in addition to his other injuries his hands, feet, and ears were found to be badly frozen. He was taken to the nearest hospital, where his injuries were successfully treated, the wound in the neck closed, and a silver cannula inserted through the cricothyroid opening. The effect of the frost bites was very severe, so much so that the patient was obliged to undergo a Symes amputation of the right foot, a partial amputation of the left foot, and the loss of most of the fingers of both hands. Notwithstanding all these injuries, he recovered.

Incredible as this history seemed, the best evidence of its truthfulness existed in the scarred and mutilated body of the man himself, for there was not one of the wounds alluded to that was not represented by its own terrific scar or by the loss of an important member. Laryngoscopic examination proved the serious nature of the injury inflicted upon the larnyx, for there had been a multiple fracture of the thyroid cartilage, fracture of the cricoid, probable fracture of the hyoid bone and such collapse of the interior of the larynx that the resulting stenosis had been impossible of relief by the then existing methods and the permanent wearing of a tracheal canula a necessity.

The sequence of events by which the man's life was saved are worthy of note.

Had he not slipped under the robes to the bottom of the sleigh he would have been massacred with his companions at the first onslaught. His struggles while hanging, although they fractured the larynx, released him from the rope. When he hid in the bushes certain to die from dyspnea unless relieved, the stridor of his breathing revealed the place of his concealment and called forth a murderous gash which providentially opened the one place through which the desperate need of air could be supplied. The pistol shots, while penetrating the skin, probably did not enter deeply into the body. At all events, no important organs seem to have been injured by them. From the nature of the principal wounds the man should have been quickly exsanguinated, but fright and shock must have produced nature's anesthetic, syncope, and with syncope, together with the intense cold of the occasion, pain was overcome and hemorrhage controlled. A sheer fall of twenty feet upon hard ice would have been enough to kill. But the patient's fall was broken by the presence of the snow and of the bodies of his comrades, the latter possibly furnishing sufficient warmth to keep him alive. The purity of the cold winter atmosphere saved his wounds from infection and the rest was accomplished by what appears to have been remarkably skillful surgical care. The history of the injuries to the larynx and their results are particularly instructive as far as the prevention of stenosis is concerned. The treatment by means of Schrotter's dilators, the best at that time known, was practically a failure. The employment of modified O'Dwyer tubes, after the method of Dr. John Rogers, Jr., especially if applied promptly after the occurrence of the injury, would have saved the patient a lifetime of disability and suffering.

The final history of this patient is even more tragic than what has already been related. He became successful in a modest way as a peddler, and in the course of two or three years married a young woman in New Jersey. A few years afterwards, in reading the paper one morning I saw a statement to the effect that what the robbers of his native country had failed in doing had been successfully accomplished by his brother-in-law, who, wearying of his presence, had shot him dead.

40 East Forty-first Street.

THE UTILITY OF ENZYMES IN MALARIA.

By F. W. LAMBALLE, M.B.,

Major, Royal Army Medical Corps.

I take up a recent book,[1] which mirrors accurately enough current opinion, and there I read "Quinine is the one specific for all kinds of malarial fevers as it absolutely destroys the malarial parasites." This is the general teaching of the schools, and when one first begins tropical practice one relies upon quinine as a certain cure for malaria. Some ten years ago experience led me to doubt this infallibility. In Hongkong about that time malaria was the chief cause of sickness among the troops. Speaking from memory the admission rate to hospital for malaria was about 2,400* per thousand. Quinine in various forms, orally and hypodermically, in different courses of treatment was tried, but no method could be relied upon to obviate a relapse. During my service in Hongkong I should have had no difficulty in producing many cases showing records of 7 or 8 relapses.

These relapse cases have been a matter of concern because of the ensuing inefficiency, and recently with the troops in India efforts have been made to systematize the quinine treatment, to ensure that quinine is taken in sufficient doses, and that the treatment is spread over a sufficiently long time. These measures are complete enough as the following details will show: (1) No case of fever is diagnosed as malarial until the parasite has been recovered from the blood. (2) No case of malaria leaves hospital until the peripheral blood is *negative*, showing no parasites. (3) After leaving hospital all malaria patients attend for further treatment on a "malaria register." (*a*) *Benign cases* receive quinine sulphate in acid solution, gr. x, daily for one *week*, and afterwards three times weekly until four months of quinine treatment has been completed.

(*b*) *Malignant cases* receive quinine in the same form, gr. x daily for one *month*, and afterwards thrice weekly for three months longer. And yet relapses occur. Patients return to hospital deaf from cinchonism, ill with fever, and showing parasites in their peripheral blood.

I think the impression is very general that benign cases are cured easily and relapses rarely. Here in Upper Burma there seems little distinction between benign and malignant cases as regards their curability under quinine. Relapses seem as frequent in the one infection as in the other, the only difference being in the cachexia, which is persistent

*The number 2,400 is correct. A startling number—the equivalent of *every man in garrison being a patient in hospital nearly two and a half times every year!*

and progressive in bad cases of malignant infection. Major Lelean, R.A.M.C., writing in the *Journal of the Army Medical Corps* (November, 1911), has had the same experience in the 7th Division in India. I quote his figures as they show the importance of the subject: "Statistics have been kept which show the relapses occurring among a total of 1,053 malarial patients who attended hospital at Meerut for three months subsequent to their discharge. During that period they received 15 grains of quinine on two days per week. The drug was administered in solution and in the presence of an assistant surgeon, who kept a roster of these men and strictly enforced their regular attendance. We do not know what the mean daily strength was exactly, but it must have been approximately 170 for the eighteen months during which the results were kept. In that period there were 734 recurrences among these men, *i.e.* at the rate of 489 per year. It is, of course, obvious that this is but an approximate calculation, but it shows a per mille per annum attack rate amongst these men of no less than 2,876, which affords a considerable margin for error without losing its startling character." And continuing, he reiterates in slightly different form the question I have already suggested "Within comparatively recent years it has been taught that the action of quinine upon malarial parasites was so certain that quinine could be relied upon for clinical diagnosis. Was that teaching correct?" I think not. Quinine has its sphere of usefulness, but it is an empirical remedy—a fundamental fact we have forgotten because the remedy is so time-honored.

In the foregoing I have used the word *relapse* in the ordinary medical acceptation of the term as applied to any disease—a recurrence. Colonel R. H. Firth, in the *Journal of the Army Medical Corps* (February, 1913), in speaking of apyrexial malaria wishes a distinction to be drawn between *relapse* and *recrudescence*. By *recrudescence of infection* he speaks of a recurrence of the fever due to increased schizogony of the parasite after a period of apyrexia. By *relapse of infection* he indicates a recurrence of the fever due to a reversion to schizogony after the establishment of sexual forms in the blood. Professor Minchin,[2] in his "Introduction to the Study of the Protozoa," says "in the 'incubation' period of the disease schizogony alone occurs in all probability, but when the numbers of the parasite are sufficient to affect the health of the host the reaction of the host against the parasite probably stimulates the production of the propagative phases and Schaudinn has described the changes of the trophozoites which become sporonts."

In the light of the recent work[3] of my friend, Dr. John Beard, on the occurrence of dextrorotatory albumins in organic nature and the part played by ferments in the protection of the animal body all these things find a ready explanation. Schizogony of the parasite produces the clinical disturbance we call fever, the sexual forms are harmless and the asexual growth of the parasite, as is the common feature with all asexual growths, can proceed to an unlimited number of generations or cell-divisions until checked by the natural protective ferments of the animal body. Just as the trophoblast is checked in its growth by the ferments of the developing embryo (Beard), so the natural protective ferments of the host react against the asexual phase of the parasite and sexual forms begin to appear. The varying degree of immunity, the degree to which the malaria remains dormant, is a measure of these natural protective ferments. In like manner, as these ferments are insufficient to destroy the asexual forms, the disease recurs. There is no essential pathological difference between the cases termed "relapse" and those called "recrudescence." Clinically there is a difference only as to the time which has passed since infection. Before leaving this portion of the subject reference should be made to the recent publication[5] by Prof. Emil Abderhalden on "Protective Ferments of the Animal Organism." In this work the author has gone a long way in the same direction as Dr. Beard's researches have led him.

In 1907 it was foreseen, and foretold, by Dr. Beard, that the parasites of malaria would be readily destroyed by the enzyme trypsin, and the scientific principles involved have been enunciated by him in papers published in 1907 and 1913.[3, 4] It may be of interest to cite one scientific conclusion from his recent memoir. In this Beard[3] writes: "Since the organisms underlying the chief tropical diseases, such as malignant malaria, trypanosomiasis, sleeping sickness, yellow fever, relapsing fever, kalaazar, etc., are, so far as these attack human beings, asexual generations, it follows that the natural means of destroying the organisms of such tropical diseases and of curing the patients are the use *in combination* of the powerful pancreatic ferments, trypsin, and amylopsin."

Not until January, 1913, did the opportunity come to me of putting these principles into practice in cases of tropical disease and of seeing whether under treatment by ferments these relapses in malaria were preventable. As a test for this enzyme-treatment out of about 100 the cases of severe infection and those showing relapses were selected. Clinically, the results are most marked, the change in the patient within a few hours remarkable, and the benefit permanent. As circumstances have arisen which have interrupted this work, and as I do not know when I can carry the observations further, I think that these clinical results demonstrating the utility of the pancreatic ferments in the severer forms of malarial infection should be recorded.

For a discussion of the nomenclature of the organisms of malaria reference may be made to: Doflein, F.—"Lehrbuch der Protozoenkunde," 3te Auflage, Jena, 1911, pp. 774-788. Following him and adopting *Plasmodium* as the generic name, the two forms dealt with in the following are *Laverania malariæ*, the organism of malignant tertian malaria, and *Plasmodium vivax*, that of benign tertian malaria.

The method of treatment has been by intramuscular injections of the enzymes, trypsin and amylopsin. My acknowledgments are due to Messrs. Fairchild Brothers & Foster for the injections employed in the following cases. Both ferments are supplied in glass-ampoules holding about one cubic centimeter. The injectio trypsini has a digestive value of 1,250 Roberts units and it is the most potent preparation of trypsin made. The injectio amylopsini is of maximum potency and contains 500 Roberts amylolytic units. The preparations are sterile and stable. I have kept some of these ampoules for nine months in Central India without appreciable loss of strength. Before injection the contents of each ampoule should be diluted with normal saline 1 in 5. Latterly I have found, when using these fer-

ments in other diseases, that by using *two needles*, which should be as fine as possible, the pain, which often follows injections of trypsin, may be avoided. The one needle is used to take up the injection into the syringe, the second one, which in this way has no trypsin upon it, to make the actual injection. My usual practice is to take up the contents of one ampoule of trypsin and of one ampoule of amylopsin in a 10 c.c. syringe, and then fill the syringe with sterile normal saline. This amount I usually give as a single dose. Baetzner,[9] using the same preparations in surgical tuberculosis, gives his injections hypodermically, but I prefer to give the injections intramuscularly and select the buttock, finding that patients suffer the least inconvenience in this way. Using ordinary surgical technique in giving these injections, I have made some hundreds after this fashion and no harm has ensued. The ferments diffuse slowly from the tissue into which they are injected, and some local edema remains for 12 to 24 hours, when it disappears. The local pain is little more than that due to the needle prick. The effect of the trypsin on the normal tissues at the site of injection is practically nil.

But the general effect, as seen in the cerebral type of case, is marked. The headache vanishes, the patient's restlessness ceases, the skin becomes moist and the temperature falls, the patient's aspect is changed totally in a few hours and he feels fresh and looks bright. As a rule a single injection is sufficient to clear the peripheral blood of parasites. But in severe infections I think that *three injections* given at intervals of about four days, are necessary to effect a cure. My previous experience[6] in the use of ferments in malignant disease has led me to repeat the injections, until the injections themselves cause a rise in the patient's temperature. This I have elsewhere called a "trypsin reaction." When this happens, I know that the patient is fully under the influence of the treatment. Usually this occurs in malaria with the third injection, and having proceeded so far the worst cases* I have to deal with have remained free from relapse.

Case I.—Private C., No. 9,457.—Malignant tertian malaria with hematuria. Contracted malaria in Maymyo, Burma, November, 1912. December 5, 1912.—Admitted to hospital. Temperature 101° F. *Malignant tertian rings* found in peripheral blood. Quinine gr. x thrice daily. December 6, 1912.—Morning temperature 103° F., evening temperature 102.4° F. Hematuria appeared. Quinine stopped. Arsenic given. December 7 and 8, 1912.—Temperature normal, but hematuria continuing. December 16, 1912.—Apparent recovery. Discharged from hospital, but ordered to attend daily and to receive a daily dose of gr. x of quinine for one month.

Relapse.—January 11, 1913.—Readmitted to hospital. Evening temperature 100° F. *Malignant tertian rings and crescents* found in peripheral blood. Quinine gr. x given thrice daily. January 13 to 16.—Evening temperature 100° to 102° F. each evening. January 17.—Quinine treatment stopped. *First* injection of trypsin and amylopsin. Evening temperature 100° F. January 19.—Evening temperature 101° F. Blood shows crescents. January 21.—Evening temperature 101.6° F. January 23.—Evening temperature 96° F. January 24.—*Second* injection of trypsin and amylopsin. Six hours after this injection the patient's temperature rose to 100° F., but the peripheral blood showed no parasites. January 25 and 26.—Blood negative. No symptoms. January 31.—*Third* injection of trypsin and amylopsin. Discharged from hospital. The patient was seen by me on March 16, April 27, and May 31, 1913, and he has had no further symptoms.

Case II.—Private G., No. 9,876.—Malignant malaria with relapses. Contracted malaria in August, 1912, and was treated in hospital from August 22 to September 2, 1912, *malignant tertian rings* being found in the peripheral blood. The *first relapse* occurred in December, 1912. Patient in hospital from December 13 to 19, 1912, when again *malignant tertian rings* were found. Patient had been continuously under quinine treatment from August 22, 1912, to January 2, 1913—the regulation four months' course of treatment.

Second relapse took place in January, 1913, patient being admitted to hospital on January 29. He was deaf from cinchonism, the blood-smears were repeatedly negative, showing no parasites, but the patient's temperature each evening rose to about 100° F. He was discharged from hospital on February 11 and ordered to attend daily for further quinine treatment.

Third relapse.—On March 2, 1913, patient was attending for his daily dose of quinine, when he appeared to me to look so ill that I detained him in hospital. His evening temperature was 99.2° F., and blood examination negative. March 3.—Admitted to hospital, complaining of pains all over, worst in bones and joints. March 4.—Blood showed *malignant tertian rings*. In the evening the temperature rose to 103° F. and patient became delirious, showing cerebral symptoms. March 5.—Very severe headache. *First* injection of trypsin and amylopsin. March 6.—Headache gone. Feels well. Temperature in evening 99.6° F. March 7.—No headache or other signs. *Second* injection of trypsin and amylopsin given. March 9.—Temperature normal, neither signs nor symptoms, blood negative. March 12.—Continuing normal without symptoms. *Third* injection of trypsin and amylopsin given. This was followed by a rise of temperature to 102.4° F. Blood-smear negative. March 13.—Blood-smears again taken; no parasites found. Leucocyte count: Polynuclear 50 per cent., large mononuclear 17.3 per cent., lymphocytes 24.7 per cent., eosinophile 8 per cent. The changes in the large mononuclear and eosinophile white blood cells are noteworthy. March 16.—Discharged to duty. April 16 and May 19 the patient was seen by me. No further symptoms.

Case III.—Lance Corporal J., No. 8,459.—Contracted malaria in October, 1912. Was treated in hospital between October 25 and 30, 1912, benign tertian rings being found in the blood. The quinine treatment was continued from October, 1912, to February 28, 1913, *i.e.* a four months' course. On March 8, 1913, patient had a typical attack of ague in barracks and was not seen by a medical officer. On March 10, 1913, patient was brought to hospital with a temperature of 104.2° F., and malignant tertian rings were found in the blood. March 12.—*First* injection of trypsin and amylopsin was given. March 15.—*Second* injection was given. March 18.—*Third* injection was given. March 23.—Discharged to duty. Up to June 16, 1913, patient has had no relapse and no further symptoms. Query: was this case a mixed infection of benign and malignant malaria, or a fresh infection of malignant malaria while the patient was taking quinine?

Case IV.—Private T., No. 9,141.—Benign tertian malaria. States he first had malaria in Rangoon some two years ago, and that he has been stationed in Mandalay since June, 1912, arriving in Maymyo, Burma, on March 8, 1913. While in Mandalay he had five relapses of malaria. March 11, 1913.—Detained with severe ague. Temperature 103.8° F. Benign tertian rings and gametes in peripheral blood. March 12.—Admitted to hospital. Evening temperature 103.8° F. March 15.—*First* injection of trypsin and amylopsin. March 18.—*Second* injection. Blood negative. March 22.—*Third* injection. March 25.—Discharged to duty. Up to June 16, 1913, no relapse and no further symptoms.

Case V.—Lance Corporal G., No. 6,638.—Benign tertian malaria. Contracted malaria in December, 1912. Was treated in hospital December 28, 1912, to January 5, 1913. Relapse on March 14, 1913. Temperature 102° F. Blood-smear showed *benign tertian rings and gametes*. March 16.—Temperature 100° F. March 18.—*First* injection of trypsin and amylopsin. March 19.—Evening temperature 102° F. (due to yesterday's injection). March 20.—Temperature normal; blood negative. March 22.—Temperature normal. *Second* injection of trypsin and amylopsin. March 25.—Discharged to duty. Up to June 16, 1913, no relapse and no further symptoms.

Case VI.—Private S., No. 8,561.—Malignant tertian malaria. Contracted malaria in January, 1913. Was in hospital from January 31 to February 14, suffering from a severe attack, since when he has been taking quinine regularly. March 4.—Arrived in Maymyo, attending three times a week for quinine. March 15.—Reported sick with a temperature of 102.4° F. *Malignant tertian rings* found in peripheral blood. March 17.—Temperature 101° F. in

*The following cases were all those of British infantry soldiers. Three natives (Gurkhas) were also treated, but my notes of these cases are too fragmentary for inclusion.

the evening. March 18.—*First* injection of trypsin and amylopsin. March 19.—Temperature normal. March 22.—*Second* injection of trypsin and amylopsin. March 27.—Discharged to duty. Up to June 16, 1913, no relapse.

Case VII.—Private S., No. 9,600.—Benign tertian malaria, in which quinine seemed to give no benefit. Contracted malaria in September, 1912. States that he has had three relapses out of hospital. Returned from maneuvers on March 6, 1913. March 21.—Reported sick. Temperature 102.4° F. *Benign tertian gametes* found. Quinine gr. v. four-hourly ordered. March 22.—Temperature, morning 101.2° F., evening 101.6° F. Continue quinine. March 23.—Temperature, morning 100° F., evening 101.6 F. Quinine gr. x thrice daily. March 24.—Temperature, morning 99.6° F., evening 100° F. Continue quinine. March 25-29.—Temperature normal. Continue quinine. March 30.—Evening temperature 100° F. Severe headache and joint-pains. March 31.—*First* injection of trypsin and amylopsin. Evening temperature 100.2° F. April 1-4.—Temperature normal; no symptoms. April 5.—*Second* injection of trypsin and amylopsin. April 8.—Discharged to duty. Up to June 16, 1913, no relapse and no further symptoms.

After nine days of quinine treatment in this case the parasites were still able to produce fever, severe headache, and joint pains, all of which vanished after *one injection* of the ferments, trypsin and amylopsin.

Case VIII.—Private W., No. 9,402.—Benign tertian malaria. Contracted malaria in September, 1912, being treated in hospital from October 2 to 11, 1912. Completed a four months' course of quinine treatment in February, 1913. On March 27, 1913, reported sick, with a temperature of 102° F., *benign tertian rings* being found. On April 1 and 5 he received injections of trypsin and amylopsin. On April 10 he returned to duty, since when he has had no further symptoms.

Case IX.—Lance Corporal F., No. 9,327.—Benign tertian malaria. Contracted malaria in October, 1912, being treated in hospital from November 1 to 12, 1912, and continuing the quinine treatment out of hospital until about the middle of January, 1913. On March 24, 1913, reported sick, temperature 104.8° F., and *benign tertian rings* were found. On April 1 and 5 he received injections of trypsin and amylopsin, the second injection causing a rise of temperature to 100° F. On April 10 he returned to duty, and has since had no further relapse.

Case X.—Private T., No. 8,014.—Malignant tertian malaria. First admission, severe double infection. May 19, 1913.—Headache and colic. Temperature 102.2° F. Quinine treatment begun. May 20.—*Malignant tertian rings* found in peripheral blood. May 21.—Temperature, morning 103.6° F, evening 102.4° F. Headache severe. May 22.—Temperature 104° and 102.4°. May 23, 101° and 100°. May 24, 99.4° and 100.4°. May 25, 99.2° and 99.2°. May 26, 98.6° and 100°. Quinine treatment stopped. *First* injection of trypsin and amylopsin. Compared with the eight days of treatment with quinine the progress made after one single injection of trypsin and amylopsin is marked. May 27.—Better and brighter. Evening temperature 98.6° F. May 28 to June 3.—Temperature normal. No further symptoms.

Case XI.—Private T., No. 9,660.—Mixed infection with debility. Patient a tall lank phthinoid subject. Contracted malaria in January, 1913. March 16.—Admitted to hospital with pneumonia of right base. March 22.—Temperature 101° F. Blood examination showed numerous *benign tertian rings and malignant tertian rings also*. Quinine treatment begun. April 8.—Discharged from hospital, but continuing the quinine treatment as an out-patient.

Relapse.—April 15, 1913.—Admitted to hospital. Temperature 103.8° F. Malignant tertian rings in great numbers. April 16.—*First* injection of trypsin and amylopsin. April 17.—Evening temperature 100.6° F. April 18.—Temperature normal. April 19.—Temperature, morning 98.6°, evening 100° F. *Second* injection of trypsin and amylopsin. April 28.—Temperature continuing normal. Blood negative. *Third* injection of trypsin and amylopsin. May 3.—Returned to duty. Seen June 15, 1913. No relapse and no further symptoms.

Case XII.—Private H., No. 9,535.—Malignant tertian malaria with cerebral symptoms. First admission. Severe cerebral type of case and double infection. May 12, 1913.—Detained. Temperature 102° F. at noon, 104° F. at 3 p. m. Blood-smear negative. May 13.—Temperature, morning 101.6°, evening 104° F. May 14, 100° and 102.4°. May 15, 99.6° and 105°. May 16, 98° and 103°. May 18.—*Malignant tertian rings* found. Quinine treatment ordered. May 19.—Transferred to my care. Headache very severe. Restless. Continuing the quinine treatment. May 20.—Headache and restlessness more marked, and patient became comatose. *First* injection of trypsin and amylopsin. May 21.—Headache gone. Patient looks fresh and eyes bright. Temperature now 99° F. All symptoms vanished. May 26.—*Second* injection of trypsin and amylopsin. June 5.—Discharged from hospital to duty.

"If a doctrine be challenged," said Pasteur, "it happens seldom that its truth or falsehood cannot be established by some crucial test. Even a single experiment will often suffice either to refute or to consolidate the doctrine.[7] Again, the great investigator, Emil Fischer, set up the doctrine of "lock and key" regarding the action of ferments by two experiments, and two only. The first experiment was to observe the fact, the second to confirm it.[8] In the foregoing pages twelve experiments are set forth and every single one of these confirmed the scientific conclusions, which led to their being made. For, as Carl Ernst von Baer wrote long ago, "That which always repeats itself cannot be conditioned by chance or passing caprice, but must depend upon a necessity."[10]

THE FUNDAMENTAL PRINCIPLES OF BIOCHEMISTRY, THEIR APPLICATION IN THE STUDY OF COLLOIDAL MINERALS, AND THEIR RESULTING USE IN MEDICINE.*

By JOHN A. HANDY, Ph.C., B.S.,

BUFFALO, N. Y.

FORMERLY INSTRUCTOR IN MEDICAL AND PHARMACEUTICAL CHEMISTRY AT THE UNIVERSITY OF MINNESOTA, MINNEAPOLIS.

The Chemistry of Life.—So old and yet so new; so simple in expression and yet so mysterious in operation and profound in meaning. Who knows what Life in all its phases really is? We note its characteristic manifestations in the mineral kingdom, in the vegetable kingdom, in the animal kingdom, and in the human kingdom. We are even intuitively conscious of a still higher form of life.†

*Read before the Section on Pharmacology and Therapeutics of the American Medical Association at the Minneapolis meeting in June, 1913.

†See recent Presidential address on "Continuity," delivered at Birmingham, before the British Association, September 10, 1913, by Sir Oliver Lodge, F.R.S., D.Sc., LL.D., principal of the University of Birmingham.

What are the various elements in nature which enter into our physical conception of Life? The intellectual giants of Science, Philosophy, and Religion in all ages have grappled with this same problem, and yet, with all our heritage of knowledge and wisdom, the problem awaits a complete solution.

The mechanistic[1] cellular theories of the biologist and physiologist, along with the nebular[2] and planetismal[3] hypotheses of the geologist and the physico-chemical[4] interpretations of the physicist and chemist, have brought forth many illuminating ideas regarding the appearance of organic life upon this globe of inorganic matter, and have developed much experimental data explaining the various properties of living matter.

The phenomena of spontaneous movement[5], irritability[6] or response to stimuli, assimilation and disassimilation (metabolism)[7*], and even the processes of growth and reproduction,[8] which are considered to be the peculiar characteristics of living matter, have all been singularly imitated by artificial means in the scientific laboratory.

However similar some of these artificial manifestations of living phenomena may be, they are not actual duplications of life or living material.[9] There appears to be some element or principle present in the living protoplasm of nature which is not present in the artificial protoplasm of the laboratory. All of these experiments point to the fact that the chemistry and physics of the living organism are essentially the chemistry and physics of nitrogeneous colloids—true organic or vitochemical compounds.

A vitochemical substance or preparation is one which consists of a colloidal mineral element or compound chemically associated with native organic substances—proteins, fats, carbohydrates, etc. —in that form of refinement of particle and degree of activity as most nearly approaches the form and combination of true organic vegetable or animal tissues. Prof. E. A. Schäfer, in his recent article on "The Nature, Origin, and Maintenance of Life," expresses the advanced views of contemporary Physical Science on the chemical constitution of living substance,[10] when he says: "Living substance or protoplasm always, in fact, takes the form of a colloidal solution. The elements composing living substance are few in number. Those which are constantly present are carbon, hydrogen, oxygen, and nitrogen. With these both in nuclear matter and also, but to a less degree, in the more diffuse living material which we know as protoplasm, phosphorus is always associated. Moreover, a large proportion, rarely less than 70 per cent., of water appears essential for any manifestation of life, although not in all cases necessary for its continuance, since organisms are known which will bear the loss of the greater part if not the whole of the water they contain without permanent impairment of their vitality. The presence of certain inorganic salts is no less essential, chief among them being chloride of sodium and salts of calcium, magnesium, potassium, and iron. *The combination of these elements into a colloidal compound represents the chemical basis of life,* and when the chemist succeeds in building up this compound, it will without doubt be found to exhibit the phenomena which we are in the habit of associating with the term life."[11]

Wolfgang Pauli[12] took for the foundation of his treatise on "Physical Chemistry in the Service of Medicine" the extensive parallelism between the laws which govern changes in the colloidal state in vitro and in the living organisms.

A rational explanation and understanding of these biochemical elements and principles necessitates a brief consideration of Nature as a whole as a basis for the larger conception of a chemistry which deals with Life itself. Nature embraces certain fundamentals which are classified as ultimates, and which appear to be universal in time and space. These ultimates are five in number. Three of these—Matter (the universal property of Nature), Energy (the universal mode of Nature), and Life (the universal element of Nature)—command our especial attention at this time. A careful study of these universals reveals another stupendous fact—viz., that our whole system of evolutionary growth and development is brought about by the operation of a great fundamental law or principle of Nature acting through and upon these five ultimates.

This great fundamental principle, which operates through all the kingdoms of Nature, is known to chemists as the Law of Chemical Affinity. It has been variously known at different times as the Law of Universal Intelligence, the Law of Motion and Number, the Law of Integration, the Organic Principle, the Law of Life, the Law of Polarity, the Law of Growth, and the Constructive Principle in Nature. "It is, in fact, that Principle in Nature which impels every entity to seek vibratory correspondence with another like entity of opposite polarity."[13]

This great law is refining in principle, evolutionary in growth, harmonic in operation, vibratory in activity, and constructive in effect. In short, it is Nature's universal formula for evolution, which refines matter, increases its vibratory activity, and generates life.

Every scientist devises for himself certain concrete pictures of the nature of the fundamental units with which his specialty deals, in order that he may express his thoughts in concrete form. He must, however, be ever ready to shift and change and modify his ideas in accordance with the development of his science. The bigotry and skepticism of the past and the dogmatism of the present must not be allowed to fetter his reason and conscience and limit him in the acquirement of Truth, no matter from whence it may come nor how simple in form.

The biochemist, from a careful study of the broad field of Natural Science, takes the data of the chemist and physicist, of the anatomist and physiologist and pathologist, out of which he constructs an imagery of his own, dealing not with atoms and molecules as such, but with the conceptions of the physical and chemical nature of protoplasm, in the processes of reaction-velocity, catalysis and ferment activity, equilibrium, viscosity, osmotic pressure, colloidal mutability, allotropic transmutations, and electrolytic dissociation in vegetable and animal tissues. He must first, however, recognize and study the operations and manifestations of certain fundamental governing elements which co-ordinate the multiple phases of mineral and cellular activity, and appear to magnetize, vitalize, animate, and vivify respectively the four great kingdoms of nature—viz., the Mineral, the Vegetable, the Animal, and the Human kingdoms.

*The terms "assimilation" and "disassimilation" express the physical and chemical changes which occur within protoplasm as the result of the intake of nutrient material from the circumambient medium and its ultimate transformation into waste products which are passed out again into that medium; the whole cycle of these changes being embraced under the term "metabolism."

These governing elements, which are four in number and also appear to be universal in time and space, we may designate as the Life Elements. The science of chemistry is principally concerned with only two of these life elements, which are defined as follows: (1) Electromagnetism; (2) the vitochemical life element. It appears that one or more of the four life elements magnetizes, vivifies, vitalizes, or animates all physical matter, including the mineral atom, the plant, the animal, and the man. It would seem, then, that what we know as magnetism in minerals, vitality in vegetation, and physical life in the animal and man, are, in fact, certain temporary relations established between physical material and the finer and more subtle life elements.[13]

The withdrawal of the life elements in each kingdom appears to produce the same result—viz., devitalization and death. Physical matter is, therefore, negative to and subject to the more positive life elements. The principle of affinity or polar attraction appears to inhere in the vital elements themselves, and not in the solid particles of physical matter. Each life element is also assumed to display dual and yet differing powers and capacities of positive and receptive energy.

In the mineral kingdom the constructive and integrating principle of Nature operates through the electromagnetic life element alone. Upon this single element, therefore, the union, cohesion, integration, and growth of minerals depend.

All the beautiful crystalline forms in Nature are simply the expression of the electromagnetic element in matter. These chemical compounds are also the offspring of the electromagnetic energies in Nature.

In the vegetable kingdom the constructive, integrating principle of Nature operates through two life elements instead of one. That is to say, it operates through the electromagnetic and the vitochemical life elements. Of these two life elements the vitochemical is the dominating one in the vegetable organic process. It controls those higher functions of Nature associated with the properties of organization, growth, and reproduction.[14] The entire plant kingdom is an expression of the vitochemical element in Nature.

The operation of the law of polarity through the life elements upon the individual units, whether between the mineral atoms or the vegetable cells, is a ceaseless effort to establish vibratory correspondence and an equilibrium of forces in a perfect union. The result of these ceaseless activities of the individual particles upon each other is a refinement of the atom and an increase in vibratory activity of the atom in the compound.

There comes a time when a portion of the mineral substance is raised to certain ratios of correspondence with the vibratory action of the next higher element of vitochemical life, which appears to lie universally and coextensively in time and space with the lower element of electromagnetism. When the mineral atom has been thus raised it becomes susceptible to the essence and co-ordination of the higher life element. Impregnation occurs. The vitochemical life element is inducted into mineral substance and the mineral atom becomes a vegetable particle endowed with vitochemical or vegetable life. Is it not reasonable to suppose that by this evolutionary process, guided by Nature's constructive principle, all life is generated upon this planet?

A familiar application and manifestation of the electromagnetic element is to be found in the ordinary dry cell or electric battery. In general, such a cell consists of an outer cylindrical cup forming the zinc electrode, which is lined with thick absorbent paper and packed with pulverized manganese dioxide and carbon mixture surrounding the central carbon rod. The whole is saturated with ammonium chloride solution and sealed with pitch to keep it from drying out.

The anatomist would describe such a cell as consisting of a vessel of some sort of material containing a black powder, which was separated from the outer vessel by a white fibrous layer, and which surrounded a hard brittle rod in the center of the vessel, the whole mass being moistened with a fluid and sealed with a gummy waxlike substance, the outer vessel being connected with the inner black rod by a reddish strand. Such an analysis is obviously imperfect. It would never lead us to discover that the cell is capable of producing an electric current. The physiologist, who deals with the functions of things, would study the current produced by such a cell, its external and internal resistance, its effects, etc., but this would tell us nothing concerning the cause of the generation of the current. The analytical chemist, on the other hand, would tell us that the dry cell consists of a certain percentage of zinc, manganese dioxide, carbon, moisture, ammonium chloride, copper, brass, cellulose, etc., information very useful in its way, but of no more value to a comprehension of the generating activity of the cell than that of the physiologist and the anatomist. Something else besides these three kinds of knowledge is essential to the complete understanding of the simple "dry cell." A knowledge of the electromagnetic life element is necessary.

If all inorganic chemical compounds are the offspring of the electromagnetic element in Nature, is it not reasonable to suppose that these potential electromagnetic energies may be liberated from substances under certain conditions of chemical activity, and that electricity is one of the manifestations of this most simple of life elements?

Again, consider the properties and activities of vegetable protoplasm with its combined potentialities of electromagnetism and vitochemical energies. Take for example one of the simplest forms of vegetable life—the yeast cell. This cell, microscopic in size and possessing the simplest anatomical structure, and consisting simply of a colloidal solution of mineral salts in true organic or vitochemical form, is capable of growth and reproduction, and of carrying out many complex reactions. The yeast cell is capable of elaborating certain nitrogenous colloids called enzymes or ferments which convert sugar into alcohol, carbonic acid and water. Under certain conditions the yeast cell converts sugar into glycogen, which it may store for a long time within itself, or which it may soon reconvert into sugar and then into alcohol. Under other conditions it may oxidize alcohol. It synthesizes protein and cellulose. It forms glycerine, succinic acid, and amyl alcohol. It may reduce sulphur to sulphureted hydrogen. It generates electricity. It performs, undoubtedly, a whole series of cleavages, syntheses, oxidations, and reductions, and yet, examined under the microscope, it appears fairly homogeneous. No structure is visible capable of explanation as to how, in this small space, so many processes can go on side by side in an orderly fashion without interfering with each other. This multiple phase activity is manifestly impossible in a test tube.

Much experimental data[15] and many interesting and clever theories have been advanced to demonstrate and explain the multiple activities of the simplest of living cells. These studies have all led to one fundamental principle—viz., that *co-ordination* is the great characteristic of life. Anything which intermixes protoplasm and thus disturbs its phases of activity destroys co-ordination, and protoplasm dies. In other words, when the vitochemical life element escapes, co-ordination ceases, plasmolysis ensues, oxidation, hydrolysis, and the various other processes of the cell run riot, devitalization results, and we no longer have living material.

When we consider all the wonderful phenomena which have been demonstrated as a result of our knowledge and control of the simplest of the life elements—the electromagnetic—in the manifestations of electricity, for example, and that we are even now just at the threshold of greater possibilities in our understanding and use of this element, we cannot without some astonishment think of the almost unlimitable scientific possibilities in store for us when we come to understand and control the forces, activities, and processes of Nature inherent in the vitochemical life element.

It is toward a clearer understanding and a scientific application of the vitochemical life element that the biochemist of to-day must direct all his efforts and apply all his knowledge of physical and chemical science if he would ever bridge over Nature's gulf between the mineral and the vegetable worlds and that between the vegetable and the animal worlds.

It was my desire to present at this time some preliminary experimental data on the application of the vitochemical principle in the preparation of various colloidal mineral salt combinations in true organic and vitochemical form. In consideration of the detailed nature of this line of research work and the limitations of a general discussion of this nature, it was thought advisable to reserve the experimental material for another paper and concentrate the effort in this discussion to a careful presentation and analysis of the underlying elements and principles of the work, as a necessary foundation for a proper interpretation of the experimental results to follow.

A simple experiment will demonstrate the action of the vitochemical life element by producing within a few minutes what looks like a profuse vegetable growth. The experiment is carried out by introducing into a colloidal solution of sodium silicate (sp. gr. 118) crystals (about the size of a pea) of salts of the heavy metals, such as ferric chloride, ferrous chloride, copper chloride, uranium nitrate, silver nitrate, gold chloride, cobalt nitrate, manganese sulphate, etc. One is then witnessing the actual transmutation of the coarse crystalline inorganic form of matter to the more refined colloidal form. Similar results may be obtained by dropping into a fairly concentrated solution of potassium ferrocyanide little pills (size of a pea) made of copper sulphate or other heavy metal salts, and sugars.[16]

A study of protoplasm leads one to conclude that the phenomena of "organic life" appear to be the manifestations of the universal vitochemical life element through colloidal matter.

Having thus endeavored to classify the vitochemical principle and to suggest its application in the refinement of nitrogenous colloidal mineral substances, which form Nature's bridge between the crystalline inorganic and the cellular organic worlds of matter, let us next consider the nature of these colloids and their use in medicine.

Among the pioneers in this great field of colloidal chemistry, which is already commanding recognition as the new pharmaceutical chemistry, are recorded the names of Thomas Graham, Michael Faraday, Berzelius, Francesco Selmi, Carey Lea, Zsigmondy, Siedentopf, and Hermann Hille. The names of Faraday, Graham, and Hille are inseparably connected with this subject. Faraday made[17] colloidal solutions of gold by putting small pieces of yellow phosphorus into dilute solutions of gold chloride, some years before Graham invented the name *colloid*. Faraday was the first to use the term vitochemical, and it may be that in so doing he sensed the possible bridge between the mineral and the vegetable kingdoms. In 1862 Thomas Graham[18] observed that such substances as common salt, copper sulphate, potassium nitrate, and other substances of a crystalline nature, diffused through a parchment membrane almost as rapidly as if no membrane were present, while other substances, such as hydrated silicic acid, hydrated aluminum, starch, dextrin, and the gums; also caramel, tannin, albumin, gelatin, vegetable and animal extractive matter, and other substances of a non-crystalline, plastic form, possessed the common property of low diffusibility through such a membrane. To the former class of substances he gave the name Crystalloids, and to the other class the name Colloids.

Hermann Hille has recently claimed to have demonstrated the fact that colloidal minerals are Nature's bridge from the mineral kingdom to the vegetable kingdom. He is the first to make a successful application of the vitochemical principle in the study of colloids and the preparation of minerals and mineral salts in "true organic" form. He is the first to point out and demonstrate that true organic substances are colloidal forms of matter, and are, therefore, allotropic modifications of inorganic substances—the crystalline forms of matter.[19]

All physical nature is divided into the inorganic world of mineral matter and the organic world of vegetable and animal matter. Chemical analysis reveals the fact that the inorganic world is composed of the same elements that are found in the organic world. From the viewpoint of chemistry of today, therefore, the difference between organic and inorganic is not chemical in character, but a difference in structure only.[20] The characteristic structure of the inorganic world is rigid and crystalline; its basis is the crystal. The characteristic structure of the organic world is plastic or colloidal; its basis is the cell. Thomas Graham classified inorganic matter as "crystalloid" and organic matter as "colloid." Organic substance (the colloidal form of matter), therefore, is an allotropic* modification of inorganic substance, the crystalline form of matter.

For example: Diamond and charcoal and the carbon of protoplasm, in a purely chemical sense, are the same, so far as we know. They are allotropic forms of the element carbon. The diamond is crystalline or inorganic; charcoal is an amorphous or semiorganic form of carbon, whereas the carbon in protoplasm is the true organic or cellular modification.

The yellow, poisonous, crystalline phosphorus is an inorganic form; the nonpoisonous red phos-

*By allotropy is understood the property which certain chemical elements have of existing in two or more distinct forms, each having certain characteristics peculiar to itself.

phorus is an amorphous, semiorganic form, whereas the phosphorus of protoplasm is a colloidal or true organic modification of the same element. The results already obtained in colloidal chemistry make it safe to proclaim that every known substance can be raised from the crystalline to the more refined colloidal form.

One of the most widely used and best known colloids is soap, which plays such an important part in the household as a detergent and disinfectant. To the same class belong liquor cresolis compositus, U.S.P., lysol, creolin, etc.

Experiments with colloidal metals by Fillipi, Henri, Stodel, Ascoli, Izar, and others demonstrate that colloidal metals are as powerful in their bactericidal action as their inorganic salts, but very much less poisonous, if at all, in their effects upon ferments like pepsin, trypsin, pancreatin, etc. The effect of colloidal metals upon the enzymes of autolysis, or autodigestion, has been found to be accelerating and beneficent.[21] In fact, colloidal metals in themselves possess ferment action which can be retarded or entirely annihilated by traces of poisons like hydrocyanic acid, bichloride and cyanide of mercury, arsenous acid, carbon monoxide, etc. In other words, colloidal metals can be poisoned like other organized substances.

The ferment action, or catalytic effect, of colloidal metals is powerful. Bredig and his pupils found that colloidal platinum still exerted a perceptible decomposing action upon hydrogen peroxide in a dilution of one part of colloidal platinum in 70,000,000 parts of the liquid. Because of their catalytic action, Bredig called the colloidal metals "inorganic ferments."[22]

Not only the metals and other elements can be produced in the colloidal form, but their salts and other combinations as well. It is invariably found that the colloidal form is very much less poisonous and injurious than the crystalline form. For example: Colloidal copper arsenate is said to be one million times less poisonous than crystalline copper arsenate.

The reason why most of the so-called organic salts of silver, mercury, iron, etc., are not much more efficient nor much less poisonous than their purely inorganic salts appears to be due to the fact that most of them are merely loose associations of the inorganic, poisonous metal with organic substances like albumin, casein, sugar, etc. In order to become truly organic, or vitochemical, the mineral part of the combination must be colloidal in Nature.

All of our wholesome, natural food is colloidal in its nature. Milk, butter, cheese, eggs, meat, vegetables, fruits, honey, etc., are all colloids—not only their protein, carbohydrate, and fat constituents, but also their mineral bodies. These mineral bodies in true organic or vitochemical form, which have been almost totally ignored in medicine and dietetics, appear to be of such vital importance that "not one of the vital processes of the human organism is possible without them." Progressive physicians are beginning to recognize that the mineral salts of our food, which were formerly considered more or less unimportant, or secondary in importance to the three main classes—proteins, carbohydrates, and fats—are of the first importance.

The natural mineral salts are not only of the first importance as tissue foods, but are also the chief waste eliminators in human metabolism. To get some idea of the promptness with which the body acts in the elimination of waste matter and to emphasize the importance of taking our mineral salts in true organic form, wherein they will act as foods rather than as irritants to protoplasm, try the following experiment: Eat a tablet of lithium citrate. Then take a clean platinum wire, hold it in a colorless flame of a bunsen burner and note that it gives no coloration to the flame. Now pass the wire along the skin of the forehead, or after rinsing the hand in distilled water draw the wire across the palm and again hold it in the colorless bunsen flame. Note the beautiful yellow color due to the presence of sodium. Next take the blue glass and observe the same yellow flame through this; the cobalt glass absorbs the yellow sodium rays and the lilac flame of potassium now shows. About a half hour after taking the lithia tablet make the same test as above with a clean platinum wire. The vivid red flame of lithium is now obtained. In one short half hour the lithium entering at the mouth has been absorbed into the blood and carried to all parts of the body and is being excreted through the skin.

Is it not true that if the physician can control nutrition he can control disease? If it is true, and I believe it is, then a thorough knowledge of the mineral salts in true organic or vitochemical form—both in their native occurrence in our natural foods and in their synthetic forms—is necessary.

The soil, in order to produce vegetation which will support the higher kingdoms of animal and human life, must contain the following sixteen elements: Potassium, iron, calcium, sodium, magnesium, manganese, oxygen, hydrogen, nitrogen, carbon, chlorine, fluorine, sulphur, phosphorus, iodine, and silicon. These elements and their inorganic compounds cannot be utilized as foods by the higher kingdoms until they have been transmuted by the subtle alchemy of the vegetative process into true organic or vitochemical form. The human body is made up of these same sixteen elements in the following general proportions: Water, 70 per cent.; solid matter, 30 per cent., of which 6 per cent. is mineral salts and the remainder proteins, fats, and carbohydrates. Every one of these sixteen elements is necessary for a normal, healthy person, and we must depend upon our vegetable and animal foods to furnish them to us. Not only are the colloidal mineral elements themselves necessary, but certain enzymes which accompany them are of vital importance and must not be removed or destroyed. For example, wheat and potatoes, two of the most universally consumed food products, are robbed of their mineral salts either through the process of manufacture in the case of our patented flours, refined cereals, etc., or through the improper preparation and cooking of potatoes wherein the skins are removed and the water drained from them after boiling. All of our refined breakfast cereals, white sugars, processed fruits, and most of our canned materials, either have been demineralized or their ferments have been destroyed.

An interesting conclusion in connection with the relative value and importance of vegetable and animal foods in the human economy may be drawn from the following facts: As a general rule the chemical changes in plants are progressive or constructive; in an animal, regressive or destructive. Some cleavages are brought about in plants and some syntheses are carried on in animals. Animals take up the organic vegetable substances which have been synthesized by plants, assimilate them and excrete waste products which are identical, or nearly so, with those substances serving as food for plants.

Animal food will, therefore, contain its own waste materials, which will be so much extra inert and poisonous material for the human organism to eliminate. In the case of plant foods we do not have this extra waste material to take care of.

The facts of modern science, with their references, bearing upon the important subject of mineral starvation and disease, have been comprehensively reviewed in a recent article by Hermann Hille in the MEDICAL RECORD of June 15, 1912. Dr. Hille draws the following significant conclusions: First, that the primary cause of disease, from a purely physical viewpoint, is chiefly mineral starvation, and, second, that minerals in inorganic form cannot be utilized by the human organism as directly and effectually as can true organic minerals.

Dr. H. Packard, in a recent article on "The Possible Factor in the Causation of Cancer," in the February issue of *Surgery, Gynecology and Obstetrics,* writes as follows: "In view of the apparently well established fact that in the vegetable world an adequate supply of the earth salts—phosphorus, potassium, iron, manganese, silica, sodium, etc.—act as a distinct deterrent on parasitic life, and make for vigorous, virile, disease-resisting, healthy life, may we not assume as much for the animal world?

Since a critical examination of the habits of life of civilized cancer-plagued people, in comparison with the habits of primitive cancer-free people, shows that the main difference is in a dietary poor in organic mineral salts in the case of the cancer victims, and a diet rich in these same food salts in the case of those who are free from cancer, the most logical and rational course is to establish this truth as the keynote in cancer treatment. A well-balanced dietary must be adopted, including not only protein, carbohydrates, and fats, but also food salts." For a more detailed discussion of the facts connected with the great subject of mineral starvation and disease, the reader is referred to a recent excellent discussion along this line by Alfred W. McCann in his "Starving America."

The possibilities of the application of colloidal chemistry in medicine are suggested, not only by some of the colloidal preparations mentioned here, but also by the results obtained by Prof. Martin H. Fisher, whose recent publications, "The Oedema"[23] and "Nephritis"[24] and their subsequent discussions[25] by William J. Gies and others are of value to every thinking and progressive physician.

A clearer understanding of colloids and a more intimate knowledge of the facts of colloidal chemistry and of the vital importance of the colloidal forms of matter for the manifestations of organic life and in the elimination of pathological conditions will not only accomplish a much needed simplification of materia medica, but will also facilitate a rational understanding of the primary causes of disease and will thereby elevate the uncertain art of healing to the dignity of an exact science. It would enable the physician to know why a remedy ought to be colloidal or organic, and why crystalline or inorganic remedies are foreign matter to the human organism and act as poisons and irritants instead of foods.

A careful study of the vitochemical principle in Nature, and its application in biochemical research, will revolutionize our chemistry of today and give us a new materia medica for the future.

33 INWOOD PLACE.

DESCRIPTION OF A NEW METHOD OF REPAIR FOR VAGINAL HERNIA, WITH A REPORT OF ONE HUNDRED AND FORTY CASES IN WHICH IT WAS USED.

By HENRY ALBERT WADE, M.D.,

BROOKLYN, N. Y.

ATTENDING GYNECOLOGIST TO THE WILLIAMSBURGH HOSPITAL; ATTENDING SURGEON TO THE BETHANY DEACONESSES' HOSPITAL.

The method of repair for vaginal hernia which I describe in this paper has been extensively tested by me in the Williamsburg and Bethany Deaconesses' Hospitals and in private practice. I have selected for illustrative report only the cases operated on in the Williamsburgh Hospital, for the reason that the clinical histories of those cases are there filed so as to be readily accessible. This series of Williamsburgh Hospital cases numbers one hundred and forty and covers two and a half years. One hundred and ten of these cases I have been able to follow up and keep under my personal observation. Previous to the completion of my investigation as to the most effectual method of repairing a vaginal hernia I had tried out the various methods in general use, with more or less unsatisfactory results. Therefore, encouraged by the indifferent success which attended my work with these cases, I sought for other lines of procedure, being convinced that thus far the essential point which would determine the ultimate success in the treatment of cases of this character had been missed and that there must be some one better method than those so generally employed; but where look for and how determine the defect?

First, what is the principle underlying and guiding the treatment of thees cases? From my point of view they are to be regarded as a form of hernia and treated according to the same general principle as those which guide the general surgeon in repairing an inguinal, femoral, or other hernia, the

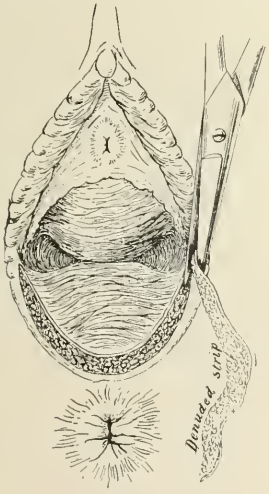

Fig. 1.—First Step.

essential here being to bring together and anchor the fascial layers.

I have observed in all cases of retrodisplacement of the uterus, when the displacement is not due to inflammatory processes, a separation of the deep fascia of the perineum. This separation may be the result of trauma after childbirth or due to a loss of tone of the surrounding structures, this latter being found in women who have never borne children and also in virgins. Viewing these cases then as hernias, the most common forms are:

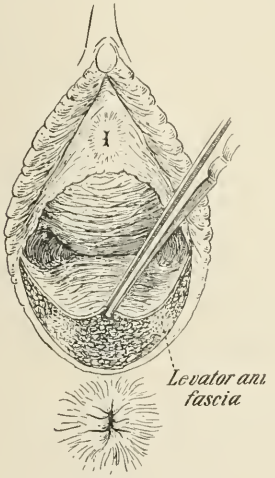

Fig. 2.—Second Step.

1. Enterocele (exceedingly rare),
2. Rectocele,
3. Cystocele, and
4. Ptosis, of varying degrees, of the uterus and its appendages.

It is with these latter, and especially retrodisplacements of the uterus, that the gynecologist is most concerned, and which demand from him his best judgment and skill in their correction. A retroflexion or retroversion of the uterus is frequently the first step in its ultimate and complete prolapsus, unless early and effectual treatment be instituted. *It is futile to endeavor to correct these displacements permanently by any method whatsoever done exclusively by the abdominal route.* The secret of success lies in the permanent strengthen-

Fig. 3.—Third Step.

ing of the pelvic floor, and by no other means can the desired result be obtained. This applies to vaginal hernias following childbirth and due to lacerations, trauma, etc., and also to hernias in virginal vaginas where the lesion is due to a loss of tonicity of the parts.

Fig. 4.—Fourth Step.

Preparation of the Patient for Operation.—The preparation of the patient begins forty-eight hours prior to the time of operation and is as follows: one ounce of castor oil, a light, soft diet; twelve hours previous to operation the patient receives an enema, a general bath, the parts are scrubbed and shaved and irrigated with alcohol and then with water. A vaginal douche of lysol, one dram to the pint, and a bichloride dressing, 1-5000, applied to the vulva. One half-hour before the patient is taken to the operating room she is catheterized and the genitals are irrigated with bichloride solution, 1-2000. After the patient has been anesthetized and placed on the operating table, the field of operation is painted with a 50 per cent. solution of tincture of iodine. I have never seen any corrosive effect subsequently from the application of the iodine.

Technique of the Operation.—The patient is placed in the lithotomy position; an incision is made beginning at the lateral mucocutaneous junction of the posterior aspect of the vaginal outlet. The amount of tissue that, without too much tension, may be brought up to the urethra, is estimated, and then the mucocutaneous junction at this point is grasped with a mouse-tooth forceps, and with slight traction a curved incision is made with the convexity directed toward the anus, extending to a point at the same level on the opposite side of the vaginal outlet. A flap of mucous membrane is now dissected upward, and with a clamp held clear of the field of operation. This flap is allowed to remain, and subsequently acts as an umbrella to protect the plastic work done below from the irritating discharges above. By means of the fingers the dissection is continued laterally on either side until a firm fascial layer is made out. Then these layers of fascia, not muscle, are brought together and held with a continuous suture of No. 2 chromic catgut. The superficial fascia is similarly united with the same strand of catgut. The skin is dissected free from the superficial fascia. This is particularly important, as without the dissection it will frequently be found impossible to bring the skin edges together with the Mitchelin clips. A clamp is placed at the posterior angle of the skin incision and the wound is securely sealed with from four to seven clips. The clips are removed at the end of six to nine days. If the clips are new ones and properly placed there should be no trauma from their pointed ends at the end of the seven days and there should be very little trouble experienced in removing them.

During the denudation and suturing, the field is swabbed frequently with a solution of mercury bichloride, 1-5000.

While the patient is convalescing no vulva pads are used. This rule is adhered to even though there be considerable bleeding per vaginam.

In the 140 Williamsburgh Hospital cases it has never been found necessary to place a finger in the rectum to act as a guide, and never has the rectum been entered while either denuding or suturing. Personally I believe there is more danger of entering the cavity of the rectum while suturing than there is while denuding. In old tears of the vagina with much scar tissue I have experienced no difficulty, much to my surprise, in separating the mucous-membrane flap.

Interrupted sutures of chromic catgut No. 2 were used in the first twenty-two cases during the year 1911. Catgut brought the skin and mucous membrane as well as the fascial layers together. The results were not satisfactory, mild infections and sloughing being of frequent occurrence.

In the next thirty-seven cases (1912) a continuous suture was employed, and skin and mucous membrane were brought together with a subcuticular stitch, employing the same piece of catgut throughout. The results were better, but difficulty

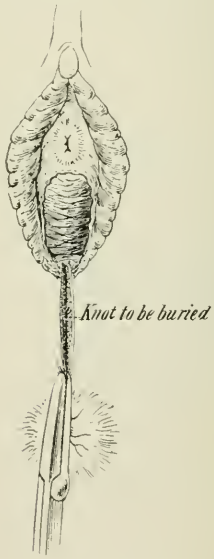

Fig. 5.—Fifth Step.

was experienced in burying the knot by the skin, and at this point healing was generally by granulation.

In the last eighty-one cases included in this report, *i.e.* those cases operated upon from January 1

to August 15 of this year, a continuous suture of No. 2 chromic *catgut* was used in bringing together the deep and superficial fascial layers. This piece of chromic catgut was threaded upon a full curved Hagadorn needle. The skin was dissected free from the superficial fascia for a distance of one-

Fig. 6.—Sixth Step.

eighth inch and the wound was sealed with Mitchelin clips. In ten of these cases where the clips have been removed at the end of the third day the skin wound has opened and healed subsequently by granulation. Where the clips have been allowed to remain from six to seven days the wounds have healed kindly and with a hair line skin scar.

The distinguishing features of this operation:

1. Fascia repair; we have a fascia and not a skin perineum subsequently.

2. The mucous-membrane flap protects the sutured tissues from the irritating discharges from above (acts as an umbrella) and the operation may be done in the presence of active bleeding from the uterus, after an incomplete abortion, and within four days after delivery in a full term pregnancy.

3. The catgut is entirely buried, by sealing the wound with Mitchelin clips. No catgut perineum can be a success if any catgut is allowed to be exposed after the completion of the operation.

4. The operation is a simple one and may be completed in from six to ten minutes.

I wish to thank my assistant Dr. Thurston Welton for the illustrations and my House Surgeon, Dr. David Feiner, for his help in searching the hospital records in the preparation of this paper.

495 Greene Avenue.

SOME OBJECTIONS TO MATERIA MEDICA STANDARDIZATION, WITH REFERENCE TO THE U. S. PHARMACOPEIA.*

By F. E. STEWART, Ph.G., M.D.,

PHILADELPHIA, PA.

PROFESSOR OF MATERIA MEDICA, PHARMACEUTICAL SCHOOL, MEDICO-CHIRURGICAL COLLEGE.

The text of my sermon will be found in the *Journal of the American Medical Association* for November 30, 1909, page 1645: "A thoroughly up-to-date Pharmacopeia—one which will truly reflect the best medical practice of the present time—will contribute more to sane drug therapeutics than any other one thing."

To prepare a new materia medica product for introduction into the United States Pharmacopeia it is necessary first to give it a name conformable with scientific nomenclature (the first step in standardization). This is objected to by certain commercial interests desiring to own the name of each new product for the purpose of creating lasting monopoly in its manufacture and sale.

The next step consists in the free discussion of each new drug in medical and pharmaceutical journals, societies, schools, and colleges. Certain objectors are entirely in accord with such discussion provided the discussion is favorable to the therapeutic claims they make for their controlled products. But free and impartial discussion, when it results in diminishing sales, is not viewed with equanimity by commercial introducers after they have spent possibly a hundred thousand dollars in advertising.

The next step is the fixing of tests for identity and purity and enforcing standards thus evolved by pure food and drug laws. Honest manufacturing houses favor this kind of standardization. It is only dishonest manufacturers who object.

The standardization of galenical products to fit them for a place in the Pharmacopeia includes determination of botanic source, physical and chemical structure, pharmacodynamic and therapydynamic properties, and therapeutic uses. Manufacturers depending upon concealing one or more of these factors to obtain and retain monopoly of sales, object to such standardization.

Again, manufacturers depending upon fictitious demand created by misleading advertising object to standardization.

Another objection to standardization is that standardization means *leveling* of all materia medica products to common standards, thus taking away from commercial introducers the advantage to be derived from advertising their products as better than those of their competitors.

What the medical profession must know in order to treat the sick properly are the side effects, limitations, and comparative value of new products in their relation to each other and to older and better known products employed as therapeutic agents in similar conditions. It is just this kind of levelization that the medical and pharmaceutical professions must insist upon if we are ever to restore public confidence in drugs as remedial agents.

Suppose that the manufacturers of potassium iodide were able to and should organize a campaign against the newer syphilitic remedies because their success means injury to sales of potassium iodide. Suppose the manufacturers of quinine should endeavor to prevent the killing off of mosquitos because malaria is carried by mosquitos and the sale of quinine is dependent upon the existence of malaria. Such action on the part of the manufacturers would be bitterly resented by the public. Yet this kind of opposition to the therapeutic standardization of new materia medica products is actually going on at the present time.

Demand created by advertising false claims represents unfair competition. Business taken away from competitors in this way is stolen. The rem-

*A paper read before the Section on Education and Legislation of the American Pharmaceutical Association at Nashville, Tenn., Aug. 17-20, 1913.

edy for unfair competition is to be found in drug standardization. It is not surprising that those guilty of unfair competition object.

Let me quote the exaggerated claims made for a certain alleged new remedy by way of illustration. I have coined the name "Antigonensis" to describe the advertised product.

"Antigonensis is a powerful and harmless systemic antiseptic in the most varied medical and surgical infections. It checks beginning sepses and often effects brilliant recoveries in desperate ones. Recent investigations show that with its direct bactericide energy it exerts a marked electrolytic and leucocytogenetic action, and thus greatly aids the natural protective forces of the body.

"Used topically, by mouth, rectally, intravenously, or by munction, Antigonensis forestalls the development of sepsis from accidental or operative wounds or childbirth, arrests beginning medical and surgical infections, and often achieves brilliant recoveries in apparently hopeless cases."

It is evident that pharmaceutic and therapeutic standardization would soon *levelize* this product and rob the manufacturer of the advantage to be obtained by claiming it to be better than competing products.

The true ideal of pharmacological practice includes cooperation between the medical and pharmaceutical professions and the manufacturing houses supplying them with materia medica products, to prevent misleading advertising. This cooperation can never be secured until all concerned are willing to consider the public health as of greater importance than the making of money. It is admitted that the making of money is absolutely necessary for the existence of the doctor, druggist, and manufacturer. The doctor must live on his fees, the pharmacist on his sale of medicines, and the manufacturer on the profit obtained by selling his wares. But dishonest commercialism should be abolished. The principle expressed by the motto "caveat emptor" (let the purchaser beware) is a very dangerous principle applied to medicine or pharmacy.

Objections to materia medica standardization come from manufacturers of commercially controlled materia medica products of all kinds. For the purpose of obtaining a clear conception of the objections and objectors let us classify the objectors into their classes as follows:

1. Secret Medicine Manufacturers.

(a) Retail druggists supplying medicines of their own make, which they recommend for self-medication, trusting patients to make their own diagnoses for the most part, but sometimes venturing to make a diagnosis for them.

(a) So-called "patent" or proprietary medicine manufacturers, who prescribe medicine at wholesale without diagnosis.

2. Manufacturing chemists and pharmacists dealing in commercially controlled specialties.

(a) Manufacturers of medicinal mixtures of secret formula for doctors to prescribe.

(b) Manufacturers of mixtures concerning which the medicinal ingredients are published, but the working formulas are suppressed.

(c) Manufacturers of chemical synthetics protected by patent and by registered names.

The objectors to standardization are as varied as the character of the manufactures. Behind the objections are motives equally complex. All object because they do not want to part with their monopolies. Some object because in addition to that reason they desire to create a demand by misleading advertising.

"How can inventors protect capital invested in the working and development of new inventions from interference and competition, if inventors publish full knowledge of their inventions for the benefit of scientific classification and standardization?" This question is frequently asked by pharmacists and reputable manufacturers engaged in the pharmacal and pharmacochemical industries.

The answer is to be found in that clause of the Constitution of the United States that gives Congress the power "to promote the progress of science and the useful arts, by securing, for limited times, to authors and inventors, the exclusive right to their respective writings and discoveries."

Inventors of new and useful arts, machines, manufactures, and compositions of matter, may obtain proper protection by patenting their inventions.

There are good reasons for believing that the proper application of the patent law to medical inventions would promote progress in medical science and in the useful arts of pharmacy and drug therapy. But to accomplish this object it would be necessary to establish some kind of a commission, board of control, or bureau of materia medica working with the Patent Office and the courts to limit the patenting of materia medica products to substances new and useful in fact; also to act as experts in infringement cases requiring higher knowledge of medical and chemical science and arts than is possessed by the legal fraternity.

The patenting of new materia medica inventions under such a board of control would promote materia medica standardization. For the statute exacts, "That, before any inventor or discoverer shall receive a patent for his invention or discovery, he shall make application therefor, in writing, to the Commissioner, and shall file in the Patent Office a written description of the same, and of the manner and process of making, constructing, compounding, and using it, in such full, clear, concise, and exact terms, as to enable any person skilled in the art or science to which it appertains, to make, construct, compound, and use the same."

It may be answered that the prejudice against patenting materia medica inventions, manifested by the medical profession, is a serious hindrance. This is true. However, this prejudice might, in all probability, be overcome by the adoption of some plan to prevent dishonest exploitation of new materia medica products by commercial introducers, also to secure free and impartial discussion of commercially controlled products by the medical and pharmaceutical press.

Much has been done in this direction by the Council on Pharmacy and Chemistry of the American Medical Association, and much by the pure food and drug laws. The Shirley amendment to the national pure food and drugs act, aimed against misleading advertising, if properly enforced, will be of great service. Similar bills advocated by "Printers Ink" are being passed by the States, and as they are backed by the advertising fraternity and their agents, we have a right to expect salutary reform. But we need some kind of strong central board of control in which the various interests involved may be represented and have a voice in the administration of affairs.

"But," say some of the objectors, "the seventeen-year limit provided by the patent law is not long

enough to get our money back. It requires an investment of at least one hundred thousand dollars in advertising a new product before the investment becomes remunerative. And it must also be considered that a certain proportion of ventures prove unprofitable. That is why we devised the scheme of patenting our products under their chemical names, and registering coined names as trade marks to be advertised as the names of the products. By forcing the coined names into the common language as nouns and retaining ownership in them we are enabled to extend our monopolies indefinitely."

This plan for defeating the object of the patent law was set aside by the decision of the Supreme Court of the United States in the Singer Sewing Machine case in 1895. According to this decision the name of a patented article cannot be commercially controlled after the patent expires.

"Then why patent materia medica products at all?" say the objectors. "Why not 'trade-mark' them and keep the process of their manufacture secret? A trade-mark never expires and the manufacturer, by controlling the name of the product, possesses a perpetual patent."

The weakness of this argument is apparent when one considers that any person who discovers by legitimate means how to make the same product has the right to do so and advertise the fact. He also has the right to employ its currently used name either as the title of the product or as a synonym. For example, what is to hinder any manufacturer of hexamethylenamine from using on his label as synonyms all of the fourteen so-called trade names or trade marks?

"We are perfectly willing to aid the government in fixing standards for our products and placing them in the Pharmacopœia, if we can still maintain monopoly," say the objectors. "What we desire is to secure the advertising advantage of having our products listed in pharmacopœia, dispensatories, medical dictionaries, text books, and other medical and pharmaceutical literature. We also desire discussion in professional journals and societies. We want the medical colleges to teach the students how to use our products. But we want to hold on to them."

That is the same as saying that these objectors want the medical and pharmaceutical professions, colleges, societies, and press to do their detail work without pay. "No," say the objectors, "we are willing to pay for the work if we can get it done in this way. What we object to is giving up our monopoly."

To this medical scientists reply that to do the work for pay would be the same as going into partnership with the manufacturers in a commercial business, and the turning of the educational machinery of the profession into a great advertising bureau for the commercial exploiting of alleged "new remedies." Those engaged in materia medica commerce are no longer in a judicial position in relation to the materia medica, and what they say about them must be received *cum grano salis*.

If this objection is true then the professional ideal taught by the colleges of pharmacy is false and there can be no profession of pharmacy.

But is it true? I do not believe it. It becomes evident that pharmacy should be a profession when it is considered that the proper introduction of new materia medica products requires the cooperative work of physicians, pharmacists, chemists, botanists, bacteriologists, and other professional men learned in the knowledge of their respective branches and expert in technique. Cooperation on the part of the professional societies and press is also required. The result of this cooperative work belongs to the workers, not to individuals. It must be contributed to the common fund for the benefit of all concerned. This means that the introduction of new materia medica products should be changed from a commercial or monopolistic plan to a professional or cooperative plan.

Now we are in position to consider the question of patenting new materia medica products in connection with a professional system. It seems to me that the question is one for the professions of pharmacy and medicine to decide. If they are willing to consent to it as adapted to the promotion of progress in medical science and in the arts of pharmacy and drug therapy, then let it be done.

But it is evident that it is unfair to ask any one person or manufacturing house to do business on a professional basis while competitors are doing the same business on a commercial basis.

Until manufacturers are willing to place their business upon a professional basis they have no right to expect professional cooperation. I believe that the profession is willing to endorse and cooperate with manufacturers under the protection of the patent law, just as they are willing to cooperate with the publishing houses under the protection of the copyright law, provided medical science and arts can be promoted thereby.

The object of the copyright and patent laws is to promote progress in science and useful arts by securing to authors and inventors the right to prevent others copying their respective writings and discoveries for limited times. The object of the trade-mark law is to protect all concerned from the counterfeiting of labels and brand marks. But all plans for obtaining and fostering perpetual monopolies are a hindrance to science and stand in the way of progress in civilization. Monopolies of this character ought to be opposed by all patriotic citizens and especially so by physicians and pharmacists.

It is evident from the above why a thoroughly up-to-date pharmacopœia will contribute more to sane drug therapeutics than any one thing. The U. S. Pharmacopœia is preeminently the standard for medicinal drugs, chemicals, and pharmaceutical preparations in the United States. It is the basis upon which rests all materia medica literature, including the dispensatories and text books. The information contained in the Pharmacopœia is taught in the medical and pharmaceutical schools and colleges and circulated throughout the country in the literature of pharmacy, chemistry, and therapeutics.

The U. S. Pharmacopœia is "the law of the land," not only for interstate commerce, but also for State commerce in most of the States. Whatever goes into it is placed there after mature consideration by a convention of representative physicians, pharmacists, and chemists who collectively decide its policy and appoint a committee for its decennial revision. The influence of the Pharmacopœia upon the pharmaceutic, pharmacochemical, and therapeutic arts is therefore incalculable.

To prepare new materia medica products for admission to the Pharmacopœia their standardization is necessary. Materia medica products cannot be properly standardized except by the cooperative work of the medical, pharmacal, and chemical pro-

fessions, whose function it is to determine for each product its nomenclature, source of genesis, physical and chemical properties, pharmacodynamic and therapydynamic actions, therapeutic applications, and proper methods of preparation. This function is being constantly exercised by the committee having charge of the revision of the U. S. Pharmacopœia.

To obtain a thoroughly up-to-date Pharmacopœia the commercially controlled materia medica must be considered. The rule adopted concerning the admission of controlled materia medica products to the Pharmacopœia is as follows: The committee was authorized to admit "any synthetized product of definite composition which is in common use by the medical profession, the identity, purity, or strength of which can be determined. No compound or mixture shall be introduced 'if the composition or mode of manufacture thereof be kept secret, or if it be controlled by unlimited proprietary or patent rights.'"

Some of the synthetic products still controlled by patents were admitted because the patents were about to expire. So-called "trade names" were not admitted. Abbreviations for long chemical names were coined and adopted.

In the light of the above facts it is evident that the rule adopted by the committee, which was doubtless the best that could be devised under circumstances then existing is not adequate to secure proper standardization. Something should be done to clear up the question of nomenclature so that a new product may be admitted under its currently used name, the same to be adopted either as the official title or as a synonym. Also the question of ethics in regard to patenting new materia medica products, either as to product or process or both should be decided, and proper action taken in the premises.

The proper application of the patent law to materia medica inventions, the same to be administered under the advisement of a board of control, representative in character, working with the Patent Office and the courts, would probably result in securing the object of the patent law in this connection, *i.e.* the promotion of progress in medical science, and in the useful arts of pharmacy, chemistry, and drug therapeutics.

The personnel of such a board of control is well exemplified by the U. S. Pharmacopœia Revision Committee. It is truly representative in character and is already engaged in the work of standardization. If to this committee Congress would give advisory authority to act in expert capacity in conjunction with the patent office and the courts, and provide sufficient appropriation to meet the necessary expense, all objections to drug standardization on the part of inventors and manufacturers would disappear, also the ethical problem would be solved, and an embarrassing situation relieved.

The Differentiation of Organic and Functional Heart Block.—A. F. Hecht states that this may be accomplished with the aid of atropine. In a case of diphtheria in which by means of the electrocardiograph manifestations of heart block were detected the administration of atropine did not change the conduction mechanism and increased simply the sinus frequency. The disturbance in the conducting mechanism persisted unchanged for four months. In a case of measles with symptoms of heart block the disturbance in the conducting mechanism disappeared entirely upon the administration of atropine. In eight days the heart's action was almost, and in three weeks entirely, normal.—*Zeitschrift für Kinderheilkunde.*

INFANTILE ECZEMA.

By BENJAMIN F. OCHS, M.D.,

NEW YORK.

ADJUNCT DERMATOLOGIST LEBANON HOSPITAL, DERMATOLOGIST LEBANON HOSPITAL AND HARLEM DISPENSARY, INSTRUCTOR IN DERMATOLOGY FORDHAM UNIVERSITY.

Among the many dermatoses affecting the infant, the most common is eczema, and then it is the weeping variety of that disease. We are reminded in our text books that it is caused by irritation; either from tight garments, from too frequent bathing, or from the use of a poor quality of soap.

Few authors mention overfeeding or indigestion as a causative factor. We have repeatedly noticed that children suffering from an attack of eczema are, as a rule, patients who *do not vomit*. Bottle-fed and breast-fed babies are very apt to have food given them whenever they cry or are peevish, and as this is not digested properly and as these children do not vomit, a toxemic condition is produced, causing in some children diarrhea, in others a reflex symptom, namely, infantile eczema.

This absence of vomiting has been forcibly impressed on us when taking the history of cases of infantile eczema. We have therefore come to the conclusion that an autotoxemia is produced and is the etiological factor in many of these cases. In fact, here the eczema is only a reflex symptom and really not the disease. In line with this reasoning, we have abstained from prescribing lotions or salves in all cases of infantile eczema until we have satisfied ourselves that the eczema is not due to autotoxemia. For that reason, when a child is brought to the dispensary suffering from an attack of eczema, we first cut down the amount of food and the number of feedings, and prescribe small and repeated doses of calomel. Many times this suffices for a complete cure. If, after a week's treatment, the child is not improved or well, we then look for some other cause and prescribe accordingly.

It has been our good fortune to find that toxemia, caused by over, or too frequent, feeding, has been the cause of the eczema, and we have been able to relieve these children promptly.

We do not believe too much stress can be laid on the fact that these children *do not vomit,* and this is really the cause of eczema. We would advise in all cases of infantile eczema to set aside lotions and salves until the above plan of treatment had been given a fair trial; and if it is found that the eczema yields to the simpler form of treatment, it is safe to assure the parents that there was but an autotoxemia, and that these cases will never become chronic. The mother is then advised how to feed the baby so that there be no future outbreak of the disease.

One fact we wish to emphasize particularly—and that is that these babies with infantile eczema *rarely, if ever, vomit,* and in getting the history of this class of cases the absence of vomiting should be a clue to the correct form of treatment.

310 Convent Avenue.

The Azurophile Granulations of the Lymphocytes in Infectious Diseases.—E. Mondolfo reports the results of his study of this subject. He finds that in normal individuals azurophilia of the lymphocytes is only an occasional or accidental phenomenon. In infectious diseases there is generally a mild degree of azurophilia. In measles however this condition is constant, and of phenomenal degree.—*La Riforma Medica.*

New York, November 22, 1913.

THE PROBLEM OF THE URINARY CHLORIDES IN CANCER.

VERY little clinical importance has as yet been attached to the quantitative variations of the excretion of chlorides in the urine. In former years a slight diagnostic and possibly prognostic significance was attached to the diminution in the urinary chlorides in pneumonia and other diseases accompanied by a pronounced exudation from the blood, but of late there has been a tendency to discount the clinical value of this phenomenon. Ten years ago Santini found that the diminished excretion of chlorides in pneumonia gives no indication of the severity of the disease and is of no prognostic moment. In conditions accompanied by starvation, as in carcinoma of the stomach, there is a reduction in the amount of chlorides excreted, but this results naturally from the diminished intake of these salts. There is a wide latitude in the excretion of chlorides in healthy persons, the elimination varying from six to twenty-two grams in the twenty-four hours.

The opinions regarding the urinary output of chlorides in cancer have been varied. Beneke, Jaccoud, and others noted a marked diminution in this excretion and attached to this a certain degree of diagnostic value. Müller believed that in cancerous individuals the destruction of the organs poor in chlorides is more active than that of the circulating albumin. Blumenthal found no differences in the urinary excretion of chlorides between normal and cancerous individuals. The latest one to investigate this subject is Albert Robin, who reports his results in the *Bulletin Général de Thérapeutique*, September 30, 1913. His work consisted in the study of thirty-six patients suffering from cancer of different organs. He found that neither the existence of cancer nor its location exercises any influence upon the elimination of chlorides or upon the relation of chlorine metabolism to the metabolism of other substances. Both the chloride elimination and the chloride metabolism are, however, closely related to the dietetic intake of chlorides.

All cancerous individuals are classified by Robin into three groups, according to the output of total nitrogen, chlorides, and inorganic residue. In the first group all of these are normal. The cancerous affection is a localized one, and if repeated examinations of the urine show a persistence in the urinary syndrome, the probability is that the progress of the cancerous process is a slow one. In the second group of cases the chlorides reach a low figure, while the total nitrogen remains at the same height as in well-nourished cancerous individuals. The high nitrogen output is explained by the fact that large metabolic demands are made on the tissue proteins by a disease associated with a rapid destructive process. In the third group of cases all the three elements are diminished to a parallel degree. The patients are living solely upon their own tissues, and present the same excretory phenomena that are manifested in other victims of cachexia and inanition.

A dietetic therapy that may be of some palliative value in the management of cancerous individuals is deduced from the above studies. Patients belonging to the first and above all to the second groups require an abundant and a mixed diet. At the same time there may be administered drugs, such as quinine and arsenic, that seem to exercise a moderating influence upon nitrogenous disintegration.

In cases of cancer that undergo a rapid course there is a retention of chlorides in the liver, but there is no such retention in slowly progressing cases. The retention is probably the result of the greater hydration of the tissues that is present in rapidly advancing cases of cancer, and may incidentally explain the diminished excretion of urinary chlorides in these cases. In cancer of the digestive tract there is apparently a tendency to a chloride retention in the blood, but the same characteristic is found in chronic gastritis, and for this reason loses all diagnostic value. This retention may be the result of the diminution or suppression of the secretion of hydrochloric acid by the stomach. Anemia may also play a rôle, for the retention is more marked in cases of chronic gastritis accompanied by a pronounced degree of anemia.

The investigations carried out by Robin, although producing results that are largely negative with respect to the chloride excretion in cancer, nevertheless place at our disposal a number of practical points in relation to this subject.

THE STATUS OF THE TRACHOMA QUESTION.

ALTHOUGH trachoma has long been recognized as a disease entity, but not so clearly defined clinically as now, yet our present knowledge of the etiological agents at the root of this disease is practically nil. The gravity of the disease from its effects on vision, and the attempts, therefore, to combat the disease have naturally centered all efforts in determining the causative agents. In other words, the bacteriology of this disease is now receiving a great deal of attention, but thus far none of the finds has been lasting and every new one has been promptly abandoned as not meeting the requirements of proof. In 1907 Halberstaedter and von Prowaczek discovered an intraepithelial diplococcus

in the scrapings from trachomatous lids. A little later Miller found an influenza-like bacillus. Williams' hemoglobinophilic bacillus could not be differentiated from the influenza-like bacillus, and therefore added nothing to the list of bacterial agents. When, however, Clausen identified the so-called "trachoma bodies"—round bodies surrounded by an areola—they were thought to be surely the causative agents. Since then many investigators have found these trachoma bodies, particularly Noguchi and Cohen, in this country, but as they have been found in other conjunctival conditions, it is now agreed that the significance of the trachoma bodies is not known. Certain it is that they are not peculiar to trachoma. Noguchi found them in only 9 out of about 250 clinically positive cases of trachoma.

The contagiousness of trachoma is much in dispute and cannot, of course, be positively settled till the causative agent is determined, and until it has fulfilled Koch's postulate—that the agent can be isolated from the disease, cultivated in pure culture, and when again introduced into the body cause the disease. Clinically the evidences of its communicability are beyond dispute, and the mere fact that not all exposed are infected does not disprove it since many admittedly communicable diseases behave that way; nor is its communicability disproven merely because one eye may be infected and the other remain free, for the same unilateral limitation may occur in pulmonary tuberculosis in which one side is involved and the other, even though communicating, remains uninvolved.

The pathology is everywhere understood as being a subepithelial infiltration of white or connective-tissue cells of the adenoid or lymphoid tissue of the conjunctiva with a tendency to cicatrize in a manner characteristic of no other disease-islands of infiltrated tissue surrounded by scar tissue. And because of the absence of this tissue in the conjunctivæ of very young children, the disease is not found in them. In clinical appearance the trachoma granules resemble such admittedly infectious granulomata as those found in syphilis, tuberculosis, and leprosy. The disease is self-limiting in that it ends only on complete scarring of the conjunctiva. The invasion of the corneal conjunctiva by this process and also the irritation of the cornea by the granules on the lid, which causes pannus, are active factors in the injury to vision. Clark estimates that untreated cases of trachoma have a prognosis of 90 per cent. injury to vision, of greater or lesser extent.

The object of treatment is primarily to hasten cicatrization, and thus to limit the course of the disease, to prevent the mechanical effects of the disease, and to treat complications as they arise. Various methods have been advocated for hastening cicatrization. All of them amount to scarification of the lids by one method or the other, and continuing this scarification after the reactions have subsided until complete cicatrization. Recently indolent areas have been actually excised. These methods have brought good results, as is evidenced by the increasing number of the cured in early life, and in the absence of visual complications. A large part of the credit for this advance in treatment is due to our own immigration exclusion laws, which have compelled the countries from which these cases come to treat them. And thousands of persons are undergoing treatment at foreign ports in order that they may pass the rigid examination here.

POLITICS AND PUBLIC HEALTH.

According to Dean C. Worcester, for thirteen years Secretary of the Interior in the Philippine Islands, a very grave danger threatens the inhabitants of those Islands in the expressed intention of Burton Harrison, the new Governor-General, to "play politics" there. The *New York Times* quotes him as predicting trouble through placing inexperienced natives in positions of trust and responsibility, old and tried officials being ousted to make room for them. Regarding changes in the land office, the bureau of printing, etc., physicians as such have no concern, but they have much to apprehend from the threatened removal of the Director of Public Health. His position was offered to a surgeon who knew well how to use the knife but had only a general idea of sanitary matters. Realizing his limitations, this surgeon very wisely declined the appointment, but the next man to whom Mr. Harrison offers the place may not be so sensible or, not having a good income from a surgical practice, may covet the salary.

Concerning Dr. Heiser, the present incumbent, Mr. Worcester, who has observed his work and its results at close hand, has the following to say: "No living sanitarian has a better record for ability and efficiency in coping with great sanitary problems than Victor C. Heiser of the United States Public Health Service, who has been Director of Public Health in the Philippines for nine years. He has practically eliminated smallpox, bubonic plague, and cholera, and has excluded beriberi from public institutions; has built the best general hospital in the tropics, and has isolated the lepers while arousing only a minimum of opposition by so doing. He has reduced the death rate of American officers and employees to less than five in 1,000, and among Filipino officers and employees to four in 1,000; he has made Manila more healthful than many of the larger cities of America and has materially reduced the death rate throughout the islands. His place simply cannot be filled for years. Should Dr. Heiser be transferred to make way for a politician, he doubtless would heave a sigh of relief, but it would be a sad day for the Philippines."

And is a man of this character, having the sanitary training of an officer of the Public Health Service and the experience of nine years as Director of Public Health in the Philippines, to be deposed because some politician wants the small salary that goes with the position? It makes one wonder whether a Department of Public Health with its head a political appointee, changed with each change of administration in Washington, would, after all, be a desirable thing for the country.

Contagious Abortion in Man.

Veterinarians have long been familiar with the diseases of cattle known as contagious abortion and in 1896 the *Bacillus abortus* was discovered by Bang and Stribolt and identified as its cause. It has more recently been recognized as extremely prevalent and the complement deviation test has been used successfully in its diagnosis. It has been found also that cows which have been infected excrete these bacilli in their milk. It has been held, however, that man was immune to this organism and that therefore the infection of the milk was of no moment. Moreover, after a cow has aborted several times as a result of this infection she may become immune and thereafter appear to be in perfect health. E. C. Schroeder, in the course of an investigation on the relative value of raw, pasteurized, and boiled cow's milk as a food for unweaned animals (*Am. Jour. Dis. Children*, 1913, vi.), found that the animals fed on boiled milk did better than those who got only raw milk. In autopsying some of these animals he found the lesions of infectious abortion and was led to conclude that perhaps it might be well to boil all cow's milk before feeding it to children. Larson and Sedgwick (*loc. cit.*) examined the blood of 425 children by means of the complement-fixation test, using the *Bacillus abortus* as antigen, and found it positive in 73 instances. The work was controlled in every possible way and agglutination and absorption tests were also made. It thus seems that man is susceptible to infection by this organism and Larson and Sedgwick observed cases of abortion in women who had come into contact with herds in which contagious abortion was prevalent and in whom syphilis and injuries could be excluded. This disease is said to be the most prevalent of all animal diseases and therefore the importance of determining man's susceptibility can hardly be exaggerated. It is to be hoped that the investigation along these lines will be continued.

Serotherapy of Croupous Pneumonia

It was once firmly believed that croupous pneumonia should be one of the first infections to yield to antibody treatment; for the events of the crisis appeared to depend purely on some phenomenon of chemical union, akin to the combination of a toxin with its antitoxin. As serotherapy failed utterly at the outset many plausible explanations were given for the unsuccess; while believers in specific therapy began to modify their sera accordingly. At a recent session of the Medical Society of Nürnberg Feith considers this subject. He prefers to rely upon Römer's serum, as constantly modified. The serum is polyvalent not only because of the number of strains of bacteria comprised, but because several different sera are utilized (from the horse, cow, sheep, etc.). Whenever this serum is injected into a pneumonic patient the immediate results are euphoria and fall of temperature. There is no influence exerted on the crisis or extension of the process. There is undoubted improvement in the sputa. The author is certain that the treatment has some positive effects. Of seven severe cases (double pneumonia or involvement of upper lobes) but one resulted fatally. The author admits, however, without any qualifications, that we have in Römer's serum no "therapia sterilisans magna."

News of the Week.

American College of Surgeons.—The convocation exercises of the American College of Surgeons were held in the Gold Room of the Auditorium Annex, Chicago, November 12, 1913. The names of the surgeons who were made members of the college were read by the secretary, Dr. Franklin H. Martin, Chicago, and the president, Dr. J. M. T. Finney, Baltimore, pronounced them fellows of the college. The number of fellows admitted was 1,050. Sir Rickman Godlee, president of the Royal College of Surgeons of England, read a message to the members of the college from the Council of the Royal College of England. In the message felicitations were conveyed to the Americans and hopes expressed that the college would grow and prosper and that by its influence the ideals and standards of surgery in America would be advanced and maintained on a high plane. The following were made honorary members of the college: Dr. W. W. Keen, Philadelphia; Dr. William S. Halsted, Baltimore, and Dr. J. Collins Warren, Boston. President Finney in his address urged every member of the college to assist in raising the ideals of the profession and to erase the blots which now disfigured the escutcheon of the business of surgery. One of the most important functions of the college, he said, is to wage a relentness war against the evil practices with which the profession is tainted, chief among which is the pernicious practice of fee-splitting and giving commissions.

The Knapp Memorial.—The Herman Knapp Memorial Eye Hospital, New York, was recently opened in its new location on the corner of 57th Street and Tenth Avenue. This hospital was founded in 1869 by the late Dr. Herman Knapp, and under the name of the New York Ophthalmic and Aural Institute—its activity has continued since that time. During these forty-four years over 420,000 patients have been treated. Its new home is in a specially constructed, seven-story, fireproof hospital building, with complete modern equipment for the treatment and study of diseases of the eye. The occasion of the removal of the hospital to a new building in a new location has been deemed by the Board of Managers a proper time to change the name of the Institute so as to make it a memorial to its honored founder.

Sea View Hospital.—The new Sea View Hospital on Grymes Hill, Staten Island, New York, which has accommodations for 1,000 tuberculosis patients, was formally opened November 12. The hospital, which is a city institution, has been under erection for the last three years, and when entirely finished will have cost about $3,500,000. The eight large buildings comprising the group are arranged in a semicircle on a high hill in the open country and will always have a surrounding of clear land. The opening of the hospital adds almost 50 per cent. to the provision made in the city, through both public and private means, for the care of tuberculosis sufferers. Dr. Edward S. McSweeney, formerly in charge of the Tuberculosis Sanatorium at Otisville, has been appointed superintendent of the new institution.

New York Dispensary.—The new building of the New York Dispensary at 34 Spring street, New York, was opened on November 17. While similar in many respects to the old, the new home of the dispensary shows some improvements. Scientific ventilation, flooring designed to deaden all noise,

and large window space are among the architectural features deserving notice. Rooms have been added also for the use of the social service department. The dispensary was founded in 1790 in the Five Points district.

City Death Rate.—For the week ending November 8, the death rate in New York City was 12.44 per 1,000 persons, as compared with 13.13 for the corresponding week of last year, the total number of deaths being 1,281 and 1,303 respectively. This decrease of 22 deaths occurred in spite of the fact that during the week there were 114 deaths from violence, or 20 more than during the same week of 1912.

Diphtheria in Paterson.—An epidemic of diphtheria in Paterson, N. J., has spread to several of the public schools and has caused some alarm among the health authorities. In a number of small towns about Paterson also there have been many cases of the disease and in most of these towns the schools and other public buildings have been ordered closed.

Plague Still Prevalent.—Fifty-two new cases of bubonic plague were reported in Guayaquil, Ecuador, on November 12, and the epidemic is said to be spreading through the outskirts also. A contract for the sanitation of the city is under consideration.

Pellagra Death Record.—The Board of Health of Spartanburg, S. C., recently published a report on the vital statistics of the town, showing that pellagra has been the cause of more deaths than any other disease, even tuberculosis. Of the 340 deaths in the town during one year, 31 were due to this disease, and more than 600 cases were reported throughout the county. With the onset of colder weather the epidemic, however, shows signs of subsiding, and the physicians from the medical corps of the army and navy, the Public Health Service, and the New York Post-Graduate Hospital, who have been studying the disease, are preparing to leave, with the expectation of returning next year. Congress now has under consideration a bill appropriating $300,000 for the building of a Government hospital at Spartanburg for the treatment of pellagra.

Effects of Salvarsan.—In order that fuller information may be gained as to the effect of salvarsan, Dr. Dreuw of Berlin, Germany, has undertaken the collection of statistics covering cases of blindness, deafness, convulsions, paralysis, etc., and of death following the injection of the drug, and he asks that physicians using it send to him reports of all such cases. Such reports will be kept entirely confidential. Dr. Dreuw believes that many cases of serious or fatal consequences following the use of salvarsan have not been reported, and that the present literature is therefore too inadequate to serve as a basis for conclusions as to the value of the treatment. He hopes to receive the support of physicians in the collection of these statistics and asks that reports be addressed to Dr. med Dreuw, Berlin, Potsdamerstrasse 31 a, Germany.

Sterilization of Criminals.—Dr. Francisco M. Fernandez, a member of the House of Representatives, introduced into the Cuban Congress on November 15 a bill providing for the sterilization of criminals. There is some concern among sociologists in that country over the noticeable increase in the number of criminals in recent years.

Gifts to Cornell.—Official announcement was made on November 16, by President Schurman of Cornell University of the gift of $4,350,000 to the Cornell Medical College, New York. Although the gift is classed as anonymous, it is generally understood that the donor is Col. Oliver H. Payne, who has previously contributed largely to the support of the school. The money is not to be used for buildings, the present equipment of the school being ample, but the income, amounting to about $200,000 yearly, will be used entirely for the current running expenses of the institution. The rumor that such a gift had been made was denied by President Schurman a few weeks ago.

Tuberculosis Day.—Sunday, December 7, has been designated as "Tuberculosis Day" by the National Association for the Study and Prevention of Tuberculosis.

Gifts to Charities.—By the will of the late Nathan Herrmann of New York, the sum of $15,000 is bequeathed to Beth Israel Hospital, while Mount Sinai Hospital and the Montefiore Home receive $5,000 each.

Nobel Prizes.—In addition to the award of the Nobel Prize in Medicine to Prof. Charles Richet of Paris, as noted some time ago, the committee now announces the award of the Prize in Chemistry to Prof. Alfred Werner of the University of Zurich, and of the Prize in Physics to Prof. H. Kamerlingh Onnes of the University of Leiden.

State Statistics.—The report of the Department of Health of the State of New York for the month of September, 1913, gives the principal causes of mortality as follows: Tuberculosis, 1,101 deaths; Bright's disease, 822 deaths, and cancer, 755 deaths.

To Regulate Sale of Mercury.—The Board of Health of New York has under consideration two amendments to the Sanitary Code, which are designed to lessen the frequency of cases of bichloride poisoning. The first amendment reads: "Bichloride of mercury, otherwise corrosive sublimate, shall not be offered for sale or sold at retail in dry form, except in a flat, triangular, or three-cornered tablet, colored blue, and the same shall be dispensed in a blue or amber-colored corrugated bottle conspicuously labeled "Poison" in red letters." The second amendment reads: "Bichloride of mercury, otherwise corrosive sublimate, shall not be offered for sale or sold at retail, except upon the prescription of a regular licensed practitioner." It is understood that the adoption of either or both of these amendments will be announced shortly.

The "American Journal of Surgery" will present in January an issue devoted exclusively to fractures and their treatment. The number will include papers by Drs. F. J. Cotton, Boston; Lewis A. Stimson, New York; Fred Albee, New York; John C. A. Gerster, New York; W. H. Luckett, New York; James K. Young, Philadelphia; Charles Elsberg, New York; William L. Estes, South Bethlehem, Penn.; E. S. Van Duyn, Syracuse, N. Y.; and E. P. Magruder, Washington.

Hospital at Lynn.—Plans have been accepted for the erection of the proposed children's hospital in Lynn, Mass., made possible by the gift of $100,000 from Henry A. Pevear. The plans provide for a three-story building, measuring ninety by thirty-five feet, and constructed of brick and stone.

Medical Examinations.—At the October examinations of the Louisiana State Board of Medical Examiners, sixteen candidates were successful and were duly licensed to practise medicine.

Memorial to Dr. Stewart.—On November 15, there was unveiled in the Pathological Laboratory

of the College of Physicians and Surgeons, New York, a tablet erected in memory of the late Hugh Angus Stewart, M.D., assistant professor of pathology, by his students and colleagues. A memorial address was delivered by Prof. William S. Thayer of the Johns Hopkins Medical School.

Dr. Jay F. Schamberg has been elected dermatologist to the Philadelphia General Hospital, in succession to Dr. E. S. Gans, resigned.

Dr. Herbert M. Goddard has been appointed laryngologist to the Jewish Hospital of Philadelphia.

Dr. James Persons Simonds, professor of preventive medicine in the State Medical College, Galveston, Texas, has been appointed assistant professor of pathology in the Medical Department of Northwestern University, Chicago. He will assume his new duties about March 1, 1914.

Dr. Francis B. Hart of Brooklyn has been appointed coroner's physician by the Board of Coroners of Queens County, New York.

Texas State Homeopathic Medical Society.—The annual convention of this society was held in Dallas on October 28 and 29, the following officers being elected for the ensuing year: *President,* Dr. C. C. Bowes, Greenville; *Vice-Presidents,* Dr. Solomon W. Cohen, Waco, and Dr. Jessie L. Givens, Bowie; *Secretary,* Dr. Julia H. Bass, Austin; *Treasurer,* Dr. W. D. Gorton, Austin.

Obituary Notes.—Dr. Archibald Dixon, Jr., of El Paso, Tex., a graduate of the Bellevue Hospital Medical College, New York, in 1891, and a member of the State Medical Association of Texas, and the El Paso County Medical Society, died at his home on October 31, aged 44 years.

Dr. John B. Longshere of Camden, N. J., a graduate of the Pennsylvania Medical College, Gettysburg, in 1846, died at his home on November 11, aged 92 years.

Dr. Wilson A. Long of Frederick, Md., a graduate of the College of Physicians and Surgeons, Baltimore, in 1882, and a member of the Medical and Chirurgical Faculty of Medicine and the Frederick County Medical Society, died from pneumonia, at Baltimore, on November 3, aged 52 years.

Dr. Gurley D. Moose of Mount Pleasant, N. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1907, died at Asheville, N. C., from tuberculosis, after a long illness, on November 9, aged 30 years.

Dr. Ira K. Gardner of New Hampton, Ia., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1870, and a member of the American Medical Association, and the Iowa State and Chickasaw County Medical Societies, died at his home suddenly from apoplexy, on November 4, aged 67 years.

Dr. John Martin Cameron of North Yakima, Wash., a graduate of the Medical Department of Victoria University, Toronto, in 1887, died at his home recently.

Dr. Hugh Logan of The Dalles, Ore., a graduate of Washington University, Medical Department, St. Louis, in 1872, and a member of the American Medical Association and the Oregon State and Wasco County Medical Societies, died at his home, from pneumonia, on October 27, aged 63 years.

Dr. Archelaus M. Winn of Lawrenceville, Ga., a graduate of the Atlanta Medical College in 1867, died at his home after a long illness, on October 25, aged 68 years.

Dr. William Royal Engel of Charlotte, N. C., a graduate of the Jefferson Medical College, Philadelphia, in 1906, formerly director of the North Carolina State Tuberculosis Sanatorium, Montrose, and more recently in charge of the Thermal Belt Sanatorium at Tryon, died on October 27, after a long illness, aged 35 years.

Dr. Amy Brush Clark died at Philadelphia on November 4 at the age of 54 years. She was graduated from the Woman's Medical College of the New York Infirmary for Women and Children, in the class of 1884.

Dr. Rudolph C. Mollman, formerly of Reading, Pa., died on November 6 at Longport, N. J. He was graduated from the medical department of the University of Pennsylvania in the class of 1900.

Dr. George W. Armentrout of Letts, Ia., a graduate of the College of Physicians and Surgeons, Keokuk, in 1889, died suddenly at his home, from heart disease, on November 2, aged 50 years.

Dr. Peter Fisher of Edwardsville, Ill., died at his home on October 30, from uremic poisoning, aged 74 years.

Dr. Simon J. O'Neil of New York, a graduate of the New York University Medical College in 1887, and a member of the Greater New York Medical Association, died at the Nassau Hotel, Long Beach, N. Y., after a long illness, on November 13, aged 52 years.

Dr. Zachariah Taylor Miller of Pittsburgh, Pa., a graduate of the Hahnemann Medical College and Hospital of Philadelphia in 1877, and professor of anatomy in the Carnegie Institute of Technology, Pittsburgh, died suddenly at his home from rheumatism of the heart on November 14, aged 66 years.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

COMPLICATIONS OF HYSTERECTOMY—PRIZE DAY AT ROYAL NAVAL MEDICAL COLLEGE—ROYAL COMMISSION—SANITARY WORK IN INDIA—FACIAL SPASM—ROYAL INSTITUTE OF PUBLIC HEALTH—TROPICAL MEDICINE AND SIR P. MANSON—MISSING ANTIVIVISECTION SECRETARY—OBITUARY.

London, October 31, 1913.

Sir John Bland-Sutton on Monday opened a discussion at the Medical Society of London on the visceral complications met with in hysterectomy performed for fibroids and the best methods of dealing with them. His contribution to the subject was a model of what such an introduction should be, stated tersely his own clinical experience and the opinions he had formed, as well as the points on which it was desired that the views of other operators should be elicited. He excluded pelvic complications, such as ovarian cysts, pregnancy, pyosalpinx, and the like as being frequent and well understood. But the experience of surgeons who do hysterectomy for fibroids was sought regarding complicating conditions as heart disease, goiter, diabetes, renal disease and intestinal cancer. As to these he related his own experience. To-day the operation seems quite common and the mortality in London ranges from 1 to 5 per cent. There are surgeons among us who can count their hysterectomies by hundreds and they should be willing to give information as to the complications they had met with and their mode of dealing with them.

Cardiac disease was found in many women on whom operation was proposed, but there was nothing peculiar as to its influence on fibroids. Sir John Bland-Sutton has removed the uterus containing large fibroids when valvular lesions were present, but competent physicians had pronounced compensation satisfactory. One woman with a large ovarian cyst and a fibroid the size of a football suffering from dyspnea, so that the anesthetist would not risk general anesthesia, was operated on under intradural injection of novocain. Convalescence was rapid, the cardiac symptoms soon disappeared and she soon became robust and led an active life. He attributes some cases of sudden death to chronic heart disease rather than to the pulmonary embolism often blamed, but which should only be admitted when the embolus is found post mortem. He has recently published statistics indicating the danger of too free use of buried sutures in this connection.

On three occasions Sir John did hysterectomy for fibroids on goitrous patients and six months afterward was surprise to find that their thyroids were much smaller. Any form of surgical operation is notoriously more dangerous when the patient is affected with exophthalmic goiter. Nevertheless he hysterectomized one such in 1908, but she died fifty-six hours after. Meantime it was noticed that in twenty hours the thyroid had decreased and the eyeballs were less prominent, and after forty-eight hours, though the condition was desperate, there was still further decrease.

Diabetes is another contraindication to surgery. But though it is a very serious responsibility, it must sometimes be necessary to operate on a patient with sugar in the urine. One woman of forty-three, with five grains per ounce of sugar, ready to face any risk, was operated on and made a rapid recovery. Another, with ten grains per ounce of sugar, with large fibroid and a suspicion of cancer, was subjected to a subtotal hysterectomy, a mass the size of a tennis ball removed, fibroid and cancerous, and the patient was active and well eight years afterward. Nevertheless Sir John said he was sure it was wise to abstain from operating on diabetics, especially young ones.

Renal complications arise from the close relationship with the uterus, bladder, and vesical segments of the ureters. Traces of albumen are common, but disappear after the tumor is removed. The colon bacillus was found in the urine within thirty-six hours after pelvic operations, but no explanation has been found. So obstetricians do not know how it reaches the urine in pyelonephritis of pregnancy. Wound of one or both ureters is serious if detected and repaired during operation, but much more so if undetected until the nurse's report draws attention to the emptiness of the bladder, which follows. Sir John quoted Lockyer's case and his great resourcefulness, which was rewarded by the patient's recovery. He mentioned also a case he witnessed when a gynecologist cut three inches out of a ureter, mistaking it for an adhesion, but tied the proximal end and the patient recovered. Dr. Barney's collected reports of injury to the ureters showed that most of them occurred in hysterectomy. If gynecologists would tell how they treated cut ureters this discussion would not have been useless.

Bowel complications were not common, but on several occasions he had met cancer of the sigmoid flexure. After completing the hysterectomy he excised the cancer in the colon and joined the cut ends of the bowel by end-to-end anastomosis. Once when adjusting the parts before closing he detected a cancerous focus in the sigmoid. He did not think the patient's condition fit for excision then. She recovered, and two months later he excised the bowel. She was in good health two years afterward. Gallstones he had dealt with in three cases during hysterectomy by removing the gall bladder. In two cases he removed it six months later. If a woman were deeply jaundiced by a stone in the common duct he would prefer to remove the stone first because cholemia is well known to predispose to hemorrhage, so that hysterectomy in a patient with persistent jaundice would put her life in great peril from post-operative hemorrhage.

In conclusion Sir J. Bland-Sutton said he was sure, small as the risks of hysterectomy for fibroids have become, we have not reached the irreducible minimum.

Surgeon-General Sir Havelock Charles on Wednesday, surrounded by a galaxy of surgeons-general and other officers, presented the prizes to the successful students at the Royal Army Medical College. The commandant (Colonel Skinner) reviewing the 106th session of the junior class, the twenty-third held in London, bade godspeed to the late professors and welcome to their successors. As to the class, he had only praise, for the young officers composing it had been most assiduous. The prize men had done remarkably well, some brilliantly.

Sir Havelock Charles directed his address especially to those about to go to India, assuring them that the greatest of all assets is character. He remembered thirty-one years ago asking Sir Joseph Fayrer's advice how to get on in India. Sir Joseph looked at him a few seconds and then said: "Do what you are told; do not grumble and go where you are sent." Of course, he continued, young men going to India have troubles, like every one else—even like the doctor with a brass plate on a door in Harley Street. But they were going to what in his opinion was the most interesting country in the world. So might the best of luck go with them. He would close with the wish of the Persian poet: "May the sweet waters of contentment spring up where'er you place your feet."

The Royal Commission indicated as probable by Lord Morley at the dinner given by the government to the representatives of the International Medical Congress in August has been duly appointed, Lord Sydenham to be chairman. The commission will inquire into the prevalence of all forms of venereal disease in the kingdom—not merely that which has lately occupied public attention—and into the effects of these diseases on the public health, and the means of alleviating or preventing these effects. But the question of returning to the policy of the Contagious Diseases Acts, 1864-66-69, is not to be considered. The commission consists of sixteen members. Six of these hold medical qualifications, viz.: Sir J. Collie, Sir M. Morris, Drs. F. W. Mott and A. Newsholme, Mr. J. Ernest Lane, and Mrs. Scharlieb. One of the first difficulties confronting the commission will be the lack of reliable statistics, for, although many writers on these diseases have published such statistics as they could collect, they generally have to confess that they are not trustworthy. For fifteen years, if not more, the appointment of a royal commission has been advocated by the colleges of surgeons and other bodies and there

was an International Congress at Brussels on the subject in 1899 at which resolutions were passed urging the various governments to appoint commissions of inquiry, at the same time declaring opposition to anything in the nature of the Contagious Diseases Acts. The recent declaration in favor of a commission signed by the presidents of the Royal Colleges of Physicians and Surgeons, the Regius Professors at the universities, and presidents of medical societies, made an impression in Parliament, members of both houses indorsing it.

A blue book circulated during the week respecting sanitary work in India shows that the improved health of the European army previously reported continued during 1911, the last year for which returns are completed. Cholera and head-stroke increased the death rate a little (4.66 to 4.89 per 1000) over 1910, but the hospital returns were lower than last year, as to admissions, those remaining sick, and invalids. The cases of enteric fever were the fewest on record. There were twenty-one deaths from cholera, an advance over seven in 1910. Anti-enteric inoculation was adopted by 85 per cent. of European troops. The hospital admissions for enteric among the inoculated equalled 1.7 per thousand of the strength; of deaths, 0.17. Of the non-inoculated the corresponding figures were 5.9 and 1.15.

Dr. E. F. Buzzard, in a paper at the Medical Society on "Facial Spasm," said he did not intend to deal exhaustively with every variety, but provide some help in diagnosis and treatment. The first duty of the medical man confronted with a case was, he said, to make up his mind whether it was psychogenic, cortical or peripheral in origin, and subsequently to distinguish between a tic, hysteria, cortical lesion, reflex irritation, post-paralytic contracture, chronic facial spasm, and fibrillotonic facial spasm. The diagnosis established, the proper line of treatment was, he said clearly indicated.

The Royal Institute of Public Health has accepted an offer by Prof. William R. Smith to present annually a gold medal of £20 value "for conspicuous services rendered to the cause of preventive medicine within the British Empire." The award is to be confined to medical officers of health and other medical officials—naval, military, or civil—in the empire.

At the annual dinner of the School of Tropical Medicine last Friday it was said £70,000 of the £100,000 asked for had been received. It was intended to devote £15,000 to the extension of the buildings, further sums to research, to the endowment fund, and in conjunction with the Seamen's Hospital to aid men returned in ill health from the tropics to secure the help of those who understood their diseases.

Sir Patrick Manson was then presented with two portraits of himself subscribed for as a testimonial of their gratitude for what he had done for the school. It was owing to Sir Patrick's inspiration, said Mr. A. Chamberlain in presenting them, that both the London and Liverpool schools came into existence.

The secretary of the Antivivisection Society has disappeared. The Hon. Stephen Coleridge says that an investigation of the society's position showed that a sum of £5,000 was not clearly accounted for and the secretary when called upon for explanation left the office.

Dr. Frederick Dale died suddenly on Oct. 25. He had been out shooting with some friends and returned to his home in his motor car looking quite well. But on entering his house he collapsed and died at once. He was much esteemed, was a J. P. for Yorkshire, honorary surgeon to the Scarborough Hospital and the Sitwell Convalescent Home.

Surgeon-Lieutenant-Colonel H. W. Kiallmark, late of the Army Medical Reserve, has died in his 81st year. He qualified at the R. C. S. Eng. in 1855. At one time he was a staff surgeon in the Ottoman Army.

Surgeon-Lieutenant-Colonel John O'Neill, Indian Medical Service, has also died, aged 65. He was in the Ashanti Expedition, 1873-74, for which he was awarded the medal. In 1875 the civil and jail surgeon, Ferozephur. Retired in 1875. He took M. D., R. University, Ireland, 1870.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

THE HOSPITAL CARE OF TUBERCULOUS INDIVIDUALS—BOVINE TUBERCULOSIS NOT A GREAT FACTOR IN HUMAN INFECTION—TUBERCULOUS INFECTION IS WIDESPREAD—DECREASE IN TUBERCULOSIS MORTALITY IS ONLY APPARENT—IMPERFECTION OF KNOWLEDGE AS TO EXTENT OF TUBERCULOSIS MORBIDITY—ISOLATION THE ONLY EFFECTIVE MEASURE IN COMBATING THE SOCIAL MENACE OF TUBERCULOSIS—UTILIZATION OF PRESENT SANATORIA FOR THIS PURPOSE—THE COST NOT PROHIBITIVE.

Berlin, October 15, 1913.

Among the papers read during the past summer there was one that aroused considerable discussion, namely, a paper by Ulrici presented before the Society for Social Medicine, Hygiene, and Medical Statistics, and entitled "The Campaign Against Tuberculosis Through the Hospital Care of the Infectious Cases." Ulrici dwelt first of all upon the difference between the human and the bovine types of the tubercle bacillus, and accepted the conclusion arrived at by Weber that the ingestion of tubercle bacilli with milk only exceptionally causes human infection. According to Weber bovine tuberculosis is a menace to human beings, for it may cause a fatal infection, but in comparison with tuberculous individuals as a source of infection it recedes into the background.

Naegeli's pathological investigations and the biological methods of testing apparently healthy individuals have shown that tuberculous infection is widespread among the race and that the majority of those infected overcome the bacterial invasion without at any time showing the least clinical evidence of any morbid process. Granting the tendency to spontaneous recovery there remains the question whether we have succeeded by our therapeutic efforts in reducing the mortality from this disease. This question may be decisively answered in the affirmative for the mortality from tuberculosis in Prussia fell from 32 per 10,000 in 1875 to 14.5 in 1912. Nevertheless a number of weighty objections have been advanced against this conclusion. Thus there can be no question that even in Prussia the causes of death given in death certificates are frequently deceptive. Moreover, the total mortality has diminished, so that using this as a basis of comparison the reduction in tuberculosis mortality has been 9.5 per cent. instead of 12.3 per cent. That the reduction in the tuberculosis mortality is not dependent on a reduction in the tuberculosis morbidity may be explained on the basis of the fact that the workmen's invalidity insurance measures have tended to prolong the course of the

disease, and also on the basis of the fact that nowadays many wasting conditions that were formerly diagnosed as tuberculous are as the result of more refined methods of diagnosis no longer regarded as such. Besides it is remarkable that since the discovery of the tubercle bacillus there has been a pronounced rise in the mortality from nontuberculous diseases of the respiratory organs. The diagnosis of tuberculosis is not welcomed by the people in general, and is frequently avoided intentionally. From all of these facts Ulrici concludes that it is quite possible that tuberculosis mortality has run parallel with the general mortality, and that no valid proof yet exists that the tuberculosis mortality has diminished to any greater degree than the general mortality. Another source of error in the mortality statistics resides in those pertaining to infantile tuberculosis. The Prussian statistics show a mortality of 2.3 per cent. while the reports from autopsies on children show a percentage as great as 15.

If the extent of the mortality is determined with difficulty, all the greater is the difficulty in estimating the extent of morbidity. Ulrici estimated the number of infective tuberculous individuals in the German empire as 350,000. He reaches the following conclusions: (1) Tuberculosis results from a direct infection from person to person. The source of infection is almost exclusively pulmonary tuberculosis. (2) Only a small percentage of individuals who have attained the fifteenth year of life escape tuberculous infection, but only a relatively small proportion of those infective show any evidence of tuberculous disease. (3) The incidence of tuberculosis is dependent on the mode of infection, particularly upon the number of bacilli taken in, on the one hand, and the resistance of the individual on the other hand. Children are particularly endangered by infection. (4) Tuberculosis mortality as well as general mortality has diminished, but it has not been proved that the diminution in the former has been any greater than the diminution in the latter. (5) No reliable data are yet available regarding the morbidity from tuberculosis.

There are three measures of combating infection: the safeguarding of all children, the improvement in the natural powers of resistance, and the sanatorium treatment of incipient cases. For the last purpose there have been expended in Germany during the last twenty years 100 million marks. A further yearly expenditure of twenty million marks is required. The results of the sanatorium treatment are good as far as the individual cases are concerned, but provide no satisfactory relief from the social damage that is inflicted by tuberculosis. The strengthening of the individual's powers of resistance by improving home conditions, by combating alcoholism, etc., may diminish the social menace of tuberculosis, but will have little effect upon the disease itself. The latter can be controlled only by preventing the massive infection, particularly of children, by effecting the isolation of all open cases of tuberculosis. This may be accomplished by enlarging the present tuberculosis sanatoria of which there are 800 in the empire. Compulsory isolation could be carried out in connection with the national workmen's invalidity insurance system.

Hitherto little has been done to bring about this isolation. Ulrici believes that in the sanatoria only one per cent. of the patients are isolated. Only 30 per cent. are bacillus-free. The hospitals accomplish still less in the matter of isolation. On an average the advanced victim of phthisis stays in the hospital from six to seven weeks, as a rule, before he dies. It is quite impossible to isolate the patient in his home. The only effective means for accomplishing isolation is to provide for the care of all tuberculous individuals in institutions. This is practically impossible at the present day. These cases, however, can be specially looked after in which children are exposed to infection in the home. Severe cases can be provided for in special institutions. The establishment of such institutions is far more important than the building of new sanatoria. It would be a good plan to at once provide for the admission of some of the advanced cases to the present sanatoria. The prospective cost is not prohibitive.

OUR LETTER FROM THE PHILIPPINES.

HUMAN PLAGUE TRACED DIRECTLY TO THE RAT—CHOLERA—FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE—MEASLES ON A TRANSPORT—PERSONALS.

MANILA, P. I., September 27, 1913.

DURING the past week there occurred a death from plague in Manila in which it was possible to trace the origin of the infection in a much more satisfactory manner than is the case in the majority of instances. On September 6 a plague rat was discovered in the block between Calle Echague and the Pasig River immediately above the Santa Cruz Bridge. An active campaign for the eradication of the rats was immediately begun and most of the area had been covered. The work consisted in rat trapping, and a general cleaning up by a gang of laborers especially employed for this purpose. Woodpiles were taken down and repiled so that there was a clear space under and behind them. Old hay, straw, etc., were removed. Many rat nests were destroyed in this way. Among the places that had not yet been reached was the Stewart Building, in which were located the offices of the Manila *Daily Bulletin*. The editor of this paper was taken violently ill on September 19 and on September 20 his case was definitely diagnosed as one of plague. On September 22 he died of typical bubonic plague and subsequent necropsy and biological findings were positive for that disease. In carrying out the insecticidal and other antiplague measures in his office a mummified rat was found in a drawer of his desk. There were in the drawer a number of fleas. One of these was captured and identified at the Bureau of Science as a *Pulex cheopis*. Stained microscopical specimens from this flea showed bipolar organisms that were identical with those of plague. On account of the fact that the flea had been transferred to the laboratory in alcohol, it was impracticable to make animal inoculations. The mummified rat, however, was ground up and inoculations made into healthy laboratory rats resulted in typical cases of plague. The important deduction in connection with this experience is the fact that the rat had been dead for at least two weeks, and probably much longer, still there were live fleas hovering about the carcass in which plague organisms were still present and the carcass of the rat contained undoubted virulent plague bacilli. This death also affords an excellent illustration and offers strong proof as to the close connection between rat and human plague.

During an examination made of the storehouse of a grocery store which is on the first floor of the

above building four other dead rats were found, and a Chinese employee of the warehouse died on September 20, after one day's illness. He was certified as having been ill for four months and as having died from pulmonary tuberculosis. The health authorities had the body exhumed and it was definitely ascertained that he had not died of pulmonary tuberculosis and the laboratory examinations that are now under way indicate that in all probability the death was due to plague.

After the two cases of cholera which occurred on August 25 no further cases were found until September 13. During the week ended September 20 there were three cases; during the week ended September 27 there were also three cases. All of them occurred in widely separated sections of the city and it has not been possible to trace any connection between them. The first case, which occurred on September 13, was in the person of a Filipino carpenter, who worked at the corner of Calle Padre Faura and Calle Taft, with a large number of laborers and lived a few blocks from the place at which he worked. This is in the Malate district and is one of the best residence sections of the city and miles removed from where the last case occurred in August. The second case occurred at Pasay, which is again several miles from where the last case occurred, and was in the person of an American who was employed in the Quartermaster's Department. There has been no satisfactory explanation offered as to the cause of the outbreak. It was apparently not introduced from abroad.

The Far Eastern Association of Tropical Medicine will hold its third biennial session at Saigon from November 8 until November 13, under the presidency of Dr. Clarac, who is the inspector of the Sanitary Service of the Colonial Troops. Practically all of the Oriental countries will be represented. The Philippine Government has detailed four representatives and it is likely that the Army and the Navy will each send a delegate.

In connection with the transmission of measles, it may be of interest to report that on the trip of the U. S. Army transport *Thomas*, which ended in Manila on April 11, an outbreak of measles took place during the voyage, which was confined entirely to steerage passengers. The last case occurred on April 10. On the vessel's arrival at Manila careful daily examinations were made of the passengers, but no further cases could be detected. On April 16 a child that traveled in the first cabin complained of malaise and was found to have slight fever. On the 17th and 18th there were no symptoms. On the 19th there was coryza with fever and Koplik spots, and on the morning of the 20th there was marked eruption.

Lt.-Col. Paul F. Straub, who has been on duty at Camp Stotsenburg, has been transferred to Manila as the assistant to the chief surgeon of the division, Vice-Lt.-Col. Henry A. Shaw, who has been transferred to the United States.

Surgeon W. A. Korn of the Public Health Service has been relieved from duty in Manila and ordered to report for duty at Hongkong in the office of the American Consul.

Dr. H. F. Smith was one of the successful candidates at the examination held in Manila during June for entrance into the U. S. Public Health Service, and he has now been appointed as an assistant surgeon in that service, and directed to report for duty to the chief quarantine officer for the Philippine Islands.

POTASSIUM NITRATE IN BRIGHT'S DISEASE.

To the Editor of the Medical Record:

Sir:—In recent years I have treated successfully thirty cases of Bright's disease with potassium nitrate. All cases except one came under observation incidentally. It is my rule to examine the urine of every patient, and I found those cases of Bright's before the disease had developed to a serious state. I comprehend under Bright's disease chronic and acute nephritis; more than half of the thirty cases treated were chronic. I give potassium nitrate in doses of from 0.5 to 1.0 gram, dissolved in 15 c.c. of water every two hours till the casts disappear and the albumin is reduced to a trace, then the same dose three times a day for several weeks after the urine is normal.

Potassium nitrate does not disturb the stomach or intestines and has no bad effect on the patient; it is taken best in a half cup of milk. In some cases causes constipation and this action has to be neutralized by some natural aperient water taken every morning. In a case of ten years' duration the action of the remedy was made very clear. When the albumin had been reduced to 0.08 per cent. potassium nitrate was not taken for two weeks and the albumin increased to 0.3 per cent. with reappearance of hyaline casts. In the following two weeks of regular treatment the casts disappeared and the albumin went down to 0.15 per cent. The following six weeks the patient took the remedy occasionally and the albumin did not increase; when during the next two weeks potassium nitrate was taken regularly every two hours the albumin went down to 0.08 per cent.

I will not say that the disease is curable in the last stage, but I am convinced that it is possible to stay the disease and prolong life.

Progress of Medical Science.

Boston Medical and Surgical Journal.

November 8, 1913.

1. Progress and Problems in Preventive Medicine. M. J. Rosenau.
2. The Surgical Taeatment of Pulmonary Tuberculosis. Mary E. Lapham.
3. Orthopedics and the Sanatorium. H. J. Hall.
4. Hereditary Chorea with Report of a Case. W. A. Boyd.

1. **Progress in Preventive Medicine.**—M. J. Rosenau refers in his Ether Day address among other things to some hygienic fallacies of the past. Fomites play but a small rôle in the transmission of infection. Nowadays the sanitarian pays little heed to aerial infection except to the extent that this may be conveyed by droplets from the nose and mouth. Ozone has no useful disinfecting power in occupied rooms. The sanitarian doubts the advisability of artificially raising immunity by means of bacterial vaccines as a wise measure for the population at large. He believes that it would be much better to fight typhoid fever and tuberculosis along the lines of hygiene and sanitation, even though it may take a long time to conquer these infections, but once conquered along these lines the victory will be enduring.

2. **Surgical Treatment of Pulmonary Tuberculosis.**—Mary E. Lapham believes that all the good results of artificial pneumothorax can be obtained by the establishing of a permanent opening in the pleural cavity. If this could be done without the production of a fistula or the infection of the cavity there would be many signal advantages over the present methods. The nitrogen is a

foreign body, it takes up space in the thorax, it alters the negative pressure upon which the successful mechanism of the thorax depends, and it interferes with the action of the other lung, the return circulation and the gastrointestinal circulation. It forces the diaphragm down, impedes the expansion of the other side of the thorax and creates many difficulties that have to be overcome in order to obtain results. By transmitting atmospheric pressure to the periphery of the lung until the intrabronchial pressure is balanced, we can prevent the expansion of the lung simply by destroying the principle upon which this depends. The lung would collapse but there would be no distention of the pleural cavity, no pressure upon the return circulation, no interference with digestion, and no crippling of the other lung. In every way this condition would be far less trying than the compression of the lung with a closed pleural cavity. The mechanical conditions are different and much less trying to the patient than an artificial pneumothorax. This method could be used in cases of bilateral involvement when the better lung is hardly able to stand the strain of a pneumothorax. The author has as yet had no opportunity to test the clinical value of this method.

3. **Orthopedics and the Sanatorium.**—H. J. Hall details the advantages of orthopedic or postural methods in the management of various types of nervous exhaustion. After a few days to a few weeks of complete rest in a darkened room, with frequent feedings, massage, and electricity, the patient, if requiring postural treatment, may be given direct treatment by the use of a simple device called the floor pad. This consists of a thin and narrow mattress laid upon the floor and made available as a corrective apparatus by bundles of sticks or wedges of wood placed underneath in such a way as to modify the bodily curves of a person lying upon it. With this pad it is possible to maintain correction or overcorrection of lateral or faulty anteroposterior curves for hours together with little tax upon the patient's strength.

4. **Hereditary Chorea.**—W. A. Boyd reports a case of this condition in a woman in whom the first symptoms developed at the age of twenty-six years. This is much younger than the average age at which the choreic symptoms appear. The first account of hereditary chorea appeared in Dunglison's "Practice of Medicine" in 1842, being an account by C. O. Waters of Franklin, N. Y. In 1863 J. W. Lyon wrote a description of this disease, calling it "migrims." The most thorough study of hereditary chorea was made by George Huntington, who published in 1872 a paper on this disease which is now commonly referred to as Huntington's chorea. His study was based upon many cases occurring in his father's and grandfather's practice, and upon three cases occurring in his own practice. All of the patients lived in or near Easthampton, L. I. According to Huntington the disease is confined to a few families and is transmitted from generation to generation. It never skips a generation. If a child does not inherit the taint, descendants will also be fact that a tendency to insanity and sometimes to suicide is marked. A third characteristic is the fact that the disease comes on, at least as a grave disease, only in adult life.

1. **Spinal Anesthesia.**—W. W. Babcock states that the morbidity of spinal anesthesia as expressed by nausea, vomiting, headache, backache, postoperative pain, and albuminuria is less than that from ether. Ocular palsy may result from spinal anesthesia where contaminated or deteriorated solutions are used. A lateral deviation of the needle with injury to a nerve root may be followed by severe neuritis and secondary palsy. Secondary degeneration of the spinal cord from the chemical action of free from it. A second peculiarity of the disease is the stovaine, properly introduced for purposes of spinal anesthesia is doubted. Functional or neurotic symptoms occur after spinal anesthesia as they do after etherization, and may, to the annoyance of the surgeon, be attributed by the patient to the injection. If a steel needle is used it may be broken under the skin during the injection. Danger symptoms may follow if the patient is moved immediately after the injection or if the proper posture to prevent the anesthetic from reaching the upper nerve roots is not maintained for at least one-half hour after the injection. Repeated intradural injections seem to be harmless. Spinal anesthesia is dangerous in circulatory subtension, conditions greatly depressing the respiratory centers, and shock, collapse, advanced myocardial disease, and large intrathoracic effusions. It is more dangerous in operations upon the upper abdomen than in those upon the lower. It does not obviate the danger of sudden cardiac arrest in operations for large uterine fibroids. The newer methods of anesthesia, including spinal anesthesia, nitrous-oxide-oxygen, and intravenous anesthesia should have their use restricted to selected patients by those who are properly qualified. If the patient cannot be properly watched for one hour after the injection, if the operator does not understand the dose and mode of diffusion of the drug, or if he is unprepared to meet emergencies, then spinal anesthesia should not be employed. For general indiscriminate use ether remains the standard anesthetic despite its many drawbacks.

3. **Surgical Experiences in the Servian-Bulgarian War.**—R. J. Behan, an American who served as surgeon to the Fourth Reserve Hospital, Nish, Servia, during the recent war, states that the wounded were of all types. Of 177 cases selected at random, there were five scalp wounds. Of these one was a very severe laceration. There were two skull injuries with fracture; eight face injuries, one with destruction of the eye, three with fracture of the lower jaw, and one with persisting parotid fistula; five neck wounds; seventeen chest wounds, in which empyema developed in five with subsequent operation; six abdominal wounds, all of which recovered without operation; sixteen upper arm wounds with four fractures of the humerus and one of the clavicle; twenty-one wounds of the forearm with two fractures of both radius and ulna and one fracture of the radius; twenty-two wounds of the hands; twenty-seven wounds of the thigh with two fractures of the femur; twenty-four wounds of the leg with four fractures of the tibia; and twenty-four wounds of the foot. Most of the cases except the fractures and infected cases were discharged in about a week or ten days. Of the 177 soldiers, fourteen had been wounded in two or more places, and twenty-four were more or less severely infected. The mildly infected cases, in which the wounds were superficial, were not counted. Of the 154 soldiers of whom there were records, fifty-six were wounded by shrapnel, ninety-four by bullets, two by grenades, and two by bayonet. There were evidences of the cruelty of the Bulgars. There were in the hospital the only four survivors of a body of thirty men of the Fourth Reserve, whom the Bulgars after capturing grouped into a solid mass, forming a ring about them with fixed bayonets, and then dancing around the cowering mass in the center, advancing and retreating from them. Each time that they

approached they prodded the victims one or more times with bayonets. After the dance was over the writhing human mound in the center was left to its own anguish. Of the thirty only four were found alive, and were sent to the reserve hospital. Of the four, three had been castrated. One of these died the same night. Of the three others, one who had a bayonet wound of the back penetrating into the rectum and pelvis died in two days. The other two recovered.

7. Blood Ptosis and Test of Vasomotor Efficiency.—G. W. Crampton has devised a test which records the efficiency of the vasomotor system in responding to the necessity of raising the blood pressure upon rising from the recumbent to the standing position. In the perfectly normal vigorous male the blood pressure will rise from eight to ten millimeters of mercury upon assuming the standing position. In one damaged by disease, overwork or unhygienic living, or weakened by inactivity, the blood pressure will fail to rise and may fall as much as ten millimeters of mercury. The heart rate acts in exactly the opposite fashion, rising in proportion to weakness as much as forty-five beats a minute, but only in exceptional cases falling. These two adjustments are interdependent, one often masking the failure of the other, and both must be considered and balanced. If blood pressure were alone considered many cases showing a high heart rate would be given a good rating when it should be poor, and *vice versa*. In the perfectly normal individual there occurs upon rising from the recumbent position a vasoconstriction effort which squeezes these veins and raises blood pressure which more than overcomes the added hydrostatic load. In the subnormal this vasoconstriction effort is relatively weak and ineffective and does not raise the blood pressure in the upper body, but allows it to fall under hydrostatic pressure. There is a blood ptosis due to the relative failure of vasomotor tone. This may be mild, merely a failure to raise the pressure or a fall of the systolic pressure five or ten millimeters, in which case one may still call the patient fairly normal. It may be a more complete failure, allowing the systolic pressure to drop to forty or fifty, at which point the patient faints from cerebral anemia. This is the familiar picture seen when a convalescent patient with an impaired vascular tonus rises prematurely from a sick bed, and, robbing the splanchnic veins of mechanical support by emptying the bladder, falls to the floor. It would then seem to be necessary merely to observe the amount of rise or fall of the systolic pressure at a convenient point in the upper body to determine the efficiency of the vasomotor system and its reverse, the amount of blood ptosis. The author has devised a scale which provides a convenient and intelligible method of recording and reporting cases and permits a numerical statement of the function in question.

8. The Protective Phenomena of Angina Pectoris.—W. J. Pulley discusses the views of Mackenzie on this subject. The latter states that angina pectoris is an evidence of an exhaustion of the function of contractility. Pain and reflex muscular contraction are the symptoms which are reflexly produced and protective in their action. That these reflex phenomena are due solely to an impairment of the contractile function of the heart does not explain the entire situation, for there must of necessity be present with it a great distress of the function of tonicity, if not a beginning impairment. The pains are protective, in that they cause the patient to cease most muscular efforts, and tend to rest the heart by taking just that much extra work off it and give it a chance to regain some of its lost reserve. The fear produced in the patient by these attacks also has a protective tendency, in that it causes the patient temporarily to cease worries and excesses of all kinds thereby tending to lower vascular supertension and rest the heart. The flushed face, in the other class of cases, is due to reflex stimulation of the vasodilators of the superficial capillaries, which also tends to reduce vascular supertension. The contraction of the intercostal muscles is protective, in that it tends to prevent deep breathing, and to act as a splint to protect the already stretched and weakened walls of the aorta. Deep inspirations tend to increase the arterial tension.

1. Neurasthenia and Emotional Susceptibility.—H. T. Pershing defines neurasthenia as a functional nervous disorder, not dependent on organic disease of any kind, not amounting to insanity, and not hysteria, manifested by irritability, early onset of mental fatigue and a great variety of unpleasant and, to the patient, alarming sensations, chiefly in the head, but also in various other parts of the body. As regards its etiology the idea of fatigue, especially mental fatigue, is forced on one, but a critical examination of the facts shows that this cannot be the chief factor in the causation. Under favorable circumstances the neurasthenic can often do a large amount of bodily or mental work to advantage as is shown by Dr. Hall's work-cure at Marblehead, Mass. Patients are often worse on Sundays or other holidays and are usually worse in the morning than in the evening. The essential fact is that they are especially subject to emotional disturbances, not that these are so overintense, but they are constantly recurring. The condition is analagous to anaphylaxis. The part of the cortex where emotional processes start has become sensitized so as to react with less cause than in the normal brain. It may be described in the technical language of physiology as a lowering of the emotional threshold.

4. Ureterovesical Cysts.—J. R. Caulk describes the cystic dilatations of the lower ureter, impinging on the cavity of the bladder, which have been more observed of late years since the use of the cystoscope, and reports six cases, five in women and one in a man. These cases show that not all of these cysts are congenital as has been claimed, but appear to be more often acquired. One of the six was due to inflammatory changes secondary to tuberculosis. One appeared in the course of a long-standing calculus pyonephrosis. One gave the history of the passage of two stones from the kidney; and one was secondary to a healed ulcer. In all there were symptoms of vesical irritability, and in one there was obstruction. Two of the patients were operated on by total resection of the cyst under the guidance of the cystoscope, a method which the author says gives very satisfactory results, and in his cases offered no particular obstacles. The suprapubic operation, whether slitting the orifice longitudinally with suture of the two mucous surfaces or a circular amputation of the cyst with suture of the two surfaces, or the hernia operation employed by Young, are more radical

measures and possibly offer better curative results. The author thinks, however, that the chances of recontraction are about as great with these methods as the operation he employed in his two cases of total resection, with denudation of a large area around the ureteral orifice. His results show that it may offer relief for two years or more, and since the operation is a minor one, done without general anethesia, and is simple in technic and non-dangerous, it should be the operation of choice in many cases. The endovesical operation he says gives no permanent benefit and the suprapubic operation seems too radical as the initial one in most cases.

5. **Untoward Results of Nephrolithotomy.**—M. Krotoszyner states that while the operative results of lithotomy have been very satisfactory at the hands of most renal surgeons, and it has been the operation of choice for renal calculi for the past twenty years, nevertheless he sees in it some dangers which, he thinks, ought to lessen its popularity. The most important of these is postoperative hemorrhage, which lends to it an almost ominous aspect. Perirenal infection and the still graver septic nephritis are risks incurred in nephrolithotomy. An infected stone-kidney and fistula of shorter or longer duration is the rule and in many cases relieved only by a secondary nephrectomy. Cases are reported of these complications and the author thinks they are a serious drawback to the operation. Posterior pyelotomy for aseptic and moderately infected cases, and for the majority, nephrectomy, are advocated by him as the safest and best. He concludes that nephrolithotomy is connected with serious immediate and remote untoward results. It should be, wherever feasible, replaced by posterior pyelotomy. Nephrectomy is the simplest, quickest, and safest curative method for pyonephrotic stone-kidney, provided the function of the other kidney is satisfactory.

7. **Repair of Defects of the Ureter.**—Dr. N. Eisendrath concludes that one can transplant portions of the bladder to take the place of segments of the dog's ureter. These transplanted segments will preserve their vitality even though they have no vascular connection with the bladder. It is immaterial whether the dividend ends of the ureter are brought into exact end-to-end approximation with the transplant or are sutured to its inner surface in the manner described. Even though the bladder mucous membrane is accustomed to the presence of urine, it will undergo cicatricial changes in the same manner as other structures, as artery vein, appendix, bowel, horn of uterus, which are lined with endothelium or mucous membrane, not accustomed to presence of urine. Even though union of the transplant occurs, it soon becomes transformed into connective tissue drawing the two ends of the ureters together with resultant stenosis of the ureter and hydronephrosis and hydroureter.

9. **Decidual Reaction in the Appendix.**—G. W. Outerbridge reports a case of the occurrence of decidua in the appendix after delivery, the second case as far as he is able to ascertain ever reported of the reaction in this locality, though the occurrence of tissues of this histological description in various other situations outside of the uterus has been described. The origin of such formations is discussed. The author rejects Taussig's theory of its being due to surface irritation by cellular detritus from the placenta passing out through the lumen of the tubes, and favors that of Loeb of the influence of a sensitizing hormone from the corpus luteum.

13. **Verruga Peruviana, Oroya Fever and Uta.**—R. P. Strong, E. E. Tyzzer, C. T. Brues, A. W. Sellards, and J. C. Gastiaburn record the results of an expedition to investigate various tropical diseases occurring in South America. In Peru the diseases particularly investigated were verruga peruviana, Oroya fever and uta. The history and literature of these conditions are discussed. The general opinion among physicians of Peru is that verruga begins as a fever lasting from fifteen to thirty days with profound anemia, prostration and a high mortality. If the patient does not die in this stage the fever begins to abate and the eruptive stage commences. It is said that if the eruption is abundant the patient is sure to recover. The authors conclude that Oroya fever and verruga are two distinct diseases. The latter is due to a transmissible virus, whereas the former is due to an organism parasitic in the red blood-corpuscles. So far this organism has not been successfully transmitted to the lower animals. It is quite evident that verruga is an entirely distinct disease and that it is not a form of frambesia or syphilis. The inoculation period in rabbits is from ten to twenty-two days; in dogs and monkeys, cutaneous and subcutaneous, and sometimes intraperitoneal, inoculation has given rise to symptoms after from eleven to seventeen days. The localized reactions and lesions have sometimes resembled closely those observed in man. The Wassermann reaction was negative with one exception in the cases of oroya fever which were examined. Moreover no fixation of complement can be obtained when a specific antigen is substituted for the antigen used in the routine Wassermann reaction. The patients were vaccinated against verruga and it seems hopeful that a successful means of vaccination against verruga may be obtained. The authors were able to show that uta is due to a species of Leishmania; the flagellate stage of the organism was obtained and animals have been successfully inoculated from a human case.

1. **The Invention of Spectacles.**—G. H. Oliver states that there is ample evidence to show that biconvex lenses were used by the ancients as burning glasses. Pliny relates that glass balls filled with water were used by physicians for burning, and were to be bought from medicine dealers, and, perhaps, formed part of the armamentarium of the practitioner. That glasses were invented at the end of the thirteenth century in Italy is abundantly shown by the great majority of contributors to the history of this subject, and either by Armati and Spina together or independently of each other. At the same time in Germany and Flanders old people were using glasses. The first medical man to mention glasses was Bernard Gordon, educated at Salerno, and professor in Montpellier. He said that they were not necessary, thanks to his remedies for eye complaints, which so excelled that they made those whose sight was failing able to read small print without the use of glasses. Guy de Chauliac, body physician to Popes Clement VI, Innocent VI, and Urban V, also lauded his own eye lotion, but added: "If this doesn't relieve you, then try eyeglasses." No one at this time knew anything at all about the refraction of light, hence the senseless talk about the various remedies. The laws of optics, relating to glass lenses, have been known only since the time of Maurolycus (A. D. 1494-1575) and the immortal Kepler (A. D. 1571-1630). The physician who first ordered glasses in a professional capacity was one Montanus, a teacher in Padua. He ordered protecting glasses, reading glasses, and, some say, prisms. Physicians at this time evinced great hostility to the wearing of glasses, and owing to the way in which they dissuaded the people from their use, it was not to be expected that it would spread very rapidly. In early times men were

strongly opposed to this custom, as at first glasses were ill-shaped and most disagreeably striking in appearance, and, more than this, they directed the attention to a physical disability. Patients wearing glasses were made fun of, and not altogether in a very tender manner. Their prohibitive costliness rendered the wide adoption of spectacles impossible. At the end of the sixteenth century the price per pair, expressed in terms of present-day value, was from fifty to a hundred dollars. From this circumstance glasses which frequently had costly ornamental fittings were seldom seen, and then in the possession of wealthy people only. The history of the development and use of the concave lens is very different from that of the convex variety; it came on the scene much later. There is no mention whatever of concave glasses by the ancients, though short-sightedness was well known, not as an error of refraction, but as a weakness of the eye. One can assume with a fair degree of certainty that concave glasses came into use about the middle of the sixteenth century.

4. Influenzal Meningitis.—A. Ross and H. E. Moore report a case of this condition and note that as regards the diagnosis of influenzal meningitis nothing has yet been noted which can enable the observer to differentiate it from the post-basic type. It is true that in some instances wild delirium is marked, but this seems by no means common. In the case recorded by the author the sudden "fitting" with rapid transition to rigidity was striking, and perhaps important clinically, since one of the cases noted by Batten began in the same way. From the statistics available, the prognosis is undoubtedly very bad, and is certainly the more severe the younger the patient. Sanger's example of a boy aged nine, who recovered, was for some time the youngest recovery recorded, but Batten's case of a child fourteen months old, who was improving long after the acute stage had passed off, shows that even at the earliest age a fatal prognosis should not be absolute. The cases that survive are so few that ultimate prognosis is very difficult. In the last instance mentioned there had been blindness, which was gradually passing off at the time when Batten published his paper. A patient of Sayce was ill six months, and developed a flaccid paralysis, while Mya, in 1902, had a case which recovered, but was left with a hemiplegia. Treatment seems to have little effect upon the disease. Vaccines have been given, but the results do not appear to be encouraging. The patient aged fourteen months, to whom Batten refers, was given 10 grains of urotropin every four hours, and recovered. In the case described by the authors urotropin was used, but the dose was much smaller.

5. Emetine in the Treatment of Liver Abscess.—R. L. Spittel favors Rogers' method of dealing with liver abscesses—namely, to aspirate them, inject emetine hydrochloride (1 grain to 1 oz. of water) before withdrawing the cannula, sealing the puncture with collodion, and repeating the procedure on a further occasion if required. The post-mortem findings of the case recorded by the author suggest that emetine besides having a specific action on the amebæ may also be an organizing and cicatrizing agent of some value. In Rogers' words, the abscess will be found to dry up.

Münchener medizinische Wochenschrift.

October 21, 1913.

The Abderhalden Seroreaction in Epilepsy.—Binswanger as a result of numerous investigations, reduces this subject to a series of questions. First, does there occur in completely developed epileptic convulsions a so-called paroxystic disintegration in the cortex? Blood was drawn at various intervals after an attack—immediately, after two days, after five days, etc. The number of cases tested was not large, but in every case Abderhalden's test was positive, as shown by disintegration products of the cerebral cortex. In one test two weeks after an attack the test was negative. The next subject for investigation had to do with the interval attacks. The author has now done away with the neurosis theory of genuine epilepsy and regards the entire disease in whatever manifestation as organic. This harmonizes with its chronic progressive course. Twenty-two cases were tested in the interval. The results were variable, quite a number being cleanly negative. When the results were positive there was a suspicion of associated dementia. In such cases, therefore, prognosis should be unfavorable, or one should think of the possibility of overlooked nocturnal attacks. Individual cases are given at length in which the test proved of the greatest value. Hysteria and affect epilepsy should read negatively, and this is readily demonstrable; but some cases of mixed type posing as hysteria, etc., may be found to be epileptic. The author's procedure is as follows: In all cases, whether or not typical, we make two groups of positive and negative findings. If in the intervals the "defensive ferments" are absent from the blood it shows that the "progressive anatomical process," as expressed by an attack, is not immediately impending, this also including psychical attacks. What therapeutic deductions are apparent here? The moment is favorable for treatment. Nothing new is suggested —simply the time-honored procedures, with special reference to operative possibilities. Naturally the serodiagnosis should not antagonize, but confirm our older resources for diagnosis. This test seems to be what has converted the author to the "panorganic" theory of epilepsy, and without this resource such a view would fall to the ground.

Pathology of the Liver.—Gunderman, who was studying the pathology of the omentum, occupied himself for a time with the rationale of gastrointestinal hemorrhage following resection of that structure. Animal study shows that ligation of the omental vessels causes ulcers of the stomach and necroses of the liver. The author repeated and amplified these studies by ligating the left branch of the portal artery which presides over three-fourths of the liver. Many of the animals did not survive the intervention, while in others the liver underwent compensatory hypertrophy and survived. The animals which succumbed showed subnormal temperatures, apathy, and, at times, convulsions. Death seems to have been due to acute uremia. Even in the survivors there were evidences of nephritis. Autopsies proved that a pure uremia had been set up by the intervention in the omentum and liver. Also gastric and duodenal ulcers were found in connection with gastroenteric hemorrhage. The author asks himself the old question as to whether uremia is the direct result of dysfunction of the liver. Detached facts of all kinds support this view. With the liver eliminated, poisons of all kinds may reach the blood. If the choledochus is ligated we obtain the clinical picture of cholemia, a condition much resembling uremia.

Choreiform Manifestations in Poliomyelitis.—At the recent French congress of pediatrists Netter and Ribadeau-Dumas reported the case of a six-months-old infant who presented the following manifestations of poliomyelitis: paralysis of both legs, one arm, and the upper part of the other arm; nystagmus; choreic movements of the facial muscles, and protraction of the tongue. Lumbar puncture showed a lymphocytosis. The infant died in the course of a complicating bronchopneumonia. Autopsy showed the characteristic lesions of poliomyelitis. Choreiform movements are frequently observed in the course of experimental poliomyelitis in the monkey, but are exceptional in the human cases.—*La Presse Médicale.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

SELF-SELECTION (CONCLUDED).

The few remaining forms of self-selection are exercised subsequently to the date of the examination. A brief description of those which are important will complete the discussion of the subject.

Self-Selection in Delayed Payment of the Initial Premium.—The agents have positive instructions not to deliver policies until they receive the first premium. When it comes to the payment of this premium, a good many applicants find it inconvenient to do so, or have grown lukewarm and reluctant to complete the transaction. In either case there is considerable doubt as to whether the policy will be placed. The agent is allowed a certain length of time, varying from thirty to sixty days in the different companies, to collect the premium and deliver the policy. This period is long enough for some illness to develop or accident to happen, in which event those who have procrastinated or have even decided not to take the policy, may change their mind and become anxious to pay the premium and get possession of the document. In order to forestall a plan of this kind it becomes necessary for the companies to insert a restrictive clause in their application blanks whereby the applicant agrees that the proposed policy shall not take effect unless and until after the first premium shall have been paid during the applicant's continuance in good health, and unless the policy shall have been delivered to and received by the applicant during his or her continuance in good health. When a binding or conditional receipt has been given to the applicant by the agent in exchange for the initial premium in cash, however, the insurance goes into force as soon as the application is approved and the policy issued.

Self-Selection Exercised When Policies Mature.—Under some policies the holders are entitled to exercise certain options either before or when the contract matures. For instance, when a twenty-payment life policy matures the holder may draw the accumulated reserve and the surplus in cash, or he may continue the policy with the addition of the accumulated reserve and surplus as paid-up insurance, no more premiums to be paid. If he were in good health at the time, he would be apt to draw the cash; but if, on the other hand, his health were questionable, he would choose the paid-up insurance, thereby selecting against the company. To provide for this contingency a policy holder who expects to take the paid-up policy must signify his intention a stated period of time, usually two years, before the date of maturity, and, failing to comply with this requirement, must undergo a physical examination. The privilege under many term insurance contracts to change to other forms of policies answers as another illustration. A term contract terminates at a stated time. If the holder may change to a life plan a short time before the date of termination and thereby continue his insurance in case he happens to be in uncertain health at the time, he will naturally do so and select against the company. If, however, he believes that his health is good at the time he will allow the insurance to terminate. The abuse of the privilege for changing the plan is prevented by restricting it to the first part of the life of the policy.

Self-Selection in Extended or Continued Insurance.—In the event of default in payment of the premium, provided at least three full years' premiums have been paid, and there is no loan thereon, it is stipulated in many policies that they may be continued for the amount insured and any existing additions for a definite time stated in the contracts. The continued insurance goes into effect automatically, whether the discontinuance is intentional or unintentional.

There is some contention as to the actual amount of self-selection exercised in this direction by holders of policies who, threatened with some lingering illness, will avail themselves of the privilege and escape paying any more premiums up to the time of their death. It is believed by some that adverse selection is common among those deciding to take up continued insurance. According to a paper by Mr. Rhodes, read before the Actuarial Society of America, in about 35 per cent. of these cases in his company the insured were fully aware of the precarious state of their health; furthermore, that there were proportionately five times as many suicides under extended insurance as there had been in his company's general business. On the other hand, some policyholders cease paying because they become poorer, or because the motives which led them to insure have become less powerful.

In a general way, it may be accepted that few policyholders have enough knowledge of insurance to enable them to select against the company in this way, and that, furthemore, most of the companies are fairly well protected from the effect of self-selection as extended insurance does not participate in the profits and as there is usually a surrender charge against the reserve on the policy.

The mortality experience of a company is affected unfavorably by the withdrawal of sound lives as well as by the carrying of those whose health becomes impaired. Every effort should be made to keep the sound lives on the books. This does not mean, however, that any reputable company would make the slightest effort to rid itself of impaired risks as long as they keep up to the terms of their contract.

Combined Life and Accident Insurance.—The Hamburg-Mannheimer Insurance Joint Stock Co., and the Albingia (both of Hamburg) give an outline of the popular accident and death payment insurance as effected by them in concert, this practice having been recently approved of by the Government Inspectors of Private Insurance. The accident-risk was covered by the Albingia, while the death payment end was taken care of by the fellow company, which also assumed all the business management. The combination is known as the U. S. Insurance Co., U. standing for Unfall or accident and S. for Sterbegeld or death payment. Payments are to be made weekly. When a risk dies from an accident or becomes a total invalid, this naturally involves a different state of affairs than is present in natural deaths. Hence a series of combinations which affects the premiums and claims. Thus a man pays 20 pfennig weekly for a policy of 1000 marks for death or complete invalidism, of 25 to 800 marks for partial invalidism, and of a death payment of from 100 to 800 marks, depending on the length of survival. The highest weekly payment is 2 marks. The insured must wait one year before his policy goes into effect.—*Zeitschrift für die ges. Versicherungs-Wissenschaft*, xiii, 4, 1913.

Book Reviews.

Über die Behandlung der Kinderkrankheiten. H. Neumann's Briefe on einen jungen Arzt. Sechste gänzlich veränderte und erweiterte Auflage, bearbeitet von weil. Prof. D. H. Neumann, Berlin, und Dr. E. Oberwarth, Berlin, mit einem Bildnis H. Neumanns. Price 12 marks. Berlin: Oscar Coblenz, 1913.

The death last year of the well-known German pediatrist, Professor Neumann, occurred just before he had completed the sixth edition and revision of his work on the Treatment of Children's Diseases, printed in the form of a series of letters to a young practitioner. Fortunately he had already collaborated with E. Oberwarth in the preparation of this edition, so that the latter was able to carry the work to a successful completion. Like the former editions, this represents a clear and practical exposition of the subject of the therapeutics of infancy and childhood, is strictly up-to-date, the inclusion of such subjects as Eiweiss-Milch, etc., and is remarkably complete.

Heart Disease, Blood Pressure, and the Nauheim Treatment. By Louis Faugères Bishop, A.M., M.D., Clinical Professor of Heart and Circulatory Diseases, Fordham University School of Medicine, New York City; Physician to the Lincoln Hospital; Late Chairman of the Section in Medicine of the New York Academy of Medicine; Member of the American Medical Association; American Therapeutic Society; New York Pathological Society; Alumni Association St. Luke's Hospital, etc. Fourth Revised Edition. Price, $3 net. New York and London: Funk & Wagnalls Company, 1913.

The principal change in this edition consists in the addition of a chapter on "The Construction and Use of Blood-Pressure Instruments." The volume presents to the student a very lucid description of the clinical aspects of blood pressure, and of its management, including the Nauheim treatment. The chapter headings amply indicate the scope of the subject matter. They are as follows: Alterations of pressure in the blood vessels; primary low-pressure cases; the management of primary low-pressure cases; high-pressure cases; the management of high-pressure cases; some obscure symptoms of circulatory disorders, with a consideration of their significance; the management of secondary low-pressure cases; general considerations; the estimation of blood pressure and the use of the nitrites for its modification; the blood-vessel tone-maintaining function of the brain; hypertonia vasorum idiopathica; Nauheim-Schott treatment; description of the Nauheim-Schott treatment; remarks on the nature and cause of heart disease; symptoms of heart disease and practical advice to heart patents; the Nauheim-Schott treatment in New York; typical cases with favorable clinical results recorded in American literature; the construction and use of blood-pressure instruments.

A Guide to the Description of Microscopic Sections of Pathological Tissues. (Part II A of a "Code System for the Hospital Pathological Laboratory.") By O. C. Gruner, M.D. (Lond.), Assistant Professor of Pathology McGill University, Montreal; Pathologist to the Royal Victoria Hospital, Montreal. Price, 35 cents. Montreal: Miss Poole's Bookroom, 1912.

The purpose of this pamphlet is to simplify the explanations necessary for those who write reports on surgical tissues. The rules are also applicable in classroom work in histology. As a systematic guide for the student of histology and for the worker in the pathological laboratory there can be no doubt that this pamphlet fills a distinct want.

Minor and Operative Surgery, Including Bandaging. By Henry R. Wharton, M.D., Surgeon to the Presbyterian Hospital and the Children's Hospital; Consulting Surgeon to St. Christopher's Hospital, the Bryn Mawr Hospital, and Girard College; Fellow of the American Surgical Association. Eighth Edition, Enlarged and Thoroughly Revised, with 570 Illustrations. Price $3.00. Philadelphia and New York: Lea & Febiger, 1913.

This is one of the very few books in which minor surgery receives anything like adequate consideration. At the same time, the general practitioner will find in this volume almost all the surgery which he is likely to want in his daily work. As the book is now in its eighth edition there is no need to enlarge on its merits; but in the next revision we would like to see included a description of Schäfer's method of artificial respiration. The proof-reading needs a little more care than it has yet received; on one page (309) we notice "dilitation," to "dilatate," and "mucus membrane."

The Narcotic Drug Diseases and Allied Ailments. Pathology, Pathogenesis, and Treatment. By Geo. E. Pettey, M.D., Memphis, Tenn., Member Memphis and Shelby County Medical Society; Tennessee State Medical Association; American Medical Association; Tri-State Medical Association of Mississippi, Arkansas, and Tennessee; also Mississippi Valley Medical Association, Southern Medical Association, and of the American Society for the Study of Alcohol and Narcotic Diseases. Illustrated. Price $5.00 net. Philadelphia: F. A. Davis Company, 1913.

In spite of the dedication, which would lead one to infer that the present volume is intended for the perusal of the patient, the physician will find this a most useful book. It differs from most of the current medical literature in that it is founded on the experience of the author. Throughout the book the author insists that it is both cruel and unscientific to treat the habitual users of narcotic drugs as if they were criminals or vicious; the condition under discussion is as much a disease as is typhoid or meningitis. The methods of treatment of previous writers are quoted and freely criticized, and the views of the author are then given in detail. The methods advocated by Wilson, Hare, Lambert, and others are adversely commented upon. For the general practitioner this is a valuable monograph, and it will serve as a companion volume and a corrective to any work on the practice of medicine.

A Manual of Surgical Treatment. By Sir W. Watson Cheyne, Bart., C.B., D.Sc., LL.D., F.R.C.S., F.R.S.; Hon. Surgeon in Ordinary to H. M. the King; Senior Surgeon to King's College Hospital, and F. F. Burghard, M.S. (Lond.), F.R.C.S., Surgeon to King's College Hospital, and Consulting Surgeon to the Children's Hospital, Paddington Green. New Edition, Entirely Revised and Largely Rewritten with the Assistance of T. P. Legg, M.S. (Lond.), F.R.C.S., Surgeon to the Royal Free Hospital; Assistant Surgeon to King's College Hospital; and Arthur Edmunds, M.S. (Lond.), F.R.C.S., Surgeon to the Great Northern Central Hospital; Assistant Surgeon to King's College Hospital. In Five Volumes. Vol. IV. The Treatment of the Surgical Affections of the Jaws, Tongue, and Alimentary Canal. Philadelphia and New York: Lea & Febiger, 1913.

The successive volumes of this important work appear with commendable promptness. In the volume before us we have authoritative methods of treatment for the various surgical affections of the jaws, nasopharynx, tongue, floor of the mouth, pharynx, tonsils, esophagus, abdominal wall, stomach, intestines, omentum, mesentery, rectum, and anus. Further, there are chapters on laparotomy, methods of examination of the stomach, appendicitis, the "acute abdomen," hernia, enteroptosis, and chronic constipation. As in the previous volumes, the authors make no attempt at giving all the methods of treatment that have been devised; and in some instances there is room for various opinions as to which is the best method. But what is given here can be relied upon as safe, and as having met with the approval of men of experience. For the man who has to do surgery at times only, and who does not limit his practice to surgery, this work should prove of unusual value.

A Text-Book of Biology for Students in Medical, Technical, and General Courses. By William Martin Smallwood, Ph.D., Professor of Comparative Anatomy in the Liberal Arts College of Syracuse University. Price $2.75; Philadelphia and New York: Lea & Febiger, 1913.

The earlier chapters of this work take the student through a consideration of the organism as a whole, the structure and functions of organs, the structure and properties of tissues, and the parts of the cell and their work. An elaborate chapter on the biology of cells acts as a background for the rest of the work, which is devoted to the biology of various plant and animal genera. There are chapters given to adaptation, heredity, evolution, and psychology and some biological factors of disease. Of course in a volume of this size it has been necessary to treat the various subjects in an extremely condensed manner, but the essential things are there and the book is an excellent structure on which to build a thorough course in biology. Nearly all of the illustrations have been intentionally selected from material which will not be a part of the regular laboratory work. This removes from the student the temptation to copy the pictures in the book and furnishes additional material for instruction. The book can be unreservedly recommended.

Society Reports.

CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA

Fourth Annual Meeting, Held in Chicago, November 10-14, 1913.

(Special Report to the MEDICAL RECORD.)

DR. GEORGE EMERSON BREWER, PRESIDENT, IN THE CHAIR.

Monday, November 10—First Day.

THE opening meeting of the fourth annual session of the Congress was held at Orchestra Hall, Chicago, at 8:15 P.M. There were approximately 4,000 members in attendance.

Dr. E. W. ANDREWS, chairman of the committee of arrangements, welcomed the members of the association, after which he introduced Sir RICKMAN GODLEE, President of the Royal College of Surgeons of England, who said that he had had the opportunity of seeing the work that was being carried on by the Congress. He was impressed with the enormous amount of clinical material which he saw at all of the hospitals he had visited, and was greatly struck with the methodical way in which instruction was carried on at these institutions.

Dr. MURRAY MCLAREN, president of the Canadian Medical Association, congratulated the officers and members of the Congress upon the remarkable success which had attended the organization from its inception. It was a happy circumstance that its membership embraced both the profession of the United States and of Canada. Medical science knew no territorial limitations. Canada might not care for reciprocity in trade, but she welcomed the closest association and intermingling of the peoples of both countries. The progressiveness, the enthusiasm, broad views, broad education, well trained able minds and skilled hands had all had their effect in placing American surgery on an eminently high plane. They in Canada looked to American surgeons and received freely from them much information, much suggestion, much instruction, and always accompanied with kindliness and courtesy.

Professor KRÖNIG and Dr. C. J. GAUSS of Freiburg, Germany, referred to the great work that was being accomplished by this gathering of surgeons.

Presidential Address: A Preliminary Report on a Simple and Rapid Method of Pyloric Closure in Gastroenterostomy.—Dr. GEORGE EMERSON BREWER of New York City reviewed the various methods of pyloric closure which had been suggested in the past; and referred to a series of experiments lately published by Tappliner, showing that all simple methods of closure, as by ligature with or without contusion, the employment of a submucous plastic, a pedunculated sero-muscular flap from the anterior abdominal wall, or closure by infolding suture, were not to be relied upon to bring about a permanent stenosis. Ligature by means of a strip of fascia taken from the rectus sheath, as suggested by Wilms, seemed to have better results; but in the opinion of the author, the only safe method was the unilateral pyloric closure suggested in 1895 by Von Eiselsberg. This rather complicated operation could be relied upon to permanently exclude from the duodenum any stomach contents, but it had the disadvantage of being a difficult and prolonged procedure, often requiring from thirty to forty minutes for its performance. Dr. Brewer emphasized the fact that the present desideratum was for a method which could be as quickly and simply executed as simple ligature, and at the same time be as permanent in its results as the prolonged operation of Von Eiselsberg. His method consisted in constriction of the pylorus by an aluminum band, which was easily passed around the tube at this point, and quickly rolled with the fingers into an unyielding ring with sufficient compression to obliterate the lumen of the tube, but not to compromise the vitality of the compressed tissues. Nine experiments upon dogs were reported, and the specimens thus obtained shown by lantern slides. From a study of these experiments, it was evident that this method of closure produced a complete occlusion of the pylorus, as proven by the fact that water would not pass the constricted point when the stomach was distended; and also by the fact that sections through the pylorus and aluminum ring showed by gross and microscopic examination, not only that the pylorus was closed, but that the vitality of the tissues was not impaired. A second series of experiments showed that the same method could be applied to the pyloric antrum, and also that the pylorus which had been closed for some months could have its function again restored by a second laparotomy and removal of the aluminum band. Although Dr. Brewer had not employed this method in the human subject, the animal experiments were so conclusive, that he believed it to be the simplest and safest method yet proposed for these cases.

Report of a Series of 156 Gasserian Ganglion Operations.—Dr. HARVEY CUSHING of Boston reported 150 cases of operations upon this ganglion with two fatalities. These fatalities occurred in the earlier cases. In one hundred consecutive cases operated on there were forty-six males, and fifty-four females. The neuralgia affected the right side in sixty-two cases; the left in thirty-six cases. Both sides were involved in two cases. He stated that it was the impression that these neuralgias occurred very much more commonly on the right side, but in the last fifty cases there had been an unusual number of left sided neuralgias which had brought the percentage up to thirty-six, whereas previously the ratio between neuralgias of the right and left side was about three to one. Two of the patients operated on were eighty and ninety years of age respectively. The average age at operation was fifty-five years, the youngest twenty-six, and the oldest eighty-six. The average age at onset was forty-five years, the youngest eighteen years, the oldest seventy-four years.

Dr. JOHN B. MURPHY of Chicago said that two monuments should be erected to Dr. Cushing, one for his courage for leaving the promising field of general surgery and taking up the unpromising field of tumors and surgery of the brain, and one for his final achievement of success in this line of work. When Dr. Cushing reported 119 consecutive operations without a single death it was an achievement of which he and the medical profession of the world should be proud. The speaker had done twelve of these operations with four deaths. In the future he would not endeavor to remove the Gasserian ganglion but would adopt the method of extracting the root which involved a little more work, a little more risk in the way of time and patience, but which gave splendid final results, as reported by Dr. Cushing.

Tuesday, November 11—Second Day.

Gastric Hemorrhage.—Dr. JOHN B. DEAVER of Philadelphia said gastric hemorrhage or the copious effusion of blood into the stomach was, as a rule, followed by hematemesis, and resulted from a number of disturbing factors in the mechanism of the upper abdominal circulation. In the minority of cases the blood was not at once ejected but was passed subsequently by the bowel in the form of tarry stools. Cases of gastric hemorrhage fell into two groups, the surgical and the non-surgical or medical. It was as great a mistake to operate on non-surgical cases as it was to withhold operation in surgical bleeding. The exploratory operation, therefore, was not available for diagnosis, and successful treatment demanded a high degree of diagnostic skill in deciding for or against operation. Profuse and even fatal hematemesis without demonstrable ulceration of the stomach had been observed in a considerable number of cases, both at autopsy and at operation. Dieulafoy had described a variety of hemorrhages due to the formation of minute mucous erosions, single or multiple. Such erosions had been observed as linear or stellate fissures in the act of bleeding during the operation. Of 459 of their cases of upper abdominal disease, hematemesis occurred in only 25 per cent. of instances and 20 per cent. of those cases were either simple ulcer or cancer of the stomach. A knowledge of the hemorrhagic possibilities of active congestion of the stomach could not be learned at the mortuary slab, but only by witnessing its bleeding surface in the living. Hemorrhage more or less acute might result from the formation of the typical acute peptic ulcer, the vessels beneath the muscularis mucosa being opened by the ulcerating process. Such hemorrhage was rarely fatal, the vessels opened were small and their walls soft and normal, permitting retraction and contraction with the formation of an occluding clot as the blood pressure was reduced by hemorrhage. In many cases acute ulcer announces its presence by bleeding and if appropriate measures were taken the hemorrhage was rarely dangerous and seldom repeated. While it was true that sudden massive hemorrhage did occur in chronic gastric and duodenal ulcer, it was also true that it was not a characteristic of ulcer to bleed profusely. Occult blood or small recurring hemorrhages were far more characteristic of ulcer and it was therefore, incumbent upon the diagnostician, in the presence of diffuse hematemesis to adduce considerable evidence in the way of history or examination before concluding that ulcer was present.

The hemorrhage due to malignant disease of the stomach, like that of ulcer, was not commonly profuse and sudden. In the early stages it was slight, even occult in the stools. It was more apt to be persistent than the hemorrhage of ulcer and tended to become progressively more marked. The hemorrhage from malignant ulceration was, as a rule, a slow seepage which gave rise to little systemic effect of bleeding, but revealed itself by the process of coffee ground vomitus or melena. Sudden hemorrhage was one of the modes of termination of gastric carcinoma, but in all but the rarest instances such an event was but the termination of an already established and evident malignant cachexia. During the past year there occurred in the practice of one of his Philadelphia colleagues a case of death from hemorrhage of an ulcerated myoma of the stomach. The growth was round, encapsulated, about 6 cm. in diameter and its growth was chiefly inwards into the cavity of the stomach, much like a submucous myoma of the uterus. Operation might be indicated in gastric carcinoma when hemorrhage chanced to be an early symptom and there was still hope of cure; or it might be indicated in advanced or otherwise inoperable cancer when hemorrhage was so profuse and persistent as to shorten even the period of prognosis given to cancer. In this case the measures to be adopted were, excision, gastroenterostomy or jejunostomy in accordance with the pathology found at operation. But four most essential questions remained to be settled. (1) The recognition of suitable cases; (2) the time to operate; (3) the type of operation to be performed; (4) the proof of our position by mortality statistics. The diagnosis of chronic eroding ulcer must be clear to warrant operation in acute gastric hemorrhage. Not only must the conditions which simulate it be considered and eliminated so far as possible but we must be in possession of a history which pointed strongly towards the existence of chronic ulcer. The most important point was a history of long continued persistent painful indigestion definitely related to the ingestion of food. In reviewing the literature thirty-three cases of operation for acute gastric hemorrhage, exclusive of his own, were collected since the independent reviews of Tuffier and Connell in 1905. In those thirty-three cases there were eight deaths (24.2 per cent.). This was to be compared with Tuffier's collective mortality of 36.3 per cent. in 1905, with Rodman's mortality of 37.5 per cent. in 1901, and with Savariand's figure of 62.6 per cent. in 1898. It was easily seen that the mortality was becoming less, a fact attributable doubtless to various causes but in part at least to increasing accuracy of recognition of the proper type of cases in which surgery was to be employed.

Dr. A. J. Oschsner of Chicago said that one must not look upon gastric hemorrhage primarily as a surgical emergency. An idea which had permeated the surgical conscience, as a result of the surgical possibilities of the last few decades, had given the feeling that when any very serious condition arose, we must attack it surgically. This was true only when the good judgment of the surgeon indicated that the patient was in such a condition that surgical treatment would give the greatest possibility of cure. A careful and accurate diagnosis was the foundation for this judgment, based upon a thorough knowledge of the history of such cases. The actual death rate from chronic hemorrhages of the stomach was undoubtedly large and must be considered from the standpoint of ulcer of the stomach, and that treatment must again be based upon a diagnosis which now could be made with a great degree of certainty.

The Operation of Gastrojejunostomy and the Principles Which Should Determine Its Use.—Mr. Herbert J. Patterson, F.R.C.S., of London, said that there was little doubt that the immediate results of the posterior operation were better than those of the anterior. The patients convalesced more smoothly, and vomiting was less common, while after the anterior operation it might be necessary to wash out the stomach once or twice during the first few days. As to the remote results, he was inclined to think that the advantage rested with the anterior operation. After the posterior operation some patients, few in number it was true, after remaining well for months or years, began to suffer discomfort. In some instances this was due to a mechanical defect at the site of the anastomosis, such as a constriction produced by contraction of the mesocolon encircling the anastomosis. He was quite clear that the mesocolon should be sutured to the stomach a little distance away from the suture line, and not to the jejunum or to the suture line as was commonly taught. In other cases the defect was due to a kink produced by contraction of a dilated stomach, or to the formation of adhesions, or to rotation of the jejunum on its longitudinal axis during the process of suturing. For a good many years he had been advocating the view that gastrojejunostomy was a physiological one. Sir Berkley Moynihan had expressed his belief that the "physiological explanation of gastrojejunostomy is rot." He would endeavor to give the reasons for his belief. First, in view of the allegation that gastrojejunostomy was a drainage operation, we must inquire, what was the effect of this operation on the evacuation of the stomach. His experience was that in cases in which there was no organic stenosis of the pylorus, the evacuation of the stomach was slightly accelerated. Usually the stomach was emptied in from three to four hours after a meal. Another means of comparing the motility of the stomach before and after operation was afforded by the study of the amounts recovered after a test meal. In 60 per cent. of a series of investigated cases the amount recovered after a test meal was less after operation than before, but the difference was not very great. In sixty-six cases the average amount recovered one hour after a test meal was 190 c.c. before operation, and 180 c.c. after operation. As a rule, when there was organic pyloric stenosis, the motility of the stomach was improved by gastrojejunostomy. He thought, therefore, we could conclude that in those cases in which the gastric motility was impaired markedly by pyloric stenosis or by adhesions, the operation resulted usually in a marked improvement in the evacuation of the stomach contents. In those cases, on the other hand, in which before operation the motility was unimpaired, gastrojejunostomy usually slightly hastened, but occasionally retarded, the evacuation of the stomach; but inasmuch as this retardation or acceleration fell within physiological limits, we were justified in saying that in cases in which, before operation, the motility of the stomach was unimpaired, the evacuation of the stomach was unchanged by gastrojejunostomy. Notwithstanding the absence of Gmelin's reaction in 27 per cent. of his cases, he believed that the presence of bile in the gastric contents was a constant and very important feature after gastrojejunostomy. His reason for this statement was the observation that in 90 per cent. of his cases there was, after gastrojejunostomy, an increase of the mineral chlorides in the gastric juice. This increase was not due to greater activity of the gastric mucosa because, as a rule, there was in 75 per cent. of his cases a diminution of the total chlorides. If this increase in the mineral chlorides was not the result of greater activity, it must be due to chlorides added from without to the gastric contents. For example, take the operation of appendicectomy, was there an increase in the mineral chlorides after this operation? In 26 per cent. of his cases of appendicectomy there was a marked decrease, in the remaining 74 per cent. there was an increase; but whereas after gastrojejunostomy the increase in mineral chlorides was accompanied by a decrease in the total chlorides, after appendicectomy the increase in mineral chlorides was accompanied, as a rule, by an increase in the total chlorides After a gastrojejunostomy there was a constant increase in the mineral chlorides of the gastric juice. This increase must be due to chlorides added to the gastric juice by the entrance of bile and pancreatic juice, because (1) the total chlorides of the gastric contents were diminished; (2) undoing gastrojejunostomy diminished once more the amount of mineral chlorides; (3) if an entero-anastomosis be perforced the increase in the mineral chloride did not occur; (4) in cases in which there was a marked excess of mineral chlorides; (5) as a rule, the increase in mineral chlorides did not follow operations other than gastrojejunostomy. Doubtless part of this increase was due to the neutralization of free hydrochloric acid and the consequent formation of sodium chloride. This did not affect his argument because (1) this neutralization must be caused by the carbonates of the bile and pancreatic juice; (2) if, before gastrojejunostomy, free hydrochloric acid be absent from the gastric contents, there was still an increase in the mineral chlorides after gastrojejunostomy. To his mind the conclusion was irresistible, that gastrojejunostomy was a physiological operation. It was easy to ascertain the changes in the gastric contents which followed gastrojejunostomy, but at present we must admit that we could only speculate as to which of those changes was the important factor in the relief of the patient. As he had already pointed out, a most striking feature after gastrojejunostomy was the diminution of the total acidity. The four practical lessons to be learned were these: "(1) That the type of gastrojejunostomy employed is of less importance than the manner in which it is performed; (2) that if gastrojejunostomy be a physiological operation its use for the treatment of gastric hemorrhage is correct and explicable; (3) that occlusion of the pylorus is an unnecessary complication of gastrojejunostomy and is based on erroneous pathology; (4) that if gastrojejunostomy be

a physiological operation, then it is as efficient a treatment for ulcers of the body of the stomach as for ulcers near the pylorus; in other words, gastrojejunostomy is preferable to excision."

Dr. Carl Beck of Chicago stated that Mr. Patterson was the father of the theory of the physiological effect of gastrojejunostomy, and what he had said in regard to the anterior and posterior operations, as well as the relative merits of each, was very important and suggestive. As to whether pyloric exclusion was practically useless, further experimentation in the workshops of surgeons would determine. At present, surgeons could only take the say-so of Mr. Paterson for it. As to the frequency of cancer of the stomach when ingrafted upon ulcer, notwithstanding the authority of Kocher, he still believed that the authority of the pathologists at Rochester was just as good, and their proof just as convincing as the pathological reports which had emanated from the laboratory of Kocher.

Wednesday, November 12—Third Day.

The Radiotherapeutic Treatment of Benign and Malignant Tumors.—Professor Krönig of Freiburg, Germany, stated that the domain to which radiotherapy was well adapted was in the treatment of fibromyoma of the uterus. Radiotherapy of fibromyomas could now be undertaken in a most thorough manner. They had made use of the Roentgen-ray treatment exclusively in a number of cases. They had also used mesothorium combined with Roentgen-rays, and mesothorium alone in the treatment of these tumors. High dosage was by no means necessary in every case of this kind. In a certain percentage of cases quite as good results had been obtained with proportionately small doses. Women over 45 years of age were more easily influenced by Roentgen-rays and the desired object, amenorrhea, with a diminution in the size of the tumor, had been accomplished earlier in these cases than in younger individuals; nevertheless they found cases among women over 50 years of age who could not be successfully treated with small doses. They had never witnessed any unpleasant effects from high dosage. High dosage had given good results. They had treated 350 cases of myomas of the uterus with Roentgen-rays. The chief aim of radiotherapy was: (1) Diminution in the size of the tumor. (2) Diminution in the severity of the hemorrhage, but without absolute amenorrhea. They had many times attained this end, especially in younger individuals, but they had to confess that they had seldom gained the desired object. Shrinkage of the tumor only began when amenorrhea was gradually established, and, moreover, relapses were frequent if menstruation had not completely ceased. The *x*-ray treatment of myoma was comparable with supravaginal amputation of the uterus. Radiotherapy for myomas of the uterus was in every way far superior to the operative treatment of myoma by means of total extirpation or by supravaginal amputation of the myomatous uterus. They had treated 254 cases of cancer with Roentgen-rays and radium. The material included those cases treated for the prevention of the secondary growth after operation for carcinoma as well as those cases in which radiotherapy for carcinoma had been used therapeutically. Of this number 150 cases were treated on purely therapeutic lines and without operation. Of these 150 cases, 140 were treated with Roentgen-ray and mesothorium combined, while in 10 cases the Roentgen-ray alone was used. Of 64 cases of carcinoma, 43 cases they had treated for the prevention of secondary growth almost exclusively with unfiltered Roentgen-rays, while 21 cases were treated partly with filtered and partly with unfiltered rays. The difference was striking. While 32 out of 43 cases died of carcinoma, they had been able to follow the subsequent history of 20 out of 21 cases, and found that 60 per cent. of the recurrences occurred the first year after operation. Recurrent cancers had been treated with radioactive substances. Of the 140 cases which they had treated with Roentgen-rays and mesothorium, three groups of carcinomas should be differentiated: (1) Those in which carcinoma had not spread beyond the primary focus, as in cases in which operative removal of the cancer was still possible. (2) Those carcinomas in which a new growth had already extended beyond the primary focus into the neighboring tissue, and in cancer of the cervix where the carcinomatous growth had spread into the parametrium and glands, so that operation was out of question. (3) Those carcinomas in which additional metastases were already present. So far as their investigations up to date went they had not succeeded by means of the technique employed in curing a single case of metastatic carcinoma. It was quite possible to produce remarkable retrogressions and checking of the carcinomatous metastases by means of intense radiation of Roentgen-rays and radium, but in all cases up to the present, the carcinoma had later on spread further. They could not say they had saved a single patient. In the second group the majority of cases were at the present time impossible of cure, in spite of any known Roentgen-ray and mesothorium radioactivity.

Dr. Howard A. Kelly of Baltimore stated that he had used radium in 360 cases, of which 188 were malignant growths, including tumors of all parts of the body—mouth, throat, neck, nose, lower part of the abdomen, the uterus, etc. He had treated 40 cases of cancer of the lower part of the uterus, where the disease was apt to spread rapidly, and the cases were considered hopelessly advanced and inoperable, and in three of them after extensive operation, radium was used. Under the usual methods a speedy recurrence would have taken place without question. In those three instances there had been no recurrence and health had been fully restored. He had also had four cases where no operation could be done on account of the general condition of the patients. Two of the patients had had diabetes and one Bright's disease, and the other a serious ailment which contraindicated operation. In those cases apparently a cure had been brought about. He had had two cases of cancer of the larynx, one of which had been well for months, and the other appeared to have recovered, but was still under observation. The speaker stated if we could have an abundant supply of radium its use for superficial cancer would yield better results than surgery. It would cure cases of cancer of the nose, eyes, lip, etc., where surgery would mutilate.

Dr. C. J. Gauss of Freiburg, Germany, discussed the technique of radium and mesothorium in the treatment of fibroid tumors and cancer of the uterus.

The Diagnosis of Lesions of the Upper Urinary Tract.—Dr. Hugh Cabot of Boston laid down four propositions and defended them. *First*, we had at our disposal methods of diagnosis of lesions of the upper urinary tract which were of extreme accuracy. *Second*, those methods of diagnosis were of value not only in lesions of the urinary tract, but in the differential diagnosis of the abdominal lesions. *Third*, that those methods of diagnosis were not being used with that frequency which their value entitled them to, and therefore a large percentage of errors was being made. *Fourth*, that those methods of diagnosis required skill and judgment in their application and without that skill and judgment they were dangerous. Dr. Cabot reported and showed numerous slides of cases illustrating errors that have been made in diagnosis.

Dr. Arthur D. Bevan of Chicago stated that his solution of the difficulties presented by Dr. Cabot would be that we needed in each clinic a complete organization, a surgeon, a cystoscopist, a radiologist, a competent laboratory worker, and a good internist. It was this sort of organization that should employ the new methods of diagnosis in lesions of the upper urinary tract rather than some special surgeon. In making a diagnosis of lesions of the upper urinary tract, and in practically all abdominal work, the evidence which it was desirable to obtain could be easily grouped under four heads according to their value. *First*, the history of a given case of lesions of the upper urinary tract was more valuable than anything else. *Second*, proper physical examination, including under the term physical examination an examination for tumors, dilatation of the colon with air, cystoscopic examination, catheterization of the ureters, *x*-ray pictures of the region with or without collargol. *Third*, the laboratory findings. *Fourth*, the importance in a limited number of cases of exploratory operation in making a diagnosis.

Pyloroplasty.—Dr. J. M. T. Finney of Baltimore read a paper in which he related his experience with pyloroplasty extending over a period of fourteen years. After he had given the results in 150 cases on which he had operated, he said the immediate as well as final results were most encouraging. While partial gastroenterostomy and gastrectomy were the operations of choice, nevertheless, on account of its simplicity and because of the satisfactory end results, he believed pyloroplasty would continue to retain its position as a safe and useful procedure.

Dr. E. W. Andrews of Chicago stated that the statistics of pyloroplasty, as given by Dr. Finney, were equal to those of any series of cases from any clinic where ordinary gastroenterostomy had been done, both as regards success of the operation and mortality.

Thursday, November 13—Fourth Day.

Report of the Cancer Campaign Committee.—Dr. Thomas S. Cullen of Baltimore, Chairman, first made mention of radium, saying that few surgeons in the coun-

try had sufficient of the material to give it a thorough trial, since it appeared that extensive doses sometimes cured when smaller amounts had but little effect. Radium (as suggested by Charles L. Parsons) should be standardized so that the buyer would know what he was paying for. Only time would tell what percentage of cases could be cured with radium. At present early surgical procedure afforded the best chance for cure. The results obtained from radium had to be taken into consideration. At the same time the men who had reported the best results were still urging early operation whenever possible. When people once understood the nature of cancer they would gladly avail themselves of surgical aid. In the past decades attempts to instruct the physicians alone had not produced any decisive results. Hence they had to go to the people at large through the newspapers and magazines. Many popular articles had already appeared. The press had responded nobly to their appeal. As a result the patients were coming earlier. Still there was need of further dissemination of knowledge by means of lectures on hygiene in women's clubs, factories, and elsewhere. Further better records had to be kept, hospital statistics had to be carefully analyzed so that accurate deductions could be drawn from them: they had to have surgical pathologists to aid in diagnosis. Thorough operations had to be insisted upon as soon as the diagnosis of cancer was made. All modern methods of recording data had to be utilized in hospitals. Patients who had been operated upon had to be followed up and the results recorded. Cancer of the uterus was one of the most frequent forms of cancer in women. There were two chief forms of cancer of the uterus, cancer of the neck of the organ, and cancer of the body of the uterus. The first symptom of cancer of the uterus was bleeding and as the disease progressed and parts of the cancer broke down the discharge became offensive. Cancer of the neck of the uterus was by far the more common and could be readily detected by the use of simple instruments. Cancer of the body of the uterus could not be seen and could only be definitely determined by scraping away some of the material and examining this with the microscope. The material removed was suitably hardened and shavings about 1/500 of an inch thick were made. These were stained and examined with the microscope. The pattern of cancer was totally different from that found in health, and the expert with the microscope could usually tell with absolute certainty whether the disease was cancer or not. The pattern of cancer as viewed with the microscope was as different from that noted in the healthy organ as were two totally different patterns of wall paper. In the years past few cases of cancer of the womb were cured. Now from 20 to 25 per cent. of patients suffering from cancer of the neck of the uterus that were operated upon were permanently relieved. Some of these patients were well thirteen or more years after operation. The results following operations for cancer of the body of the uterus were much more comforting, at least two-thirds being permanently cured. These results were a wonderful improvement on those of twenty or thirty years ago when nearly all died. Cancer of the uterus was most common between the 30th and 50th years, but had occurred in early womanhood and might also attack the aged. Any woman with bleeding that could not be definitely explained ought to be examined at once and any patient having much bleeding at the time when the "change of life" occurred ought to seek medical aid forthwith. The bleeding might be due to cancer or might be caused by some simple ailment. When women realized what splendid permanent results might be obtained by early operation and fully appreciated the necessity of finding out just what was the matter with them, instead of procrastinating until the disease was far advanced, then the percentage of permanent cures would be greatly increased.

Publicity and Ethics.—Mr. Samuel Hopkins Adams of New York stated that much could be done in health education of the public, whether in cancer, in tuberculosis, in the venereal plagues, or in epidemic diseases, by lectures; but more could be accomplished by the magazines. The universal agency, however, of popular education was the daily press. Between that great agency of enlightenment and the medical profession there had been raised a barrier fraught with difficulty, the barrier of the unwritten law of the profession, which said to the doctor, "Thou shalt not appear in print." The daily paper, with all its sins, was the one agency by which the medical profession could impart immediate, positive, and direct universal education—a saturated solution of enlightenment. Nothing else would do it. There was no sacred reticence required of a doctor other than the reticence that guards the privacy of his patient. The time had come when the old obsolete ban of silence should be lifted and the propaganda should go on through the agency best fitted to spread it, the daily newspapers.

Publicity and Education through the American Society for the Control of Cancer.—Dr. Edward Reynolds of Boston stated that we knew now that in many situations the malignant diseases were preceded by what we might call, for the sake of brevity, a precancerous state, such as the adenomatous stage in the development of cancer of the body of the uterus. We were able to diagnose this condition with certainty in many forms of the malignant disease whenever the patient came to us in that early stage, and we knew that in that stage a radical operation promised in many situations of the disease an almost absolute immunity from recurrences as opposed to certain death if the patient reached us too late. We were individually doing our best to publish to the world the importance of early diagnosis, but collectively, and as a profession, we had as yet done nothing. We could exert but little influence upon the over-conservative, the timid and the other weak and halting members of the profession, but our patients, the great lay public, had a right to demand that every member of the profession should be forced to do his duty in this direction. We were each of us individually doing our best to accumulate further information about the disease, but as a profession we had made no organized effort toward the systematic and widespread investigation which was the necessity of the day. We had not as yet had the organization, the money, nor the trained workers which were essential to success. The surgical profession was more than ready to give its time and its trained ability to the work, but the profession formed neither a large, nor, as a whole, an affluent percentage of the community. The money for any such widespread organization must come from the numerous and more wealthy laity, for whose benefit this movement was being inaugurated. The American Society for the Control of Cancer was a body which was composed of prominent members of the profession and of influential members of the laity. It was actively at work in perfecting a widespread organization of national scope for the active prosecution of this campaign. It had already been guaranteed and, indeed, for the most part, had already in cash the large amount of money which was necessary even for initial expense of the organization. It had already under salary a general executive secretary, whose past career was a guarantee of his possession of the necessary power of organization. It planned to work in cooperation with all the existing organizations in the study of cancer and in the promotion of the necessary publicity of all the points on which we already had assured knowledge. It had already been assured of hearty cooperation from the more important of these preexisting bodies, and had received the endorsement of all, or nearly all, of the great national medical associations. It asked the sympathy and effective aid of every member of the profession and of every interested layman and laywoman. It was essential to so large an undertaking as this that its initial organization should receive the time and attention and the very large amount of labor which was essential to its perfection. He believed we were rapidly approaching the day when we would put our appeal for aid, in both money and work, before every one and before the public, in the concrete form which would make rapid progress possible.

Education and Publicity through the Council on Health and Public Instruction of the American Medical Association.—Dr. Frederick R. Green of Chicago said that our knowledge of the causes of disease, its method of transmission and the possibility of its prevention imposed a duty on the profession toward the public, which was being recognized as a most important function of the medical profession. Since the scientific medical men alone possessed the technical knowledge necessary for the handling of such problems, we must look to them for such knowledge. But when an effort was made to apply this knowledge for the production of practical results, it was found that while the specific cause of a disease and the like history of the organism might be known in the most minute detail, the prevention or suppression of the disease was a social, and not a scientific, problem. Increasing knowledge of the cause of diseases, perfection of methods for their prevention, as well as the recognition of the paramount importance of regulation of social conditions for such prevention, made it necessary that there should be an educated public sentiment back of all of our efforts for disease control. The real force in this country and the only effective force was public opinion. Laws were the crystallization of public opinion and not one of its formative influences. When this principle was fully recognized we would cease to advocate the adoption

of mandatory laws without first creating a discriminating and intelligent public opinion on the necessity and importance of such regulation. If the education of the public was properly carried out the number of laws required would be greatly diminished and the effectiveness of those in force would be proportionately increased. The necessity for public instruction on the prevention of disease had been recognized by practically all of our state boards of health, and by many of our municipal health departments as well as by the various federal bureaus working on public health and allied subjects. It had also been recognized by the organization of a large number of special voluntary societies, composed of those interested in some social problem and devoted to the arousing of public sentiment on this specific subject. What could the Council on Health and Public Instruction of the American Medical Association do to enlighten the public on this subject? The answer was obvious. It could place at the disposal of the American Society for the Control of Cancer and the Committee of the Clinical Congress of Surgeons of North America all of the resources of the Council on Public Health Education. Through the Press Bulletin, suitable material on the subject could be placed in the hands of 5,000 editors, without any cost to the Society or to the Committee. Through the Speakers Bureau addresses could be given to the public on cancer and its menace. Through the Bureau of Literature, local pamphlets and leaflets on this subject could be distributed. Later on through the Lantern Slide Bureau of Exhibits material on cancer and its control could be placed before the public. The agencies at work on this problem at present were the American Society for Control of Cancer; the Committee of the Clinical Congress of Surgeons of North America, and the Council on Health and Public Instruction of the American Medical Association. The work to be done seemed to be threefold and to be peculiarly adapted to these three organizations. The first thing was to interest the public and especially the wealthy and influential public in the problem of the control of cancer. This was a movement for the public welfare, and there was no reason why the public should not assume part of the expense. This was the work for which the recently organized Society for the Control of Cancer was admirably adapted. The second necessity was the careful investigation of the entire problem of cancer, its age, its race and sex incidence, its relative frequency in different occupations and locations, and all of the clinical facts connected with its appearance. The speaker stated that there was today in the records of our different hospitals throughout the country an enormous mass of undigested material on this subject. This was clearly a clinical and surgical problem. The third requirement was the distribution to the public of the results of such an investigation. This was obviously a task for the Council on Health and Public Instruction of the American Medical Association, representing, as it did, the organized profession of the entire country. Through its machinery, it could, without any additional expense, place before the public any information which may be desired on this question.

Educational Value of Cancer Statistics to Insurance Companies, the Public, and the Medical Profession.—Mr. Frederick L. Hoffman of Newark, N. J., stated that during the year 1910 the average age at death in cancer and other malignant tumors combined was 59.2 years for the registration area of the United States. For males the average age at death was 60.4 years, and for females 58.4 years. Considered by organs or parts affected, the average age at death in cancer of the buccal cavity was 63.1 years; in cancer of the stomach and liver, 61.2 years; in cancer of the female generative organs, 53.8 years; in cancer of the breast, 58.3 years; in cancer of the skin, 68 years, and in cancer of other organs and parts not specified, 56.9 years. Cancer was distinctly a disease of advanced adult life. Of the mortality from all causes in the registration area, ages 45 and over, the proportion of deaths from cancer was 8.6 per cent., or, respectively, 6.4 per cent. for males and 11.2 per cent. for females. During the decade ending with 1911 the cancer death rate for all ages had increased from 65.8 per 100,000 of population in 1901 to 83.9 in 1911. The cancer death rate of males had increased from 48.7 per cent. to 64.2 per 100,000 of population, or 31.8 per cent., and the cancer death rate of females had increased 83 to 104, or 25.3 per cent. Considered by divisional periods of life, the death rates had increased at all ages and for both sexes, with unimportant exceptions at ages 5-14 inclusive. For males the increase in cancer during the 10-year period, and at the ages 45-54 was 21 per cent.; at ages 55-64 it was 30 per cent.; at ages 65-74 it was 40 per cent., and at ages 75 and over it was also 40 per cent. For females the increase in the cancer death rate at ages 45-54 was 11 per cent.; at ages 55-64 it was 27 per cent.; at ages 65-74 it was 32 per cent., and at ages 75 and over it was 44 per cent. There was sufficient evidence to sustain the conclusion that in quite a number of cases of suicide the underlying motive for self-murder was the insufferable torture of a hopeless case of cancer, and while here again the statistical evidence was incomplete and not available for the country at large, there were a sufficient number of individual cases on record to warrant the conclusion that the recorded cancer death rate was perceptibly diminished on this account. Cancer, in the experience of life insurance companies, had been the subject of occasional consideration but not of very extended and thoroughly specialized inquiry. A review of the available statistics, extending over more than a century, tended to confirm the conclusion that during the long intervening period of time the mortality from cancer had gradually and persistently increased, from a comparatively low rate of frequency to proportions which might appropriately be considered a menace to civilization. The earliest data are those of the London Equitable Society, for the period 1800-1821, in which, out of 1930 deaths from all causes, only 25, or 1.3 per cent., were from cancer; or, eliminating deaths under age 40, it appeared that out of 1,720 deaths from all causes, 24, or 1.4 per cent., were ascribed to cancer. A large number of physicians had been reached in an effort to improve medical education with reference to the earliest possible diagnosis of the disease. Since in Germany a large number of confinements were without proper medical attendance, but under the supervision of more or less qualified midwives, a special effort was made to reach this class, also with fairly satisfactory results. Finally, the public at large was reached through articles prepared by laymen for publication in the principal newspapers and periodicals. A special leaflet was prepared for public distribution on a large scale, which contained in the simplest form the required but pertinent suggestions to women, and especially that class approaching the change of life. One of the chief objects of the campaign had been to warn the public against blind faith in alleged cancer cures, and treatment by unqualified physicians or quacks. Winter was able, in 1911, to report that out of 1,000 cases of cancer of the uterus in his experience, 12 per cent. of the women had come to him during the first month of the probable beginning of the cancerous growth; in 30 per cent. of the cases the duration had been over one month; in 27 per cent. over three months, and in 40 per cent. over six months. One of the most recent contributions to the subject was a study of the statistics of cancer of the breast, by Dr. Ernst Schwarskopf, of the surgical clinic of Prague, who found that out of 350 cases of cancer of the breast, 321 were operable and only 39 were not operable. Practically all of the early cases which came to him, say of less than six months' duration, were within the operative group. He included a table giving the operative mortality among early surgeons, and those of more recent times, which showed a most gratifying reduction in the fatality rate. The investigation suggested a corresponding collective study of the subject for this country, which probably more than anything else would aid the efforts of the Society for the Control of Cancer to bring about a nation-wide interest in the facts, and by degrees, a reduction in the mortality rate from this always lamentable disease. For the present purpose the speaker had made a special analysis of the General Memorial Hospital of New York with the following results: This hospital, during the period 1902-11, treated 1,337 patients on account of malignant disease. Of this number, 531 were males and 806 females. Of the total number treated, 460 or 34.4 per cent. were cured; the number of improved was 391 or 29.2 per cent.; the number of not improved cases was 266 or 19.9 per cent., and 115 or 8.6 per cent. were either not treated or remained in the hospital at the end of the period. There were 105 deaths equivalent to a fatality rate of 7.9 per cent. There were the strongest possible reasons for believing, however, that if the cancer facts, including medical and surgical experience, were brought together in an authoritative form, they would not only materially aid the work of the American Society for the Control of Cancer, but the various cancer research funds, as well as the individual practitioner in his relations to the patients and the public at large. With this end in view, however, it was necessary that there should be intelligent and active cooperation between the laity and the profession, on the one hand, and the life insurance companies and the federal and state governments, on the other.

A Very Recent Investigation of the Outcome of the Cases of Cancer Recorded in the Johns Hopkins Hos-

pital and the Surgical Pathological Laboratory.—Dr. Joseph C. Bloodgood of Baltimore said that in 85 cases of benign lesions of the lip there were 100 per cent. cures. In lesions of the lip which to the sight and touch seemed benign, but which under the microscope proved to be early cancer, there were nine cures, 90 per cent. The failure to cure in the one case was due to an incomplete operation on the lower lip. When the lower lip only was removed and not the glands, they had cured but seven patients, or 63 per cent. The failure to cure in four cases was due to the involvement of the glands under the jaw. When the complete operation was performed, that is, removing the lesions of the lip and the glands of the neck, there had been 20 five-year cures, or 95 per cent. If the lesion of the lip had had previous treatment and had recurred on the lip, and the recurrence was cancer, the probability of a cure was reduced from 63 to 20 per cent.; 95 to 60 per cent.; and 50 to 20 per cent. The operation for recurrent cancer of the lip reduced the probability of a cure at least 42 per cent. Similar figures could be duplicated with lesions of the tongue, face, skin of the body and extremities. The same investigation was now complete with over 100 lesions of the skin and mucous membranes. As to cancer of the breast, in the least malignant forms of cancer of the breast there were 35 patients cured, five years or more after operation. There were 15 patients who came for treatment so early in the disease that a diagnosis of cancer could not be made out until at the operation when the lump was explored. Everyone of these patients had remained well five years or more, that is 100 per cent. of cures had been accomplished when the operation had been in the early stage in the less malignant forms of cancer of the breast. In this same form of cancer there had been 20 patients who came for treatment late. The same complete operation was performed, but the percentage of cures was but 64. Results, therefore, in the less malignant form of cancer of the breast were; 35 cases, 76 per cent. of cures; early cases 15, 100 per cent. of cures; of 20 late cases 64 per cent. of cures. The figures 35, 15 and 20 represented the actual number of cured patients. The percentage of cures for all cases of cancer in which complete operation could be done and in which the period of time since operation was five years, was now 42. Five years ago the percentage was only 35. In cancer control and precancerous lesions the great hope for increasing the number of cures of cancer and decreasing the number of deaths from cancer lay in the education of the public and the profession on the significance and potential danger of the precancerous lesion; the education of the surgeon as to the best surgery, and the education of the surgeon and the pathologist as to the recognition of the earliest stage of the beginning of cancer in the benign precancerous lesion. Incomplete treatment in the earlier stage of cancer often yielded a worse result than complete treatment in a later stage.

Officers.—The following officers were elected: *President*, Dr. John B. Murphy, Chicago; *Vice-President*, Dr. George E. Armstrong, Montreal; *Secretary*, Dr. Franklin H. Martin, Chicago; *Treasurer*, Dr. Allen B. Kanavel, Chicago. The next meeting of the Congress will be held in London, England, the fourth week in July, 1914.

A special committee was appointed to take up the work of standardization of surgery. This committee is composed of Dr. Lewis S. McMurtry, Louisville, Kentucky, chairman; Dr. Charles A. Peck, New York City; Dr. Henry P. Newman, San Diego, California; Dr. William L. Cousins, Portland, Maine, and Dr. Charles A. Davison, Chicago, Illinois.

Friday, November 14—Fifth Day.

Further Observations on Chronic Intestinal Stasis.—Sir W. Arbuthnot Lane of London mentioned a case that taught him how a patient might lead an active and happy life with only a small portion of the jejunum left after operation. In this case he removed a large portion of the jejunum after which the patient gained in weight rapidly and her strength improved correspondingly. The knowledge he gained from operating on this and similar cases had been of the greatest importance to him and had enabled him to save a number of lives. He referred to the circumstances which led him to remove the large bowel for chronic intestinal stasis. Chronic intestinal stasis was one of the most formidable causes of crime. Several patients had attempted suicide on account of chronic intestinal stasis, and in all such cases the removal of the large bowel had restored the sufferer, not only physically but mentally. The headache of varying intensity which these unfortunates suffered was also relieved by the operation, also the sleeplessness which accompanied it. Such patients put on fat; the pallor and staining of the skin disappeared and were replaced by a healthy color. He quoted Dr. James Mackenzie as saying that the bulk of degenerative changes in the heart were due to auto-intoxication. Dr. Mackenzie sent him a case in which he removed the large bowel with the greatest benefit to the cardiac condition, as well as to the general well-being of the patient. To summarize: Of 106 cases in which he had performed the short-circuiting operation for chronic intestinal stasis there had been four deaths.

On the Relation of the Ductless Glands to the Work of the Surgeon.—Dr. Roswell Park of Buffalo, N. Y., said that the internal secretions, so often spoken of as hormones, exercised an apparently controlling influence on many of the organs and functions, and this not alone on the ordinary body functions, but on the nutrition and regulation of individual organs and their particular activities even to the extent of becoming responsible for the development of certain mental traits or personal characteristics which might make or mar the individual, and might thus affect both his physical and intellectual welfare. For example, dwarfing or gigantism, each of which seemed due to the perverted activity of one or more of the ductless glands, naturally affected the social and school life of the growing child, and to such an extent that when conspicuous deformity resulted the entire course of life was affected to an extent which might be appalling. The hypophysis. As a whole this was a persistent organ, and, therefore, must have throughout life a continued function. Extracts of the whole gland increased blood pressure, caused uterine contraction, increased peristalsis, lower carbohydrate assimilation, and had a mydriatic effect. Used to excess they caused emaciation, degeneration of the liver, and increased metabolism. Extirpation produced in animals a peculiar cachexia, reduced pulse rate and respiration, fibrillary tremors, and death from apathy and coma. The overgrowth of the pituitary sometimes occurring after typhoid fever, or its clinical evidences, was to be considered as the result of toxins which stimulated its growth, as well as perhaps that of the epiphyseal bony borders, thus accounting for excessive overgrowth after this fever. Something of the same kind was often seen after marriage when the stimulation of the sex glands seemed to extend in short time to the hypophysis. Influence of the ductless glands in general on growth and development. In youth a loss of the genital glands led to overgrowth of the truncal skeleton, while the cranium did not seem to grow so fast. The distribution of fat about the body was disturbed. Epiphyseal consolidation in those locations where it naturally occurred least or last was delayed. This would account for the overgrowth, and it was not necessary to seek for its cause in the pituitary. The sexual glands, therefore, especially at puberty, exerted a marked influence over the development of the bones during the last portion of adolescence. Even to-day there was much to learn concerning the functions of the thyroid. It was once regarded as a reservoir by means of which blood pressure in the brain was equalized. It seemed to have an influence on the formation of the blood, slightly resembling the action of the spleen, possibly vicariating for it. The most important part of its work appeared to be elaboration of iodothyrin. Certainly iodin was its most important constituent, and in this the thyroid was richer than any other organ. The parathyroids. These four little bodies had only within late years been given their proper consideration, and in that short time had attained an importance in pathology quite disproportionate and in inverse ratio to their size. It was now generally believed that nearly all causes of tetany in man were of thyroidal origin, and due to defective function and consequent evidences of hypoparathyroidism. The thymus seemed to have had much to do with the development of the entire bony system; when its activity was reduced ossification was much interfered with, and proceeded irregularly and from scattered points; sometimes it failed utterly, as when the first pair of ribs failed to ossify, and the other were left weak and subject to early deformity. As to the parathyroids, we could scarcely do more than transplant. With the thymus we might have to extirpate or transplant. With the adrenals, transplantation had been attempted so far with questionable success. The genital glands might be removed for various causes, but removal was rarely demanded for the conditions under present consideration. Conditions which required surgical intervention were the thyroid, extirpation, which must be partial, save when dealing with malignant disease, ligation of blood vessels, transplantation as tracheotomy; operations for consequences of osteomalacia, achondroplasia, etc., involving the pelvis as cesarean section, etc., operations on the teeth and jaws for various congenital defects, cleft palate, etc.

A Summing-Up of the Goiter Question.—Dr. Charles

H. Mayo of Rochester, Minn., stated that various enlargements of the thyroid were the result of temporary excessive pathological demands, as at puberty, pregnancy, infection, menstruation, etc. Many goiters of the simple and mild exophthalmic type undoubtedly recovered spontaneously and, in many instances, various forms of medical treatment might hasten the recovery and restoration of the gland to an apparently normal condition. Simple goiters of long standing were often thrown into degeneration by giving iodine, causing thyrotoxicosis but not exophthalmos, although some symptoms were the same in these two forms of toxic goiter. Encapsulated adenomas and simple colloid goiters which had resisted treatment were in most instances best treated by removal of enough of the gland to remove the disease. In simple goiter the more enlarged lobe should be extirpated; encapsulated adenomas should be enucleated and thyroids which were bilaterally enlarged should have double partial resections with division of the isthums. Exophthalmic goiter was essentially a disease chronic in character, presenting exacerbations and ameliorations of symptoms extending through a period of months or several years. While this disease was amenable to surgical treatment by the removal of a large part of the hypersecreting gland, this procedure should by no means be considered emergency surgery, and during exacerbations all cases should be considered medical. Surgery was indicated during the upward wave of improvement. Extreme conditions, especially dilatation of the heart, might require preparation medically before instituting operative interference, and this should be confined to a preliminary ligation of the left upper pole. Should reaction follow this, ligation of the right upper pole was indicated a week later and thyroidectomy reserved until the patient had gained in weight and general health. Otherwise thyroidectomy was made at a second operation. In operating on the thyroid the best exposure was obtained by the curved transverse incision through skin and platysma between the anterior jugular veins, making a wide separation of the flaps and a midline vertical division of the muscles to expose the thyroid. This division should be made high near the insertion to break the line of the scar and preserve the function of the muscle. In some cases the wound might be closed without drainage, the cavity being filled with salt solution. As a rule, however, patients were more comfortable if drainage was instituted for 24 hours. A subcuticular closure of the wound with catgut, approximating the platysma muscle, secured an almost imperceptible scar. The great reduction in mortality following operations for exophthalmic goiter was due less to details of technique than to the better judgment in the preparation of patients and the selection of the time, type, and extent of operation.

Some Uses of Fat in Surgery.—Dr. John F. Binnie of Kansas City said that fat was well suited for transplantation in many instances. It was undoubtedly the connective tissue, the basis of the fat, which was of value in the transplant, but in other instances other varieties of connective tissue would be valueless as compared to that which was infiltrated with oil. The control of hemorrhage was difficult to obtain in wounds of the liver. Tampons of foreign material while useful had obvious objections. The sutures were liable to tear out in the friable tissues. Such wounds might be treated by omfental grafts. The omental plug became adherent to the raw surface of the liver wound, prevented hemorrhage, and became converted into fibrous tissue. A number of liver wounds had been successfully treated by omental tamponade. Dr. Binnie related numerous cases in which fat had been and could be used to great advantage as a transplant.

Peridental Infections: Their Relation to Neighboring Organs.—Dr. V. P. Blair of St. Louis stated that it was now recognized that the clinical manifestations of disease that we classify were in most cases the direct or indirect results of infections that gained entrance to or were harbored in, some particular organ or part of the body. The appendix, the urethra, the kidneys, the skin and the tonsils had been recognized as important primary or intermediary foci of infection. But while the mouth was the most prolific of all, still it was only lately that oral sepsis began to receive the attention that it deserved. Exclusive of the tonsils it was the teeth and their immediate coverings that here furnished the great atria of infection that menaced every tissue and structure in the body. Pyorrhœa alveolaris in an advanced form was not a common affection, while dental caries was the most common affliction of civilized races, hardly 5 per cent. being exempt. After caries had penetrated into the pulp chambers there was an open avenue to the vascular tissues about the apex of the teeth and thence through the blood and lymph streams, and possibly the nerves, to all of the body tissues. Pathogenic organisms lodged and incubating within the pulp chamber, and root canal might thus be disseminated. The percentage of antral empyemas that were credited to dental infections was variously estimated up to 50 per cent. Based upon observations made during eighteen years as demonstrator of anatomy in the dissecting room, it was his belief that infection of the antral mucosa of dental origin was rather rare but that infection and suppuration in the submucosa was exceedingly common. He had observed two cases of torticollis with early scoliosis that were relieved by opening an alveolar abscess in each. Of nine cases of Ludwig's angina which he had seen four were due to dental sepsis. The purely local effects of peridental infection were not always of a chronic character. They might be extremely acute and very extensive, going to an acute alveolar abscess, a necrosis, cellulitis, or adenitis. He had seen three cases of sarcoma or malignant endothelioma and one of Hodgkin's disease beginning in the cervical lymphatics. Two forms of cellulitis of the neck were worthy of special mention; one—the chronic Holz phlegmon, three cases of which he had observed to be of dental origin, and the so-called Ludwig's angina which latter when not promptly and properly treated in the past had been credited with a death-rate of 40 per cent. Hugo Stark had found in 113 children with chronically enlarged cervical lymph nodes that 80 per cent. had carious teeth and in 41 per cent. of this 80 per cent. no other cause, not even heredity, could account for the lymphangitis. In a few cases of tubercular adenitis the tubercle bacillus was found in a carious tooth corresponding to the infected node. It was now recognized that the so-called metastatic or secondary parotitis was directly dependent on oral sepsis traveling up the excretory duct and they had been able to express pus from Stenson's ducts before any suppuration was evident in the glands. Premature loss of the teeth might change the shape of the jaws and secondarily the nasal chambers. Irregular eruption had been cited as a cause of nasal spurs and deviation of the septum. Of one hundred and ninety-seven cases of ankylosis of the jaw, which he had been able to gather from the literature, in only five cases was infection of the teeth given as a cause. In twelve cases of his own two more were due to scar bands in the cheek due to intraoral slough, but a dental origin of the sloughing was not certain. Like any other joint the temporo-mandibular might be indirectly affected by chronic suppuration in any part of the body. The view that baldness may be dependent upon dental disorders is strongly supported by the French. Among the most interesting were the sensory, mental, and physical derangements that might be due to dental abnormalities. In ninety-four cases of tic douloureux which he had examined, dental irritation was the apparent cause in twenty-six, but thirty-five out of the ninety-four began in the third division of the nerve. Troemner observed that in fifty-eight cases of mental derangement thirty had impacted teeth, and that in twenty-two of twenty-eight cases of mental derangement operated upon definite improvement had taken place within two weeks after operation. He had also observed similar instances and in examining cases of epilepsy that were sent to him for operation he paid particular attention to the condition of the teeth.

The Surgery of the Faucial Tonsil as It Relates to the Functions of the Tongue and Soft Palate in the Production of Voice.—Dr. G. Hudson Makuen of Philadelphia said that the faucial tonsil differed from other tonsils not only in respect to the conditions attendant upon its location in the pharynx, but also in respect to its development. The faucial tonsil was not a homogeneous but a complex organ, and it was more highly specialized than the other tonsils which combined to form the so-called Waldeyer's ring. In addition to the possible systemic functions of the tonsil during childhood, it had during adult life certain important mechanical functions which were chiefly operative in phonation and articulation, and even in old age after it had undergone what had been called physiological sclerosis, its mechanical functions continued, and the tonsil then served as a protective agent to the faucial region in that it built up and strengthened that portion of the intrapharyngeal aponeurosis known as the capsule of the tonsil by the addition of its own connective tissue. The capsule of the tonsil was even more essential to the maintenance of the normal structural relations of the pharynx than the tonsil itself, and its removal was to be deprecated from the standpoint of one who had any regard for the phonatory and articulatory functions of the adjacent muscles. The mechanical functions of the tonsil in phonation and articulation were threefold: First, it served to maintain the normal anatomical relations of the

soft palate, the tongue, and the larynx; second, it served to keep the pillars of the palate apart and to direct them in their phonatory and articulatory activities; and, third, it had in itself important acoustic properties in artistic vocalization. An extracapsular tonsillectomy required a more or less extensive dissection of the mucous membrane covering the tonsil, the important muscles adjacent to the tonsil, a large portion of the intrapharyngeal musculoaponeurotic sheath, and in some instances also a portion of the peripharyngeal aponeurotic sheath. This extensive dissection resulted in a large granulating cavity in which union took place between the cut or lacerated surface of the mucous membrane, muscles, and musculoaponeurotic sheath or sheaths, binding them all together at central points of cicatrization, and several months after the operation the old landmarks that formerly characterized the distinctive features of the walls of the pharynx were practically gone forever. Instead of the beautiful clean-cut sharp edges of the palatal pillars during phonation and articulation and the well-marked pharyngeal recesses, both between and on either side of the pillars, they had plain oval pharyngeal walls with occasional bands of tense fibrous tissue coming into greater prominence when the mouth was open and the tongue depressed. Moreover, the normal mucous membrane of the parts having been destroyed, its place was occupied by smooth cicatricial tissue having a glistening surface and no mucous secretion whatsoever. The three important peripheral organs of phonation and articulation, viz., the soft palate, the tongue, and the larynx, were anatomically and physiologically interdependent, and they possessed many points of similarity. The integrity of the soft palate was essential to the distinctive structural characteristics of the pharynx and to the normal action of the tongue and larynx. The palatopharyngeus muscle, owing to its direct connection with the larynx, had important cord-stretching functions, and the valvular action of the soft palate in phonation and articulation was well known. Radical surgery of the tonsils, the doctor said, must necessarily result in a greater or less distortion of the pharyngeal structures, and, therefore, in an injury to the voice. The normal tonsil or the one in a healthy condition and of normal or approximately normal dimensions was not only beneficial to the voice, but it was absolutely essential to the attainment of the highest artistic results in singing and speaking, but just as the normal tonsil was helpful in voice production, the abnormal tonsil might be altogether prejudicial, and it might be prejudicial to such an extent as to make some kind of tonsillar surgery absolutely imperative. Before doing radical tonsillar surgery it seemed only reasonable to demand a thorough differential diagnosis. It was easier to enucleate than it was to investigate, and especially was this true with their improved technique, in the perfection of which they had spent so much valuable time. Future years would find them trying not how to enucleate, but how to avoid enucleation. The extracapsular tonsillectomized pharynx was always necessarily a damaged pharynx, and the operation ought to be done only when absolutely necessary, and when the damage to the pharynx and to the individual threatened to become greater by leaving it undone. In the majority of instances the only good reason for doing an extracapsular tonsillectomy was the difficulty of doing an intracapsular tonsillectomy, which consisted in a careful dissection of the gland from within its pocket in the intrapharyngeal aponeurosis. This was a difficult but not impossible operation, and the fact that some tonsillar tissue might remain adherent to the capsule was no objection to it because when the operation was properly performed good drainage, the *sine qua non* of every operation, would be thoroughly established.

Operations on the Extraocular Muscles.—Dr. Edward Jackson of Denver said that operations on these muscles had had periods of great popularity, and almost complete disuse; because of failure to apply well-known facts of physiology to the ocular movements. Most movements required the cooperation of all the muscles; and the operation on one muscle changed the balance for all movements. Tenotomy of the internal rectus and external rectus were liable to leave the position of the eye in control of the secondary adductor muscles; the superior and inferior recti, or the secondary adductor muscles the obliques. Contraction of the secondary adductors has as much effect in producing convergent squint as contraction of the internal rectus. Hence tenotomy should be extended to the nasal margins of the tendons of the superior and inferior recti. The vertical movements were intimately associated with wheel-rotation of the eye. Paralysis of the superior obliques was to be corrected by transplanting the insertion of the superior rectus back and out, so that it would have more power to cause wheel-rotation with less power to turn the eye up. By changing the insertion of a muscle upon the eyeball its function could be radically altered.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 16, 1913.

The President, Dr. William M. Polk, in the Chair.

Wesley M. Carpenter Lecture.—Dr. William H. Park delivered this lecture. His subject was "Antitoxin Dosage, Anaphylaxis, Active Immunization Against Diphtheria." He said that the single dose of antitoxin in diphtheria which was advocated by the writer at a meeting at the Academy last year was again advised and further arguments given. Experimental evidence was presented which showed that in animals, a single dose of antitoxin given after infection would save when the same and even larger amounts given in divided doses would utterly fail. Additional cases of diphtheria treated with one subcutaneous injection of antitoxin were detailed in which the antitoxin content of the blood was tested from hour to hour. This continued to increase in all cases for the first three days. The apparent improvement following a second dose of antitoxin was shown to be due, partly to the continued absorption of the first injection, and partly to the necessary time required for recovery of the local process. When the first injection was of fair size, the second added no real effect. During the past year, over 95 per cent. of all cases of diphtheria treated at the Willard Parker Hospital have received but one injection of antitoxin and the mortality has been the lowest in the history of the hospital. The usual amount given is 5,000 units in the milder cases, 10,000 units in the moderate or rather severe cases and 20,000 units in the malignant cases. In the latter, the antitoxin was given intravenously whenever possible. The same number of units given intravenously was fully fourfold the value of the same amount given subcutaneously. Intramuscular injections had the advantage over subcutaneous, in the rapidity of absorption, but when fairly large amounts were given, it was difficult to insure that the antitoxin remains within the muscle. As a rule cases not requiring intravenous injections could be treated by either the subcutaneous or intramuscular methods. So far as the danger of anaphylaxis from primary subcutaneous injections were concerned, the results in the Health Department service were given. Over 30,000 cases of diphtheria had been treated with antitoxin since 1895 in the contagious disease hospitals. There had been no fatal case of anaphylaxis and only one in which dangerous symptoms developed. In over 100,000 persons injected outside of the hospitals, there had been but two fatal cases, in one of which marked status lymphaticus existed. In a great many children in the scarlet fever service, a primary immunization injection of diphtheria antitoxin had been followed by a second larger subcutaneous injection at a period at which anaphylaxis should be marked. In no case had any dangerous symptoms developed. Unless, therefore, there was a history of asthma, there seemed no reason to avoid the giving of a primary serum injection on account of fear of later having to give another injection, either in the near future, or after a number of years. Following the example of von Behring a number of children had been injected with toxin antitoxin mixtures to actually immunize them against diphtheria. Different proportions of toxin and antitoxin had been used. The best preparation seemed to be one in which the toxin, so far as its poisonous effects were concerned had been somewhat more than fully neutralized. About four-fifths of the children receiving such an injection developed after 10 days from ½ to 2 units of diphtheria antitoxin for each cubic centimeter of blood. This persisted for a number of months in gradually lessening amounts. It was probable that there was a distinct need in cities where diphtheria was endemic for active immunization. For outbreaks in institutions and in families where diphtheria was present, passive immunization was undoubtedly the better method.

College of Physicians of Philadelphia.

At a stated meeting held November 5 Dr. Samuel D. Risley read "A Memoir of the late Dr. Roland G. Curtin."

Dr. George E. de Schweinitz presented, on behalf of the donor, Mrs. Byron P. Moulton, a portrait of the late Dr. Charles T. Hunter, a graduate of the medical department of the University of Pennsylvania in the class of 1868, at one time resident physician in the Pennsylvania Hospital, later demonstrator of anatomy and demonstrator of surgery in his alma mater, surgeon to the Episcopal

Hospital, the University Hospital and the outpatient department of the Pennsylvania Hospital.

Dr. Gwilym G. Davis read a paper entitled "Results of the Operative Treatment of Poliomyelitis, with an Illustrative Case." He exhibited a boy, 11 years old, who had an attack of poliomyelitis in the first year of life, and who after treatment with massage and electricity for a year or two wore braces for a period of seven years. The left lower extremity was flail-like and everted, and there was a tendency to knock-knee. With a view to relieving the conditions and conferring upon the lad some degree of usefulness arthrodesis was practiced at the ankle-joint, the outer tendon of the biceps was attached to the patella and the fascia lata was slit and a portion attached to the great trochanter of the femur. The result after a reasonable time, quite realized expectations and the boy since has been able to get about with comparative ease.

Drs. Jay F. Schamberg, A. I. Ringer, G. W. Raiziss, and John A. Kolmer presented a communication entitled "Research Studies in Psoriasis," accompanied with lantern demonstration. With a view of determining whether psoriasis was of parasitic or neuropathic or metabolic origin a systematic and detailed study was undertaken in the laboratories of the Polyclinic Hospital with the aid of a grant by an anonymous benefactor. It was found in all of the cases studied under exact conditions that nitrogen-retention was a characteristic and constant feature, and that the symptoms improved whenever nitrogen was withheld from the diet and became aggravated when the amount of nitrogen in the food was increased. The explanation probably resided in the fact that nitrogen was largely taken up at the site of the lesions, but whether this relation was causative or consequent had not been determined. Careful bacteriological examination failed to disclose the presence of a specific microorganism, but there was some response to the complement-fixation test.

Dr. Robert N. Willson read a paper entitled "The Treatment of Heart-disease." He dwelt especially upon the necessity of directing attention to the heart-muscle. Of primary importance is the matter of prophylaxis, and this has to do with questions of food and rest and activity and indulgence in toxic substances, such as alcohol and tobacco, and the avoidance of infectious disease. In the line of direct treatment first place must be given to rest, and, in addition to the recumbent posture and freedom from care and anxiety, opium, in the form of morphine, is at times of the greatest usefulness. Of course, intoxication from within must be avoided and the activity of the bowel and the kidneys sustained. Applications of cold or of heat over the heart, with or without blistering, are often serviceable.

Dr. James E. Talley demonstrated on the screen a large series of electrocardiograms by means of which it is possible to disclose the presence of conditions that otherwise would remain unrecognized.

Meningitic Symptoms Caused by Escape of Threadworms Through a Perforated Appendix.—R. N. H. Anglin Whitelocke reports the case of a girl aged 5½ years who was admitted to the hospital with a diagnosis of tuberculous meningitis. The difficulty in making a rational diagnosis was increased by the existence of an almost positive tuberculous history on the one hand, and by the entire absence of any other known cause on the other. The nervous symptoms played such an important rôle, and the abdominal pain was so generalized at the first and subsequent examinations, that there was little to direct attention to the local focus in the lower abdomen. The only truly localizing and diagnostic symptom was the continued flexure of the right lower limb. A true organic nerve lesion was imitated through the reflex irritation produced by the active animalcules wriggling about on the exquisitely sensitive peritoneal surface. There was an immediate cessation of the urgent symptoms as soon as the cause had been removed. Especially interesting to the surgeon is the behavior of the omentum in coming to the rescue in this case, as it so often does in others, by limiting and preventing the extension of local mischief. In this particular case it appears not only to have checked the peregrinations of many of the worms, but it seems to have actually killed them. The colony of dead worms was to all appearances enwrapped by the adherent omentum, and the individuals were held in bondage as it were in the immediate neighborhood of their place of exit from the cavity of the appendix. There was an absence of infection as the result of the perforation in spite of the free escape of a foul semi-purulent discharge on to the peritoneal and wound surfaces. A drainage-tube was used only during the first twenty-four hours after the operation. The case is unique in the author's experience.—*British Journal of Children's Diseases.*

Therapeutic Hints.

The Treatment of Facial Acne.—In moderate degrees of this condition Brocq recommends the following ointment:

℞ Camphor,
Resorcin, aa 0.50 gram.
Precipitated sulphur, 3 grams.
Soft soap, 0.75 gram.
Prepared chalk, 6 grams.
Pure vaseline, 10 grams.

This is applied after the face has been thoroughly bathed with hot water and soap or with ichthyol soap. The ointment is kept on all night and washed off the following morning.

Sulphur lotions are sometimes preferable to the above. The following has produced good results:

℞ Precipitated sulphur, 25 grams.
Spirits of camphor, 60 grams.
Rose water,
Distilled water, aa 200 grams.
Glycerine, 15 grams.

This is applied by means of a pledget of absorbent cotton.—*Bulletin Général de Thérapeutique.*

The Treatment of Ejaculatio Præcox—S. Baglioni and G. Amantea have essayed the treatment of this condition by instructing the patient to apply to the glans and chiefly to the coronal sulcus, a five per cent. solution of stovaine. This solution is applied to the parts by means of absorbent cotton soaked in it, and is retained for twenty minutes preceding coition. The result is a partial anesthesia of the glans which considerably prolongs the act of intercourse. Ointments containing the same percentage of stovaine were ineffectual.—*Il Policlinico, Sezione Pratica,* October 12, 1913.

Massive Injections of Mercury in the Treatment of Syphilis.—Ehlers of Copenhagen, in a communication made before the recent International Congress of Medicine, reported his investigations on this subject. His object was to attain Ehrlich's *therapia sterilisans magna* by means of supermaximal injections of mercurial salts. He employed the solution of benzoate of mercury, as recommended by Desmoulière and Lafay:

℞ Benzoate of mercury, 1 gram.
Sodium chloride, 1 gram.
Milk sugar, 10 grams.
Sterile distilled water, 100 grams.

Ehlers found that a 2 per cent. solution of benzoate of mercury was still better than the above. He began with injections of 2 centigrams each, but he proceeded cautiously. He gradually increased the dose to 25 centigrams. Favorable results are reported with the use of this method which is regarded as superior to the use of salvarsan, at least from an economic viewpoint.—*Revue de Thérapeutique,* October 1, 1913.

Two New Arsenical Derivatives.—Under the names "galyl" and "ludyl" two new antisyphilitic arsenical compounds have recently been described by de Beurmann, Mouneyrat, and Tanon. Galyl is tetraoxydiphosphaminodiarsenobenzol. Ludyl is phenyldisulphaminotetraoxydiaminodiarsenobenzol. These compounds are said to have the following advantages; they are not vasodilators; they do not coagulate albumin; they are but slightly neurotropic; they are readily soluble in distilled water; they are sterilized by heat; they have a marked parasitotropic action upon not only the microorganism of syphilis, but also upon the other spirilla and the trypanosomes.

THE FREUDIAN CONCEPTION OF THE PSYCHONEUROSES.*

By H. W. FRINK, M.D.,

NEW YORK.

DEPARTMENT OF NERVOUS DISEASES, CORNELL MEDICAL COLLEGE, NEW YORK.

Of all the contributions to medical knowledge made in the past twenty-five years there are few, if any, that have excited more widespread interest, discussion, and, I may add, antagonism than has the work of Freud in abnormal psychology. The fact remains, however, that the number of physicians who have put Freud's teachings to any practical test is still extremely small, and, consequently, there has been little opportunity for the profession at large either to observe the results of psychoanalytic treatment or to form undistorted conceptions of the principles upon which it is based. I have therefore attempted to outline some of Freud's most important doctrines concerning the psychopathology of the neuroses, hoping that such a presentation may not only prove to be of interest to this society, but that it may tempt some to investigate personally this important field of work.

But before taking up the psychoneuroses from a psychological standpoint, let me first identify them clinically. The psychoneuroses as a whole may be subdivided into three groups:† Hysteria proper or "conversion hysteria," anxiety hysteria, and the compulsion neuroses. All these three conditions are equally disorders of the psyche, but while the manifestations of anxiety hysteria and of the compulsion neurosis occur chiefly in the emotional and volitional spheres, the symptoms of conversion hysteria are somatic ones. Thus in conversion hysteria we have the pains, anesthesias, paralysis, contractures, tremors, or convulsions, which are known well enough to demand no description.

In anxiety hysteria fear is the chief symptom This fear is generally referred to some external situation or condition, and thus we have fears of open places, of crowds, of being alone, or of darkness; or fears of dirt, of contagion, of knives, or of animals. These fears are, in effect, prohibitions which limit, in varying degrees, the patient's activities. He is comparatively free from fear as long as the prohibitions can be obeyed. If they are overstepped, however, and he finds himself in the dreaded situation, there ensues an attack or panic, *i.e.* a feeling of intense terror accompanied by such symptoms as tachycardia, dyspnea, perspiration, etc.

The third group of psychoneurotic disorders, the compulsion neurosis, includes those conditions commonly called psychasthenias, namely, morbid doubts, fixed ideas, or obsessions. As examples I may mention the following: A lady is tortured by the fear that she might have caused the *Titanic* disaster, although she realizes that there is no possibility of her having done so. Another doubts continually whether she is telling the truth and takes the most elaborate pains to verify even her most simple and harmless statements. A man is forced to ponder over the question of how people would appear if their heads were on a different part of their bodies. Accompanying these morbid thought activities there is always a more or less pronounced feeling of anxious uneasiness. To many of you, cases of compulsion neurosis and of anxiety hysteria as well, are doubtless known under the much misused term, "neurasthenia."

Returning now to the subject of my paper, let me introduce an important part of Freud's theories by calling your attention to certain of the phenomena of hypnosis. Suppose I hypnotize a man and give him the suggestion that fifteen minutes after he awakes his arm will become completely paralyzed. I rouse him from the trance; he remembers nothing that I have said to him while it lasted. Nevertheless, when fifteen minutes have elapsed, he suddenly discovers that he is utterly unable to move his arm, and, until I give him the contrary suggestion, this condition of paralysis remains.

This matter I bring up in order to show to what an extent a person may be affected by ideas that are entirely out of his consciousness. In the case of my hypnotic subject, my suggestions, all the ideas causing his artificial paralysis, he has completely forgotten. Though his paralysis is caused by ideas alone, these ideas are not in his consciousness. But since these ideas, although out of consciousness, influence his motor system just as effectively as they could if in consciousness, we must assume that they have some sort of psychic existence, and we may express this by saying that the ideas are in *an unconscious state* or, preferably, in *the uncouscious.*

The psychological concepts, "unconscious ideas" and "the unconscious," are an essential part of the theory of the psychoneuroses. The symptoms of these disorders have been shown by Janet, Prince, Freud, and others to result primarily, not from a disturbance of consciousness, but from the activity of certain groups of ideas which exist independently of the patient's main stream of consciousness, and of which he is not aware. These split-off psychic groups, or, as they are called, complexes,‡ are there-

*Read before the Society of the Alumni of Bellevue Hospital, May 14, 1913.

†In practice we seldom see pure cases of any of the three types of psychoneuroses. Most of our cases are "mixed neuroses," *i.e.* they show symptoms belonging, both psychologically and clinically, to more than one of the groups mentioned above.

‡By the term "complex" is understood all the ideas, impressions, feelings, etc., belonging to, and associated with a given theme or subject. Thus we may speak of a "father complex," a "sadistic complex," a "money complex," a "baseball complex," etc. A complex is not necessarily wholly unconscious, but a part, at least, is unconscious.

fore quite analogous to the forgotten suggestions in the hypnotic subject. Thus, we may regard the psychoneurotic symptoms and the posthypnotic phenomena as counterparts of one another. Neurotic symptoms and suggested paralysis both depend upon mental activity which goes on without the individual's conscious knowledge—depend upon, in other words, thought activity *in the unconscious*, or, upon *unconscious* ideas.

But while others went little beyond simply determining the existence of pathogenic groups of unconscious ideas in the psychoneuroses, Freud carried his investigations much further. He wished to know what these unconscious ideas were, why they became unconscious, and what could be done about them. Without attempting to give the history of his efforts to solve these problems, I shall state at once that, in the opinion of those who have followed his work carefully, he has succeeded most brilliantly. Not only was he successful in determining the origin, nature, and content of those thought complexes that made his patients sick, but, in addition, he made the interesting and important discovery that when these complexes are completely brought back into the consciousness of the patient the symptoms of the malady permanently disappear. Thus originated the therapeutic method known to us as psychoanalysis.

Of the various methods devised by Freud for ascertaining the content of unconscious complexes, I shall mention only one, that of "free association." It is carried out as follows: The patient is given a comfortable position upon a couch or in an easy chair and is then instructed to tell all the thoughts that pass through his mind. He must, as far as possible, abandon all tendency to direct or control his thoughts, and must become, as it were, a mere spectator of his own mind, repeating without comment or critique whatever drifts through his consciousness. Proceeding in this way the patient furnishes a great mass of psychic material—fragments of history, memory impressions, long forgotten desires, ambitions, day-dreams, etc.—which is brought out in a more or less rambling and disconnected manner. This material is of more value than one might at first suspect. For when, in freely associating, the patient abandons all conscious effort to control and direct his thoughts, the trend of his associations is then in great measure determined by his unconscious complexes, and, consequently, the associative material obtained either gives some hint as to the content of these complexes, or contains elements directly from them. By studying these hints and fragments, therefore, an accurate knowledge of the patient's unconscious trends may be ultimately obtained.

But I wish to emphasize, however, that the process of free association does not proceed as smoothly as one might expect. Of course, some difficulties are due to the fact that the patients are unwilling to relate thoughts of a private or embarrassing nature. But other and greater difficulties arise from another source. Not infrequently the patients stop and insist that they have nothing more to tell, that their minds are absolutely blank. They assure the physician that they have told everything, that nothing further occurs to them, and that it is useless to continue.

Such interruptions of the flow of associations are of great theoretical as well as practical interest. For, as Freud learned, these blockings of thought are most apt to occur when some idea contained in, or closely related to an important complex has entered the patient's consciousness, or is about to do so. In other words, when the patient is on the point of thinking of something important he is apt to feel that he is thinking of nothing. This peculiar circumstance is explained when we learn that the patients *do not wish to know what their unconscious complexes contain*, and that, furthermore, there exists some psychic force or mechanism, which by a censor-like action tends to protect them against acquiring such knowledge. This force Freud has called "repression." To its action may be attributed most of the blockings that occur in free association, while from the necessity for overcoming or circumventing this action arise the greatest difficulties of psychoanalysis.

It is now desirable that we consider what repression is and how it originates and, at the same time, arrive at some explanation of the fact that patients are unwilling to possess conscious acquaintance with their unconscious thoughts. Some preliminary statements, however, are necessary.

In the first two or three years of childhood the so-called higher or inhibitory emotions are not yet developed. Practically speaking, the child knows no shame, no disgust, no sympathy, no morality. There is therefore nothing within himself to prevent his gratifying any desire or impulse he may happen to have. On this account most of his voluntary activities have no other motive than a desire to obtain immediate pleasure.

In the first months of life the pleasures of the child are very simple sensory ones—the taking of nourishment, the movement of the limbs, the sensations derived from being rocked and carried, certain agreeable feelings that accompany the voiding of excrement, etc. But when at the close of the first year the child's environment begins to become increasingly important and interesting to him, a corresponding widening of his sphere of desire occurs. He is no longer satisfied with simple bodily feelings; he now wants to examine everything he sees, to be continually in the society of certain preferred persons, to possess all objects that attract him, etc. An important group of feelings and longings allied to, or forerunners of, the complexly organized sex-impulse of the adult become more and more prominent and demand satisfaction. In fact, the desires of the child soon become so numerous and varied that to fulfill by actualities even a small part of them would be utterly impossible.

But a new factor comes into play when the child begins to imagine and "make believe." He is then no longer entirely dependent upon reality for the gratification of his desires. If, for example, he wants a horse but cannot get one he may achieve a partial gratification of this desire by simply *imagining* that he has one; or, combining imagination with a bit of reality, he can be quite content with a broomstick. It thus becomes possible for the child with the aid of his imagination to gratify in one way or another the larger part of his desires.

But this happy state of affairs does not continue indefinitely. In the third or fourth year the inhibitory feelings make their appearance, and, as a consequence, certain pleasures in which the child formerly indulged without hesitation he now learns to regard as shameful, immoral, or disgusting. There results in this way a conflict between desires for certain physical pleasure-activities on the one hand,

and ethical or esthetic feelings on the other. In this conflict the higher emotions ordinarily triumph and cause the child to abandon of his own accord certain former pleasures and to suppress his desires for the same. This renunciation includes not only objectionable pleasures that concern reality, but also, though to a lesser extent, the corresponding pleasures of the imagination. That is, the child not only feels that he must not *do* certain objectionable things, but also that he must not *think* them or *wish for* them. Finally a point is reached when the sway of the higher emotions is so powerful and the resulting suppression of certain cravings so effective that they disappear from this consciousness entirely. That is, conscious longings for the pleasures now regarded as objectionable are no longer felt in response to the stimuli or conditions formerly inducing them and furnishing such gratification. On the contrary, only displeasure is felt; *i.e.* the inhibitory feelings of shame, disgust, etc., which originally lead to the suppression of desire.*

This complete reversal of reaction—repugnance replacing desire; displeasure replacing pleasure—constitutes the major part of the psychological process to which we have referred by the term *repression*. The desire which disappears from consciousness and is replaced by reactions of an opposite character is said to be *repressed*. It is clear, therefore, that the force which we have spoken of as repression is essentially an affective process, that is, it depends upon *feelings*. We are therefore prepared to learn that the activity of repression is not limited to excluding from consciousness simply the desires of childhood which become objectionable. It may, as psychoanalytic experience has adequately demonstrated, operate in the same way upon any desire or temptation arising at any time of life, upon the associated ideas or memories belonging to such temptations, or, within certain limits, upon almost any sort of psychic material that becomes out of keeping with the individual's main trends of conscious thought. We might, therefore, conveniently describe repression as *a sort of forgetting* which tends to remove from one's consciousness those wishes, memories, or ideas which, upon ethical or esthetic grounds especially, have become unpleasant or offensive. It is a normal and necessary process; one which goes on in all sane and nondefective people after the first years of childhood are passed. There need be no doubt of its existence. All of us, whether neurotic or not, find it difficult to recall having had many desires or temptations of which we are sincerely ashamed. All of us find it comparatively easy to forget facts which might tend to convince us that on certain occasions we have, or might have, acted in a selfish, conceited, dishonorable, or otherwise objectionable manner.

But our interest in the subject of repression concerns the material repressed even more than the process itself. For the repression of any psychic element means merely that the individual ceases to be conscious of it; not that it ceases to exist. The repressed element is not destroyed, but simply rendered unconscious. In the unconscious, the repressed material may be preserved almost indefinitely, and, entirely unknown to the individual's conscious personality, it may to a surprising extent influence his life and actions. Indeed, it is this repressed material—the abandoned pleasure-cravings and make-believes of childhood; the overcome temptations, sensual day-dreams, and suppressed hatreds of later life—that forms the pathogenic groups of unconscious ideas in neurotics upon which the multitudinous symptoms of the psychoneuroses depend.

But now a question arises. If repression is a normal process; if everyone has banished different groups of objectionable thoughts to the unconscious, then everyone must have unconscious complexes. Why, then, do these unconscious complexes make some persons sick and not others? Why is not everybody neurotic?

Questions of this kind cannot be fully answered. It is sufficient for our purposes here to know that normality or abnormality depends upon the extent and stability of repression. The normal man is he who overcomes the desires and tendencies that are objectionable to him and confines them to the unconscious permanently.* Those who repress to a very small extent, or in whom repression fails absolutely, are the defectives, certain of the insane, and the sexual and civil criminals. Between these two extremes comes the neurotic. The neurosis corresponds to a *partial* failure of repression. The neurotic neither fully gives way to his primitive or perverse tendencies, nor does he subdue them as completely as does the normal person. The neurotic compromises. He excludes his objectionable desires from consciousness, and prevents any *direct* gratification of them. Yet he does permit an indirect gratification, which expresses itself in consciousness through a sort of make-believe like that of childhood. But this make-believe coming from the unconscious is carried out in ways so roundabout, distorted, and disguised that he has no conscious awareness that any wish-fulfillment is going on. The phenomena produced in this way, representing a gratification of cravings no longer conscious, are known to us all as neurotic symptoms.

A convenient though not altogether accurate way of representing to ourselves the composition of the neurosis is for us to think of the neurotic as a being with two minds in one body. The one mind, corresponding to the conscious personality, possesses all the moral and esthetic feelings and strives to conform to the requirements of culture and civilization. The other mind, corresponding to the unconscious, contains all those primitive, instinctive, and childish tendencies rejected by consciousness. It knows no law and no motive except the pursuit of pleasure. But the first mind, corresponding to consciousness, dominates the individual's thoughts and actions and opposes the tendencies of the second. Therefore, to express itself and obtain pleasure through the actions or conscious thoughts of the individual, the second mind is forced to resort to measures so indirect, distorted, or disguised as to deceive the first. That is, *the symptoms must be unintelligible to the consciousness of the patient in order for them to*

*For instance, brothers and sisters when very small often like to go to the toilet together. Later, when their inhibitory feelings have developed, any circumstance which could compel them to perform their excretory acts in each other's presence would not only fail to give pleasure, but would cause positive displeasure; that is, embarrassment, disgust, etc.

*This, of course, is true only in general. Even the most normal and moral person never achieves an absolutely complete suppression of all the inner tendencies to which he objects. It should be remembered also, that when a tendency generally considered undesirable is manifestly unrepressed in a given individual, one must not invariably consider this a failure of repression. There may have been no effort to repress this tendency, *i.e.* the individual's education and environment may have been such that he never learned to regard it as objectionable.

exist. And that these symptoms seem unintelligible, bizarre, or meaningless to other people, is, under these circumstances, not at all surprising. The general fact that the neurotic derives pleasure from the neurosis is, however, by no means unrecognized even by superficial observers, as the mocking statement that "So-and-so is enjoying very poor health" obviously bears testimony.

The theory of unconscious wish-fulfillment in the neurosis can perhaps be made more acceptable and understandable by means of examples. I will begin with the very simple analysis of an hysterical symptom. A clinic patient, who exhibited various phobias and hysterical manifestations, once came to me with the complaint that for three weeks she had suffered with unpleasant abdominal paresthesias; viz., sensations of fullness and heaviness in the hypogastric region, together with a feeling as if something was moving in her pelvis, and that her womb was going to burst. In addition there was a considerable tendency to nausea and vomiting, and an emotional condition of such great anxiety and depression that she was unable to work.

The analytic explanation of these disturbances is as follows: She had been married eight years but had never been pregnant. She attributed her childlessness to the fact that before their marriage her husband had had gonorrheal epididymitis. She had always been very desirous of having children and particularly so during the last few years as her husband's business keeps him away from home much of the time and she is very lonely in his absence. She feels that if she had a child to occupy her mind she would be much happier and more satisfied with life.

Under such circumstances it is perfectly obvious that she could scarcely avoid thinking that, at the expense of only a temporary relaxation of her moral scruples, she need not continue to be deprived of the joys of motherhood. A train of thought of this nature was brought into prominence two or three weeks before the onset of her abdominal symptoms by some unmistakably amorous advances on the part of her sister's husband. The temptations thus arising were particularly powerful for the man was not only very attractive to the patient, but, as he already had several children, she felt no doubt as to his reproductive ability. Still later a new motive for infidelity was added. The patient suddenly made the discovery that her husband had been having sexual relations with another woman. Two days after this discovery the abdominal symptoms which I have mentioned appeared. Their origin is clear. On the one hand two motives, a desire to pay back her husband in his own coin, and a great longing to have children, impelled the patient toward breaking her marriage vows. On the other hand, all her feelings of morality and fidelity, and her horror at the thought of sexual relations with her own brother-in-law, not only opposed any such action, but made it (as far as her consciousness was concerned) absolutely unthinkable. The result was a compromise. She remained true to her husband, but she developed a symptom the significance of which is evident. It is a sort of *make-believe* pregnancy, which not only serves as a partial fulfillment of the desires she is repressing, but at the same time flgives her a kind of revenge upon her husband by causing him the annoyance of having on his hands a wife who is sick and irritable.

I hope that in relating the findings of the analysis of this symptom, I have not given the impression that the facts I have disclosed were clearly before the patient's consciousness at the time the symptom developed, or that she felt no opposition to knowing them at the time of the analysis. Either impression would be entirely incorrect. I am sure that to direct questioning she would have replied that she had gotten over wanting children, that she had no recollection of any thoughts of infidelity, and that her brother-in-law's advances occasioned her no other feelings than horror and disgust. The thoughts brought out by analysis were, during the period the symptom existed, almost entirely out of her consciousness; that is, were *repressed,* and in order for her to become conscious of them she had to take sides with me against herself, overcome her resistances, and realize things that she did not at all want to know. The same forces that led her to repress immoral thoughts in order to retain her self-respect, opposed the return of these thoughts to her consciousness in the analysis. The same resistance is met with in every analysis. No person willingly realizes the content of his repressed complexes, and since these complexes contain those very thoughts that he would be most ashamed of having, an unwillingness to be made aware of them need not be considered strange.

In the preceding case we have seen that an objectionable idea, serving as a wish-fulfillment, is converted into a bodily symptom. In anxiety hysteria no such somatic conversion takes place, and the chief symptom of the disorder is anxiety or fear. This fear, like all other psychoneurotic symptoms, results from imperfectly repressed desires. But since many have found it difficult to believe that desire could, in any way, be the cause of fear, let me devote a few moments to the discussion of this peculiar relation.

Suppose a man has an intense craving for alcohol. It is perfectly clear that as long as he had every opportunity to gratify this desire and no objection to doing so, his desire would cause him no fear. But suppose that, through some circumstance such as a religious conversion, he suddenly stops his alcohol and resolves never to touch it again. It is not unreasonable to conclude that under such circumstances he might be afraid to go into saloons. His desire would then be the cause of fear. Now, if it were possible for him to suppress his desire to such an extent that he hardly realized he had it, yet at the same time it remained as strong as ever—in other words, if he could make the desire unconscious without diminishing its vigor—we might expect him to feel some sort of fear of being in saloons, restaurants, and other places where liquor is served, *without being aware of the cause of this fear.* His condition would then be exactly like that of a person suffering from anxiety hysteria. But, as a matter of fact, a chronic desire for alcohol cannot exist in an unconscious state. As we have seen, however, other desires of a more natural sort can so exist, and these desires, operating in exactly the same way as in the case we have imagined, can produce fear. This, in fact, is the mechanism of anxiety hysteria.

Let us now attempt to illustrate this by a few extracts from the analysis of a case. A woman of twenty-three, married three years, began six or seven years ago to experience a marked feeling of fear if she were left alone in the house. She felt a still greater fear of having to pass through any hallway alone, and, if she were compelled to do so, she invariably had intense panics, accompanied by weakness, tachycardia, pallor, etc. It was not until

she had been under my care some time that she told me that associated with these panics was the terrifying idea of there being someone behind her who was about to jump upon her back and choke her. That this was pure imagination she was, of course, quite aware. She had a number of other phobias and obsessions, but I will not describe them here, for a full report of the analysis of even those fears I have mentioned is too long to be attempted. I shall relate only enough to make the fear understandable and to show the psychological mechanism of anxiety hysteria.

The repressed desires upon which the above mentioned fears were based are of such a nature as to require a little explanation. I have previously alluded to the simple sensory pleasures of the infant. The most primitive ones consist of different sorts of stimulations of certain sensitive parts of the body; namely, the genitals, the urinary and intestinal orifices, the mouth, and the mammary regions. These pleasurable stimulations are, in fact, incidental to such necessary acts as the taking of nourishment and the voiding of excrement, or they may be produced artificially through masturbation, thumb sucking, etc. Normally these sensitive zones, except the genitals and, in females, the breasts, lose their irritability and become incapable of furnishing any positively pleasurable sensations. In some individuals, however, the infantile irritability of one or more of these zones may persist, and the region be susceptible to pleasurable stimulation throughout the person's life. When this does occur, the part retaining its earlier sensibility may usurp the rôle in the person's psychosexual life ordinarily played by the genitals. This is exemplified in certain perversions. The passive pederast has little or no interest in the normal sexual act, but does crave coitus per rectum—or, in other cases, the mouth attains an erogenous significance normally belonging to the genitals. In a different group of cases—neurotics, in fact—though the sensibility of an erogenous zone may be retained, the longings and fantasies relating thereto are not, as in the perversions, *conscious* ones, but are *repressed* and confined to the unconscious. Such was the state of affairs in the patient we are discussing—she had a strong "anal-erotic complex," but this complex was, for the most part, unconscious.

The first hint that the fears I have mentioned depended upon a complex of this nature she gave in describing a particularly severe attack. She was leaving a certain house at night and had passed through a door at the bottom of the stairway. This door slammed behind her before she had opened the outer one. Thus she was for a few moments shut in the entry-way between the two doors as if in a very small room. Before she could open the outer door and escape to the street she was seized with a terrible fear that someone was coming through the back (inner) door to choke her. Concerning the door in front of her she felt no fear whatever. Immediately after telling me this, she made a rather suggestive slip of speech. She was speaking in German, her mother tongue, and used the words *von dem Hinterer* (from *the* behind, *i.e.* gluteal regions) when she had intended to say *von hintern* (from behind). After this, she told me that she felt no particular fear when alone in a house *so long as she stayed in the front part.* Finally she reproduced a great number of memories belonging to her anal-erotic complex, *e.g.* recollections of anal masturbation, day dreams of coitus per rectum, rectal birth fantasies, etc. She was able to recall having had momentary cravings for pederasty almost all her life and even after she was married. Wishes of this sort, imperfectly repressed, formed the basis for her phobias. Of the truth of this statement no further evidence is required than that furnished by a record of the occurrence of her attacks. This showed that they appeared when she found herself in a situation suggesting *back* part, *back* entrance, *back* opening, or *back* passage. Thus the fear, which really referred to repressed thoughts and longings concerning a part of her own body, was disguised and protected against interpretation by her consciousness by being projected to external situations symbolic of its origin. The idea that someone was going to jump upon her back and choke her depended, in part, upon a play on the two German words *ersticken*, meaning to choke or suffocate, and *erstechen*, meaning to stab or thrust, and corresponded to a wish for someone to assault and forcibly commit pederasty upon her.* The wish for an assault was probably augmented by her desire for children. Her husband had never been able to impregnate her and she had often wondered if the efforts of some other man might not be more productive.

I have attempted to show that in hysteria proper and anxiety hysteria the thoughts upon which the symptoms depend are, for the most part, unconscious. In the compulsion neurosis a different mechanism exists. Here the thoughts which form the basis of the symptoms remain, for the most part, in consciousness, but the emotions belonging to and derived from these thoughts are transferred to some other, associated, but less unpleasant idea. This mechanism, in which a feeling, for instance, one of self reproach, is displaced from the disagreeable idea causing it, to some other not essentially disagreeable idea, operates not only in the neurosis but in perfectly normal people. The following story will serve as an example.

At a bachelor dinner a certain man ate very heartily, drank enormous quantities of wine and spirits, and went home in a most hilarious condition. The last course of the dinner consisted of fruit. Upon awaking next morning, the man found himself suffering from that symptom-complex sometimes known as a "hang-over." As he stumbled toward the water pitcher he remarked to himself in tones of great disgust: "What a fool you were *to eat that fruit*—fruit never did agree with you."

The psychological mechanism of this remark is perfectly evident. The feeling of self-reproach belonging to the idea of drinking alcohol had been displaced (not perfectly, of course) to the inoffensive idea of eating fruit. The motive for this displacement is obvious. The man would much rather reproach himself for eating fruit than for alcoholic intemperance.

Now, note the similarity in mechanism between this man's remark and the following case of compulsion neurosis. The young married woman mentioned presented among her other neurotic symptoms, a compulsive idea which came on as follows: One day while walking through the Metropolitan Museum, she stopped to look at an exhibit of mummies. As she stood there she began to wonder why the mummies did not decay. Then there came

*The idea of choking has an even more important significance in connection with some of her infantile conceptions of birth and the soul. A full explanation of this symbolism is too lengthy to be undertaken here.

over her a feeling of great anxiety and uneasiness, and she found, to her dismay, that she could not get the idea of mummies out of her mind. When she came to me two days later—she was under my care at the time—she could talk of nothing else. Over and over again she asked: "Why don't mummies decay? Aren't there any germs in them? Is there some medicine that keeps them from decaying? Aren't they really dead?" etc. In spite of the fact that she fully realized the absurdity of her obsessive thinking she could not stop it, and thoughts of this kind, accompanied by a feeling of intense fear, kept tormenting her, while nothing I could say either relieved or satisfied her. The symptom persisted some time before I found the cause of it. It owed its origin to the fact that she had once been a sufferer from tuberculosis. Indeed, between her fourteenth and sixteenth years she had spent most of her time in different sanatoria. She left the last one before she had fully recovered and returned to her home here, where, in spite of rather adverse conditions, she apparently became entirely well. But this important part of her history she never told her husband. She was afraid to tell him during her engagement for fear she would lose him. After her marriage she was equally afraid to tell him for fear he would be angry and accuse her of deceiving him. To ease her conscience she always tried to persuade herself that she had never had tuberculosis and that all the physicians who so diagnosed her case were entirely mistaken. In support of this view she advanced the arguments that she had never had a positive sputum, and that she had made what appeared to be a perfect recovery in the unfavorable climate of New York City. Yet in spite of these efforts to justify herself she never felt at ease about the matter and always wanted to tell her husband the truth; partly, that all might be open and above board between them, and partly, because there was great danger of his accidentally finding out her secret by meeting someone who had known her when she was sick.

She had been married somewhat over a year when a new complication arose. *Her husband* developed tuberculosis. This made it necessary for him to give up his business and leave for a sanatorium. Thus the motives which already existed for the patient's keeping her secret received reinforcement. She was now afraid that if her husband discovered that she too had had tuberculosis, he would not only be extremely angry at her deception, but also would accuse her of having infected him. Her love for her husband was certainly not increased by such considerations, while the prospect that for a long period he might be incapacitated and unable to earn anything, made it difficult for her to regard her marital venture with any high degree of satisfaction. These and other circumstances, coupled with the fact that if her husband died the problem of confession would cease to exist, placed the possibility of his decease in such a favorable light that she heartily wished for it to become a reality. But her husband not only failed to oblige her in this respect, but, on the contrary, he added to her perplexity by leaving the sanatorium in which he was at first and going to another in which she herself had been an inmate. Naturally, she feared that in this institution there might be someone who would remember her as a patient and accidentally disclose her history to her husband. It was at just this stage of the situation that her obsessive ideas concerning mummies appeared. The symptom, in fact, represents a displacement over to the new idea of mummies of the conflicting emotions belonging to her tuberculosis complex.

Let us try to represent to ourselves the condition of the patient's mind at the time when this transfer took place. All her thoughts were centered upon tuberculosis. Feelings of love and hate, of fear and hope, of guilt and self-justification battled with one another without ceasing. Should she tell her husband and face his anger, or hold her peace and risk his finding her out accidentally? Should she hope that he might die and in this way solve her problems, or that he might improve, take up life with her again, and thus expose her to the danger of reinfection? Had she really had the disease or not? Could she be sure that she had entirely recovered?

Questions of this kind kept pressing into her mind. And these questions she could neither answer nor evade. As she looked at the mummies, the striking similarity between their withered, drawn, and emaciated appearance, and that of certain advanced cases of tuberculosis which she had seen, half consciously impressed her. Thus there was formed an association between mummies and tuberculous patients, and this association made it possible for her to transfer all the feelings of remorse, doubt, and fear belonging to her tuberculosis complex over to this new idea. In this way, by using the mummy as a symbol for the consumptive, she was able to effect a sort of escape from the ideas which caused her so much distress. The mechanism of this obsession is the same as that in the story I related. An innocuous idea is substituted for a painful one. The patient would much prefer to worry about mummies than about tuberculosis.

In the light of this interpretation there is nothing astonishing in the fact that she was not able to banish the thought of mummies from her mind. It is also clear that her questions, "Why don't mummies decay? Is there some medicine that prevents it? Aren't there any germs in them? etc.," as well as the accompanying emotions were directly connected with the most important problems of her life. (It should be remembered in connection with the above questions that tuberculosis to many people means a *decay* of the lungs.)

In this paper I have given only the briefest reports of the analyses of single symptoms, and even these reports are incomplete. I could not do otherwise, however, for the analysis of an entire case usually requires several months to perform and a complete report of it would fill hundreds of pages. But it is greatly to be regretted that a complete analysis cannot be given, for these fragmentary reports do not present a true picture of the inner mental life of the neurotic. It is only from such complete reports or from actual psychoanalytic experience that a correct impression of what really goes on in a nervous person's mind can be gained.

Those who have had such experience; that is, those who have been willing to spend almost unlimited time in helping neurotics to tell what they really do think about, have had no great difficulty in confirming practically all of Freud's conclusions. To those of you who doubt the pathogenic power of unconscious ideas, who consider the analytical interpretation of the symbols and mechanisms in dreams and neurosis as fanciful and far-fetched, and who deny the importance of sexuality in nervous disorders, let me say that if you will only apply Freud's method of letting the patients tell all the

thoughts that come to their minds, and without being discouraged the first time a subject says: "I can't think of anything more, Doctor," persist for a reasonable length of time, you will surely have ample reason to cease doubting and denying the things just mentioned, though without some technical knowledge you are not likely to effect any cures.

In closing let me express the hope that I leave you with the impression that the troubles of the neurotics are, at bottom, real ones; that the seeming absurdity of their morbid thoughts and fears is largely dependent upon our own lack of understanding; and that these patients, as a class, deserve much more sympathy from medical men than is usually accorded them.

THE SCOPE AND TECHNIQUE OF PSYCHO-ANALYSIS.*

By C. P. OBERNDORF, M.D.,

NEW YORK.

Psychoanalysis should not be regarded exclusively as a therapeutic measure, but also as a system of individualistic psychology which rests upon the discovery that unconscious mental mechanisms are potent operative factors in the acts of daily life as well as in the production of symptoms manifested in many mental diseases.

The caution and modesty with which psychoanalytic theories—the result of years of continuous research on the part of their originator, Freud of Vienna—were presented for the consideration of medicine and psychology, is characteristic of the unbiased and scientific attitude of their author. While the theories, which are still undergoing revision, may appear whimsical or even fantastic if considered superficially, the essential contentions are gradually being accorded cognizance from the conservative school of descriptive psychiatrists who were long inclined to scepticism. Of recent years the extension of psychoanalytic research has progressed so vigorously and a brief exposition of the many sided subject is so difficult, that I shall limit myself to some simpler theoretical phases and the therapeutic technique.

Some thirty years ago Breuer and Freud, while investigating the origin of hysterical conditions, discovered that certain of the symptoms of this disease disappeared when the causes for their inception had been brought to light and the emotional desires, which for some reason were suppressed at the time, were fully experienced by the patient in relating them to the physician. However, a second discovery soon followed, namely, that all such mental impressions and processes which were originally considered by Freud to be the causes of the pathological emotional states, could be demonstrated to practically the same degree in normal and even exceptionally efficient individuals. It followed, therefore, that hysterical conversions were only distorted bodily representations of the attitudes which are normally formed by us all as the expression of emotional conditions. So, too, it soon became manifest that even our more precise thought and action, which apparently depend only upon logic and reason, are influenced by innumerable secret forces whose presence the thinker fails to realize.

The Unconscious.—Unconscious influences are regarded by the Freudian school as not only vast but paramount determinants of psychological processes. While any thought conceived by the mind —even a pathological thought—may become unconscious almost at the time of its genesis, it may still continue to exercise a certain amount of effect upon the mentation and conduct of the person harboring it. Most of the unconscious thoughts which are pathological are conceived not during maturity but in childhood, and perhaps owe their abnormal character to an infantile predisposition.

The unconscious mind thus becomes a reservoir of all impressions, both normal and pathological. From the very trivial things which are recalled by patients from early childhood, it has seemed to me that no impressions—hypothetically not even those of babyhood—are ever totally lost, but are merely stored away in this reservoir, possibly never to appear again. While most pathological impressions are received early in life, they soon vanish so far as their conscious import is concerned, much as the waters from a spring in a sandstone country sometimes sink immediately below the surface and disappear into subterranean channels.

Freud grants that psychical and physical traumata in adult life exert a certain influence in the production of hysterical and neurotic manifestations, but considers them none the less intrinsically associated with pathological unconscious processes or psychical insults of a sexual nature encountered in childhood. Notwithstanding the early origin and obscurity of these trends, their course, submerged in unconsciousness, may persist powerfully, and like the subterranean brooks mentioned above may become lost rivers, and eventually reappear as streams of some magnitude, so they too may emerge to the surface, not only at unexpected times and places but in somewhat altered form.

Method of Investigation.—Free Associations. The psychoanalytic method, by which suppressed and long forgotten impressions are restored to consciousness, is intended to acquaint the patient with repressed complexes which are militating against him so that he may more intelligently cope with them in consciousness. While Freud at first resorted to hypnotism to abolish the censorship of consciousness and provide a free egress for all thought associations, hypnosis, as well as its successor, the method of allowing the patient to repose in a room where all external distractions are removed so that he may lapse into the borderland between sleep and waking, have proven unessential. Freud himself adheres to the plan of having his patient in a recumbent position during the free association but most analysts allow the patient to assume any comfortable position. The patient who remains in a waking state is requested to associate freely on whatever may come into his mind, not

*Read before the Society of the Alumni of Bellevue Hospital, May 4, 1913.

only to relate ideas of pertinent interest, but to allow his thoughts to wander to whatever fancies, incidents, events, or stories may occur to him. While this is taking place the physician directs his own attention not only to the most emphasized and palpable factors, but also to apparently insignificant details and expressions, as a means of discovering the determinants of the infantile sexual life.

As experience with psychoanalysis progressed, it became evident that the mere recalling of psychical insults during childhood into the patient's conscious memory did not produce the awaited result of an alleviation of the patient's symptoms. It therefore became necessary to withdraw the particular stress which at first had been placed upon the recitation by the patient of forgotten occurrences and instead attribute the disturbing factor to resistances which had been engendered in the patient's mind through ignorance at the time of the experience or which had subsequently resulted from it. Such resistances were found to be still actively on the defensive in the patient's mind against his instinctive trend correlated with the trauma. Thus, although the patient became aware in his conscious thinking of the forgotten occurrences, he failed to connect them with that group of circumstances which gave birth to the repression. He also failed to realize the presence of very similar wishes and tendencies in the situation confronting him. The function of the analyst, therefore, is not only to investigate the infantile conflicts and resistances established in connection with them, but at the same time he must inevitably resort to reeducational explanation.

Concerning Suggestion.—The adoption of the waking method of analysis minimizes the validity of the imputation made by critics of pschoanalysis that the associations discovered are largely the product of the analyst's own imagination, suggested to the patient who, in the hypnoidal state, is particularly susceptible. The fallacy of this assumption becomes apparent after even a slight acquaintance with neurotic patients, who resent any imputation which they consider detrimental to their character; for the desire to present themselves in the best possible light may be said to be characteristic of them.

It has also been advanced that the entire procedure is nothing more, from a therapeutic standpoint, than an elaborate system of suggestion and, to be sure, the rôle of suggestion cannot be entirely eliminated. The fact that the patient is told that the neurosis or habit disorder is due to some lack of mental adjustment or to some repression which, when discovered, will cure him, is in itself a rather powerful form of suggestion. Such a criticism cannot be satisfactorily refuted, but if it be so, it is suggestion of the most individual type, based on the minutest investigation of the patient's secret yearnings, forbearances, struggles, and conflicts from earliest infancy.

The Association Test.—In addition to the method of free associations, Jung of Bleuler's clinic in Zurich, where is conducted perhaps the most critically discerning investigation of the Freudian principles, introduced the association test, a method long known to psychologists, as a means for eliciting complexes which the patient did not care to reveal. This test, which has become popular knowledge, consists in allowing the patient to state the first word which enters his conscious mind when he hears certain stimulus words, constituting a standard list, and recording the time required for response. Although increasing experimentation with this test has disclosed vagaries and certain sources of error,[1] very broadly speaking, a retardation in the length of time taken by the subject to reply to a given stimulus indicates some painful thought association in connection with this word. The patient fails to reply with his normal alacrity because he does not wish to reveal some disagreeable memory and during the time delayed in responding has been ransacking his mind in search of a suitable substitute for the word which primarily came into consciousness.

As the association test after all constitutes merely a means of rapid psychological orientation with the patient's general mental trend, I have for some time employed in my own stimulus list what may be called "double-barreled" words. By this I mean words which normally permit a diverse range of association dependent upon the patient's habit of thought—such words as drink, prick, ball, peach, bar, deer, etc.—and which thus afford a direct means of gaining insight into the type of personality under examinatiton.

Dreams.—While free associations furnish one route for penetration into the realm of the unconscious, dreams, according to Freud, form the most tangible connection between unconscious and conscious thought and may be regarded as one of the most valued assets of the entire technique. Freud asserts that in the phenomenon of dreaming, the conscious mind's censorship is decreased, though not entirely abolished through sleep. The diminution of censorship in dreams permits the fantasies and yearnings of the unconscious mind to filter through to the light and thus provide the most significant means of studying unconscious associations

In the dream work unconscious associations appear in a distorted, grotesque, condensed, symbolic, or intensified form and on this account the dream may appear to be merely a conglomeration of glaring incongruities if considered as an entity. Nevertheless when the separate items composing it are considered individually and the mass of thoughts associated with each item is unraveled, the unintelligible jumble will be found to represent a purpose.

A patient undergoing analytic treatment is therefore asked to record what he remembers of his dreams whenever they occur. What the patient reports constitutes the manifest content of the dream but it is the function of the analyst to unfold the memories and fancies which lie behind it—what is technically known as the latent dream content. When this has been accomplished it can usually be demonstrated that in its final delineation the dream represents as fulfilled a wish which may have been long cherished though it had been deferred from gratification by repression or otherwise. The wish, then, furnishes the impetus which gives rise to dream formation.

According to some of the more recent investigators (Maeder,[2] Alfred Adler) another, though secondary function of the dream exists, namely, that practice and preparation for future waking activity. A certain class of dreams which stand in close relationship to actual problems suggest a solution of the undecided question, often in disguised form. The dreamer may subsequently actualize the suggestion or solve his problem according to the dream direction, though no analysis of the dream has been made prior to his waking acts.

The dream thus represents a solution of a problem

or a wish as fulfilled and may attempt to satisfy many psychical strata at one and the same time. It may exhibit not only the wishes of the day but also those of childhood, though the latter are usually carefully concealed. Moreover the abundant and ramifying material of the latent dream content is altered and concentrated in the dream, principally through the combination of the homogeneous and the similar.

Symbolism.—Naturally the interpretation of dreams, in which symbols may represent actualities, a picture of childhood be superimposed upon one of adult life, or two persons be combined as one, is open to criticism and doubt. Especially has the interpretation of symbols, by which psychoanalysts claim that the genitals and other parts of the body are represented in dreams, invoked much derision and mockery. Still it is undeniable that in our daily conversations, euphemistic references, not only to the genitals but to other delicate subjects is usually symbolic. For instance, on a dreary day in the smoking room of an ocean liner to relieve the monotony, some one suggested that a list be compiled of the symbols for money. In a few minutes no less than twenty words were named, all of which were familiar symbols to the Americans present. It seems reasonable to assume that, inasmuch as all the material for dream work must necessarily come from our waking existence, we should transfer symbolism there as well.

This question is further complicated by the fact that the symbol of one period does not constantly remain identical with the same individual nor does the same symbol have the same significance to different persons. For instance, the color combination of yellow and black, which became fixed in my mind as a child as indicating the Austrian army, in high school days represented a rival preparatory school, whereas now it would stand for an American university. So, too, while at first it seemed perplexing to learn that "fine" in the dream of a certain patient indicated masculine, the origin proved to be very direct and at one time probably symbolized the same to many of us. Those who in childhood have played the game of "forfeits" will recall the phrase "heavy hangs over your head" which is followed by the query "fine" or "superfine"? instead of the blunter expression "boy or girl"?

Resistances.—The difficulties encountered in the analysis of dreams depend not only on their intricate character and latent roots, but also upon the resistances which the patient develops, both consciously and unconsciously, to the revelation of painful thought associations which have been voluntarily and carefully kept guarded. One of the commonest tendencies is to allow the recollection of unpleasant events to slip into the background, so that in reverting to childhood days we are apt to regard them as singularly happy, notwithstanding all their troubles and disappointments.

Many patients enter psychoanalytic treatment with much misgiving or with such eagerness as to arouse suspicion on the part of the physician, for either may be construed as an evidence of resistance—the first indicates distrust of the physician to ameliorate the symptoms; the second, a desire quickly to unburden what the patient considers to be most pertinent and thus prove the method a failure. This in turn would permit the patient to retain his illness—a thing which many patients in spite of their protestations, unconsciously desire. This is comprehensible when it is understood that a neurosis often forms a compromise between an unconscious wish and a repression—it is the patient's effort to "keep his cake and still eat it." Unconsciously he desires to cling to the compromise.

The first object of the physician is to overcome these resistances, which is accomplished by permitting the patient to transfer his longings and even his hatreds temporarily to the physician himself. While such transference is an absolutely essential and really unavoidable part of the technique during the initial stages in order to secure any degree of cooperation, it subsequently lapses without detriment to the patient.

Transference alone may serve to alleviate many symptoms of which a patient complains, but the result is usually transient as it is dependent upon the persistence of the transference. In such cases the treatment is purely one of suggestion and not one of psychoanalysis. As Freud recently remarked,[3] "the treatment is worthy the name of psychoanalysis only when the force of the transference has been utilized to the subjugation of resistance, for only then does a recurrence of the sickness become an impossibility, even after the transference has been destroyed, as of course it should be."

The complete analysis of a dream requires much time and the following example is reproduced merely to demonstrate how the wish of the day, repressed as unworthy, may filter through in the dream. Its infantile source and some of the other deeper determinants which lie in back of it, are not revealed for personal considerations.

"I dreamt I heard the telephone bell ring. I went to the phone rather annoyed. The voice over the phone sounded indistinct and at first I could not understand what was said. I asked "Who is this?" I received the impression of a name beginning with "S." Then over the telephone came "she has jumped out of the window." In connection with the dream I might mention that some four days before its occurrence another physician had asked me to see a case of agitated depression for him. After becoming acquainted with the situation in the household, I advised that the patient be committed to an insane institution because of her suicidal tendencies. The family asked time to consider this and agreed to let me know, but failed to do so.

Two days after my visit the physician telephoned to inquire if I had received any communication about the case as since my visit he himself had heard nothing. I stated conditions to him and while he seemed perfectly satisfied with my action, I felt that he had not been quite justly treated by the patient's family. I was convinced, however, that my advice had been for the best and the thought flashed across my mind that my prognosis might be substantiated. This was immediately repressed as unworthy. Moreover, I entertain very strong feelings in regard to this attitude in medicine and recall the shock in student days at one of the hospital physicians who remarked that he "hoped the old codger would die" so that his diagnosis might be verified. Subsequently as an interne I had an intense desire to prove myself correct in diagnosis, so that I had quite a struggle against my own tendencies toward autopsy medicine.

Now it so happens that the name of the depressed patient began with "S." My desire to forget her was carried over into the dream, but the wish which I had turned aside as incompatible with my ethical ideals, namely, that the patient fulfill my prophesy, is expressed unmistakably.

Extension of Freud's Theories.—The interdependence of ordinary thinking and unconscious thought associations has been utilized in explanation of those puzzling little errors of daily life, such as misunderstanding the meaning of a sentence, the forgetting of names and slips of the tongue and pen. Such harmless mistakes, usually barely noticed and willingly pardoned, have been shown to be fully determined expressions of unconscious, opposing or offensive ideas which interrupt the train of thought primarily intended. In misspeaking and in slips of the pen, the suppressed tendency rather than the intentional one, is often expressed. The following may serve as an illustration:

A patient who was referred to me suffering from a fear of insanity, after relating various complaints of a neurasthenic character, remarked: "And then I have erections without emissions." When asked why this should alarm him, he quickly corrected himself, saying, "Oh, no, I have emissions without erections." It later developed that as these seminal losses without erections constituted one of the main symptoms on which he had based his fear of insanity, he was very anxious to have them relieved. The slip of the tongue, in relating his complaint, therefore expressed the condition which he desired, namely, the restoration of normal erections.

A large part of recent Freudian work has concerned itself with the study of the sublimation of sexual energy into science, the arts, philosophy, and other activity and the application of analytic knowledge to the explanation of historical and mythological problems. While I am convinced that much of this is valuable, its discussion would carry us far afield from the scope of this paper. However, I might remark parenthetically that the use of psychoanalysis for the interpretation of ancient and modern literature has appeared to me as rather futile, since in so doing we interpret objectively and not subjectively—a violation of the most important Freudian principle.

On the other hand, careful study of the so-called functional psychoses, notably dementia præcox, has yielded strong substantiation of many of Freud's contentions. However, comparatively slight benefit is to be expected from analysis in cases of dementia præcox, as such mentalities when the disorder is well developed are beyond the possibility of adjustment.

It is quite likely that some day an organic basis for dementia præcox may be established with perhaps a remedy in the form of some glandular extract, but this should not affect the psychological interpretation of the mental mechanisms shown in this perplexing disorder. While the cortical changes in the brain are undoubtedly responsible for the forgetting in paresis and senile conditions, owing perhaps to the hopelessness of these disorders, no one has, to my knowledge, ever undertaken to ascertain accurately just which type of facts is first forgotten. Possibly a hint may be taken from the popular construction placed upon the remembering of old people—that they recall those things which are dear to them longest—in other words, they tend to forget unpleasant events first.

Selection of Cases for Therapeusis.—Psychoanalysis, because of its novelty, has suffered a surplus of popularization, notably in the monthly magazine. It is not presented to medicine as a panacea for all the mental ills of humanity, yet it contributes immeasurably to the understanding of hitherto inexplicable manifestations in psychoses, neuroses, and every-day thought. Eventually it must be influential for a more intelligent educational direction of childhood activities, especially in the sexual sphere, and for mental hygiene during adolescence. One of the greatest contributions of the Zurich clinic to the advancement of psychoanalysis has been the requirement that any person desiring to engage in analytic work must himself first submit to analysis.

As a curative measure psychoanalysis is most promising in cases of psychoneuroses in intelligent persons between the ages of 15 and 35, whose native language is that of the examiner, and in whom any physical basis for the complaint has been carefully excluded, preferably by other physicians. It is also desirable that patient and physician be total strangers before the commencement of the analysis in order that the impersonal attitude in the treatment may be rigorously preserved. Moreover, the patient should be so situated that he can devote not less than three hours a week for three months or more. A frank understanding before any treatment is undertaken, as to both its nature and the results obtainable, proves far more satisfactory to physician and patient alike in the end. While a positive cure should never be offered, a definite improvement may be confidently expected. The more experienced one becomes in analytic work the more firm is the conviction that no *short cut to permanent and effectual analytic treatment exists.*

It must be repeated that to attain success requires not only a thorough working knowledge of abnormal psychology and especially Freud's theories, but the utmost patience on the part of the physician, for any attempt to hasten the revelation of material to be utilized in the analysis has merely the effect of increasing resistances. Nevertheless there is an augmenting list of therapeutic successes reported by trustworthy men treating phobias of various kinds, hysterical manifestations and neuroses, which verify the value of Freudian procedures after the prolonged use of routine neurological methods had failed.

THE MIDDLE-AGED WOMAN: WHAT CAN BE DONE TO INCREASE HER EFFICIENCY.*

By KATE CAMPBELL MEAD, M.D.,

MIDDLETOWN, CONN.

There was a time, not so very long ago, when women of fifty were considered old, while their husbands were still in the prime of life. Our teachers of gynecology, in lecturing on the menopause, laid the cause of the ill health of the middle-aged women to the carelessness of the obstetrician, and the obstetrician laid the blame on nature and the natural lack of nerve tone in women. It seemed to be the general opinion of physicians a generation ago that though puerperal fever was rare the accidents of labor were the cause of woman's disability after the cessation of her reproductive years.

*Read at the meeting of the Alumnæ Association of the Woman's Medical College of Pennsylvania, June 6, 1913.

In fact she was considered obstetric junk which could be repaired at any time, after a fashion; but obviously the repairs should have been made as soon as possible after the damage was done to her tissues in order to save her from the scrap heap of human relics.

And now the question is, should the blame still be laid on the obstetrician if the woman at fifty is junk, or are all medical practitioners at fault for not educating the parents as to the hygiene of their own life, and the health, and dress, and occupations of their children? Dr. Agnes Vietor[1] tells us that three times as many women as men have flat-foot, curved spines, gall-bladder trouble and hysteria; and Dr. Robert Hutchinson speaks of some of these women of fifty as "abdominal women," with their misery and dejection, their flatulence and constipation, their continual suffering from genitourinary disease and mucomembranous colitis; and we wonder if the eight thousand women[2] who die annually when their children are born are a fiftieth part of the number who are injured during, or shortly after, the puerperium by careless midwifery or by hard work too soon after confinement?

Whatever the answer to this question may be, there are multitudes of other invalid women who have never had a husband or a baby, but who are victims of a false system of education which lays stress on excessive neatness in their housework, or extreme fashion in dress, or the acquisition of money, at the expense of health and good physique. And there are others who have become infected, whether innocently or not, with one or the other of those black plagues, gonorrhea and syphilis, and at middle age their life is misery.

I cannot refrain here from drawing a picture of such a patient. She smiles affectedly when she says that she has a "frightful backache and those bearing-down pains;" she is fat, but she says she "can't eat a thing and never sleeps;" and when asked what is her trouble, she answers smartly, "That's what I came to find out," or "The doctors all say it's change of life." She is a good many kinds of junk. Her eyes are not properly fitted to glasses, because she is a victim of the optician or of the itinerant vendor of eye-glasses. Her nose and throat are swarming with germs for which she believes there is no cure. Her teeth are decayed and the gums are foul with pus. She has palpitation of the heart from faulty digestion, and she will add that she has "gastritis of the bowels," "pneumonia of the stomach," heart disease due to "bulbular" trouble, appendicitis, gallstones, kidney trouble, womb disease, and generally malaria and rheumatism, or "plumbago," as it is sometimes called. Now these diagnoses are either homemade from newspaper advertisements, or they are the hasty opinions of busy practitioners who take no trouble to examine the patient carefully, either to find out where her various organs are and what they are doing, or what is the condition of her blood or her blood pressure. She has been given bromides, or pepsin, or quinine—all sorts of tonics—and finally, as a last resort, she has been sent to a surgeon. Many a woman of fifty is a wreck because of careless prescribing or of futile surgery prescribed for its psychic effect. That she needs psychic effects I do not deny. She has no thrilling plans for the future, she knows what position she is likely to hold in society, and she is either placidly content or dissatisfied and soured, ready to blame her doctors, her family, or anything but herself. The rational treatment of these patients of middle age must, therefore, depend on an accurate diagnosis of each case, and although surgery may sometimes be necessary for such diagnosis we may here think of it as a last resort. We know, to be sure, that it is often difficult without surgery to distinguish the symptoms of appendicitis from those of salpingitis and oöphoritis. Petterson of Copenhagen, for example, found very little disease of the appendix in 50 per cent. of the gynecological cases sent to him for removal of the appendix, and Natvig,[3] to the contrary, found a diseased appendix to be the cause of many cases sent to him for removal of the ovaries or tubes. Alperin,[4] in a recent article, calls attention to the reflex pains in gynecological patients, and gives what he considers a set of good rules for the correct diagnosis of difficult cases. He makes deep pressure on the umbilicus and finds the pain radiating to the seat of the trouble, whether it is in the uterus, the tubes, or the appendix, and this sensation he attributes to the extra congestion of the blood vessels in the diseased tissues. In 309 cases he had only 12 failures, but, perhaps because of faulty technique, I cannot make a single diagnosis by that method. My patients feel only the pain at the point of pressure, and never any radiating or reflex pain.

Speaking of gynecological pain, Von Rosthorn affirms that there can be very little pain either in the uterus, ovaries, or tubes until the disease reaches the surrounding connective tissue which is supplied with sensory nerve fibers. Pressure or traction on the ligaments through congestion because of retarded venous circulation, or of actual inflammation in the periuterine connective tissue from infection by the colon bacillus or from gonorrhea, causes sacral pain in every case. DeLagenhagen,[5] seeking for a first cause for these abdominopelvic pains and spasms, thinks that they may be due to a neuroarthritic tendency accompanied by venous stasis and defective nutrition in the pelvis. Varicose veins and arteriosclerosis of the pelvic arteries[6] may account for the increased blood pressure in the genitourinary organs, causing not only pains but also hemorrhages at the climateric, this condition being essentially what Findlay[7] has found in the walls of the uterine blood vessels and which caused the degeneration of the muscles.

Goodall[8] also believes that not only this circulatory condition but the overstretching of the uterine muscle during pregnancy, and its subsequent subinvolution and retroversion, may be an important cause of fibroid and fatty degeneration of the uterus. Dalché[8a] agrees with him, but Jaschke[9] suggests that myomata and fibroids of the uterus may be a result of oversecretion of the ovaries and thyroid gland; and Schenckt[10] tells us that such tumors are congenital, and that when the circulation is diminished at the menopause they create poisons which increase aortic tension and irritate the entire system. Whatever may be the cause of tumors of the uterus and its adnexa, or of hemorrhage at the climacteric, we are constrained to be sure that we are not dealing with a cancer of some kind. A patient of mine, after two curettages in which no cancer cells were found continued to bleed until treated with two doses of rabbit serum, after which she menstruated

normally for a year and then flowed again for some months. Having had anaphylaxis to the rabbit serum I gave her 100 c.c. of fresh horse serum, the coagulating power of her blood being 45 minutes. She again had serum sickness, but the coagulation time was reduced to 5 minutes, without stopping the bleeding. I then curetted her again, and this time cancer cells were found in the scrapings. A hysterectomy brought to light a small adenocarcinoma near the opening of the left Fallopian tube, and a small fibroid tumor in the uterine wall.

Another patient of mine menstruated profusely until she was sixty years old in spite of negative curettages at home and in Europe, and all sorts of treatment with hot air, electricity, packings, and styptics, but she finally stopped flowing without further surgery, and she has continued perfectly well for fifteen years. In still another patient the first curettage showed cancer cells, for which her uterus was removed by Dr. Robert L. Dickinson of Brooklyn, but no cancer was found in the small excised organ. And in still another case, after months of slight hemorrhage with no ascertainable cause, a hysterectomy showed only two small benign fibroids in the fundus of the uterus. In each of these cases, therefore, there must have been a different cause for the bleeding.

Besides the annoyance of climacteric hemorrhages, the middle-aged woman has all sorts of nervous symptoms. Dickinson examined over a hundred cases of neurasthenia, and in every case he found some abnormality, either endometritis, oöphoritis, sclerosis of the uterine vessels, venous enlargements, or disorders of the rectum or bladder. Bossi[11] and Walthard[12] attribute 10 per cent. of the neurasthenia, hysteria, insanity, and crime to intoxication from infective lesions of the ovaries and uterus. Dercum,[13] on the other hand, finds very little causal relation between the neurasthenias of the menopause and pelvic disorders, tracing the nervous symptoms back to lack of self-control and the bad habits of a lifetime. She has found more retropositions without than with nervous symptoms, and very little neurasthenia, or hysteria directly traceable to splanchnoptosis or lacerations of the cervix and perineum. Dr. Mary Rushmore[14] deplores the numerous operations for the repair of slight lacerations of these organs in the vain hope of curing a coexisting neurosis. Further, Polak[15] offers a note of warning against ovariotomies, believing that a slightly diseased ovary in its place is better than a carelessly replaced stump or a twisted pedicle; and Byron Robinson is quoted as saying that the Alexander operation is merely a temporary operation for cosmetic effect. If, therefore, we have such good authority for postponing an operation we must, before sending the patient to a surgeon, be sure that it will be of great benefit to her, taking time to study a puzzling case. Sutter[16] of Munich even goes so far as to show statistics from his clinics indicating that a morbid, nervous system is the cause of the uterine trouble and not its effect.

We must, however, admit that there are many neuroses which at least seem to be dependent on chronic disorders of the sexual organs. Ewald,[17] for example, says: "If the normal process of menstruation causes retardation of the gastric secretion, how much greater reflexes will be referred to the stomach and intestines by amenorrhea and dysmenorrhea, the climacteric period, and chronic disorders of the uterus which are associated with an irritability and even with a direct excitation of its nerves!" And he reports cases of dyspepsia and sialorrhea that resisted all treatment until a retroflexion of the uterus was discovered and corrected by a pessary.

Moreover, Dr. Chas. F. Hoover,[18] in an article on "Functional Diseases of the Heart," says: "The beginning and end of menstruation are often associated with palpitation, rapid heart, and sudden vasomotor oscillations. . . . but it is very difficult to know if the heart symptoms are the result of the reflex disturbances or consequent on the neurasthenia which so often accompanies affections of the generative organs." He cites the not uncommon case of a patient who felt faint after defecation because of the traction on her relaxed perineum. This traction caused vascular relaxation of the splanchnics through irritation of the abdominal sympathetics, and the same reflexes have caused death in patients who were undergoing some simple operation on their genital organs.[19]

We have reason, therefore, for replacing these organs and holding them in place by simple means if possible. The vagina is a valuable support to the uterus in our four-footed relatives, but it serves the erect individual very feebly, and when its slight support fails either from intraabdominal pressure or lack of perineal base, the nervous control of all the pelvic organs is thrown out of order; but, as Theilhäber[20] says, this alone would not cause subjective symptoms unless the organs became inflamed. A movable uterus is supposed to give no pain, no matter what position it is forced to take; and Waite[21] has found that constipation, irritation of the bladder, and dysmenorrhea are none of them caused by a retroversion or by an anteversion of the uterus.*

It is, therefore, somewhat surprising that for the last twenty years gynecological treatment has been mostly surgical. Surgery is, to be sure, more brilliant, and, in some cases, the proper fitting of a pessary is more difficult than a laparotomy. It has been said, too, that pessaries cause cancer, but in 255 cases where badly fitted pessaries had been worn, Neugebauer[22] found only eight in which cancer subsequently developed, and these may not have been the result of the pressure or of any erosion due to the pessary. In hundreds of patients to whom I have fitted pessaries there has been only one case of cancer, the growth occurring in the interior of the uterus and not in the cervix. Moreover, we have all seen more cases of erosion with-

*Dr. Lucy Waite of Chicago, has found the following malpositions of the uterus: out of 3000 recorded cases there were: anteversion, 27 per cent.; anteflexion, 40 per cent; retroversion, 22 per cent.; retroflexion, 6 per cent.; lateral version, 2 per cent.; prolapsus, 3 per cent.; *i.e.*, ante positions, 67 per cent., which corresponds to the 71 per cent. found by another author, and retropositions, 28 per cent., agreeing with the 29 per cent. of others. There were 15 per cent. of retrodeviations, out of 1000 cases, which showed no symptoms. At the Johns Hopkins Hospital there were found 1186 cases of retroflexion which showed no symptoms, out of 13,600 gynecological cases. Dr. William J. Mayo reports that 25 per cent. of the gynecological patients at his hospital had retroversion, many of them without symptoms. Moreover, 29 per cent. had movable kidneys without symptoms. Pinkham, of New York, found one case of retroversion in every five gynecological cases, all of which were due to parturition and its sequels. Of his 341 cases sixty were treated by pessaries, of whom eleven were cured, forty-six benefited, and three not helped; twenty-three required ventrosuspension, and three the Alexander operation.—(*Am. Journ. of Obstetrics*, May, 1907.)

out than with pessaries, and often a stubborn erosion will heal when the circulation of the uterus is restored by a well fitted pessary.

Kelly,[23] in his "Medical Gynecology," gives ten pages to the subject of pessaries, speaking of them as palliative, and suggesting their merely temporary use unless the patient is too old or too feeble for an operation. He has found that the essential contra-indications for the use of pessaries are (a) inflammation in any part of the pelvis, and (b) a total rupture of the perineum. The least tenderness of the ligaments or any traction on them is, I find, a decided obstacle to the comfortable wearing of a pessary, and a pessary certainly must be unobtrusive, but with even a mere shell of perineum a Schatz pessary can be comfortably worn in cases of complete prolapsus uteri. In Garrigues' "Gynecology"[24] pessaries are mentioned only to be condemned. He gives four lines to the question of prolapse and ten pages to the directions for operating in such cases. For retroversion he says, "pessaries are a poor make-shift and are used much less frequently than formerly." Thirty-six lines are then given to the subject of pessaries and six pages to the operation for retroversion. The "General Remarks on Pessaries" occupy two pages, followed by the crushing statement: "Personally, the writer has discarded them, except Emmet's in cases of retroversion or retroflexion where operation is refused." Bandler,[25] on the other hand, is much fairer to medical gynecology than many writers. He says: "One must start with the realization that most abnormalities of the position of the uterus can be relieved quite as well by supporters and correctors as by surgical operations. A preliminary treatment may be necessary before the pessary is inserted, such as hot air, Bier's apparatus, massage or electricity, or medicated tampons, but in the end the patient will be healthier and better than if she had been subjected to the shock of some surgical operation with its subsequent worries lest the shortened ligaments should stretch, or the perineum tear, or a hernia develop in the scar. But the pessary must be skillfully fitted for the work it has to perform and medical students should spend months studying uterine orthopedics instead of operations." Dührssen,[26] in Germany, is also fair to medical gynecology. He gives 45 pages to the use of pessaries and 172 pages to the anatomy and surgery of the pelvic organs. He says that injuries from pessaries are due to the stupidity of the physician who inserts the instrument or to laziness of the patient in taking douches and in failing to report to the physician any discomfort or foul-smelling discharge she may notice. It may be said that pessaries do not restore uterine tissues to their normal condition and tone, but neither do operations; both relieve the uncomfortable symptoms and restore the patient to health and strength, but the pessary does this without the nerve strain of an operation. It is true that a patient who is wearing a pessary should visit her physician three or four times a year for examination. But to the woman of middle age this should not be an extra burden, for she should have her urine and blood-pressure examined as often as that, just as she should make semi-annual visits to her dentist and oculist, if she would keep herself in good condition.

Giles[27] sums up the rules for the use of pessaries as follows: Operate only, (1) where pessaries are permanently necessary, (2) where pessaries cannot be worn successfully, (3) where the patient prefers operation to repeated examinations and treatment, (4) where the case is complicated by diseases of the appendages, (5) where there is prolapse or complete procidentia. Many operators add the following suggestions: Place a pessary in the vagina after an Alexander operation or after a ventrofixation, and also after confinement where the heavy uterus has a tendency to retro-deviations, and let it remain "in situ" until the ligaments have become strong again.

Dr. H. E. Boldt[28] says that a pessary that has been well fitted need not be looked at more than once in five or six months, and the patient should be told that she will have to wear a supporter for from two to five years; he reports the permanent cure of 20 per cent. or 25 per cent. of cases of backward displacements of the uterus by pessaries. This accords with the experience of G. G. Babcock[29] of Edinburgh, who uses a pessary in the cure of retrodisplacement almost to the exclusion of any other treatment, and F. H. Davenport of Boston reports the cure of 50 per cent. of picked cases of retrodisplacements, and of 33 per cent. of all cases of this sort by suitable pessaries. It is, therefore, evident that the disinclination to use pessaries is not due to the pessary, but to the lack of skill of the gynecologist, and the lack of adequate teaching of this subject in the medical schools. One must take into consideration the strength of the ligaments and the deflecting planes in the abdomen and pelvis in order to readjust the intraabdominal pressure. This is exactly the function of a well-fitting pessary, the Hodge pessary, for example, which extends up behind the uterus sufficiently to take up the slack in the uterosacral ligaments, but which is so freely movable as to assist the uterus in deflecting downward any superimposed pressure. The Schatz pessary does more than this, for it not only deflects the pressure but serves as an efficient base where the perineum is relaxed or badly torn.

While we have found in practice that chronic backache in the middle-aged woman is often due to retropositions of the uterus and curable by pessaries, there are many other backaches due to other causes, such as rheumatism, strain, neuralgia, sacro-iliac diseases, caries of the spine, fracture of the coccyx, hemorrhoids and other diseases of the rectum, and pendulous abdomen. Moreover, according to Garrigues,[30] any pain and tenderness of the fourth or fifth lumbar vertebra is due to "disease of the internals," and "any tender spot on either side of the second sacral vertebra is due to cellulitis of the uterosacral ligaments." Many authors, however, dwell especially on general splanchnoptosis as a cause of these backaches. Reed[31] and Pfahler,[32] for instance, in studying *x*-ray pictures of the abdomen, have found that there is often a prolapsed cecum, low in the pelvis and full of feces, or a colon out of place and bending in angles or flexures, or adherent to the peritoneum and constricted in places, which simulate uterine diseases in their pains and neurasthenic symptoms as well as in their toxemias. It frequently happens that a loop of prolapsed bowel, full of feces, feels like a floating kidney. I recall a case where three well-known specialists agreed in the diagnosis of a prolapsed kidney which gave the patient some trouble and required frequent replacing. I replaced it for the last time the day before she died, and at autopsy this "kidney" was found so snugly anchored in its proper position as to be very difficult to remove, but the splenic colon was twisted and enlarged and so full of feces as to feel like a

kidney. Many surgeons testify to this same error in diagnosis.

Whether we think we have a case of nephroptosis, or of coloptosis, or of splanchnoptosis, we can find much literature on this subject, for the bibliography of articles on ptoses is long and instructive. Twenty-five years ago we heard very little about this condition or its cure by surgery or mechanical means, and now we have Rovsing's[33] report of 163 cases of gastropexy, all favorable, as well as his advice about the correct belts and corsets to lift and hold the abdominal organs. We have also Dickinson's[34] arguments in favor of properly supervised gymnastics and the cultivation of nature's corset, "the well-set-up anterior abdominal wall with its strong uplift during contraction," to cure the middle-aged woman with relaxed abdomen, fat hips, and pendulous breasts. And we are taught by Reynolds and Lovett,[35] an orthopedist and a gynecologist, how to train our patients to proper postures in order to readjust their center of gravity, regain their balance, and retain their replaced viscera where they belong.

Some of us remember Dean Bodley's remarks to the chemistry class which was standing before her desk one day. She said softly, "Ladies, please pay attention to your attitudes in standing. If your abdomens are the parts of your anatomy of which you think the most, let them be in evidence, otherwise do not call attention to your bodies, but let your mental characteristics shine." It is, however, unfortunately true that the woman of middle-age sometimes finds neither careful attitudes of the body, nor mechanical treatment, nor surgery equal to the work of curing her ill-feelings so that her mind may work properly. Each individual presents a different psychic element, caused by her own way of responding to external and internal stimuli. When once the habit of introspection and myopia has developed she will need more or less continuous psychic treatment. She falls an easy prey to the Christian Scientist and to quacks, and enjoys patent medicines and all narcotics.

For such a patient there is yet another form of treatment which may take the place of drugs and is thoroughly scientific. I refer to the vaccine therapy, which is as well adapted to gynecological ailments as to other bacteriological infections. In examining smears from the vagina and cervix uteri of patients who were suffering from some genito-urinary trouble Dr. Jessie W. Fisher[36] has found in 13 of the cases the same bacteria that she found in their throats and noses. In these cases she found the colon bacillus three times, staphylococcus seven times, a streptococcus once, and *M. catarrhalis* twice. For these patients she has made autogenous vaccines which have been very successful in curing the disease from which the patient was suffering and thus preventing toxemic symptoms. Allen[37] suggests that where there have been failures with vaccines the dosage has been wrong. In gonorrheal cases, for example, the dose is frequently too small, and in many cases an autogenous vaccine should be given with the gonococci. He suggests 50,000,000 as a beginning dose of gonococci, and increasing the dose if necessary. He says: "The intervals may vary from five to seven and ten days. Treatment may have to be prolonged, but with care the patient will be cured." Allen says further: "Acute endometritis and salpingitis are nearly always secondary to one of two primary causes, either gonorrhea or parturition, 80 per cent. being gonorrheal with a coexisting colon infection. Puerperal infections are generaly streptococcal, and in all the cases thus far reported as treated with autogenous vaccines there has been a large percentage of cures."

Dr. E. W. Cushing, of Boston, also finds vaccines useful in chronic gonorrhea and puerperal infections, etc., but he obtains the best results in those cases infected with the colon bacillus, staphylococcus, and pneumococcus. In this I quite agree with him, but I must add the gonococcus to his list. In three recent cases I have used with brilliant results a polyvalent autogenous vaccine containing gonococci. In one of these cases, owing to a faulty staining of my own, I did not discover the gonococcus, and at first treated the patient with staphylococcus and colon and catarrhalis vaccine, on the mere hypothesis that her case was like another which I was treating. After a few treatments which did the patient no good I had a smear examined by Dr. Fisher, who found it to be swarming with gonococci; accordingly the proper vaccine promptly stopped the discharge.

It may be as well to report here three cases from my practice to show the short time required for the treatment of such patients:

Case I.—Mrs. S., gonorrheal infection, with chronic endometritis and salpingitis. Has twice been operated on for retroversion and ovarian adhesions. Dr. Fisher made an autogenous vaccine for her, which contained 200,000,000 gonococci, 600,000,000 staphylococci, and 200,000,000 colon bacilli. After five treatments the patient began to feel well; she had few of her old aches and pains, and she grew stout, while the dryness of the vagina disappeared together with its heat and congestion.

Case II.—Mrs. G., profuse leucorrhea for twenty years, during which time she had been continuously under a doctor's care, being treated with all kinds of local treatment. The uterus poured out a continuous stream of thick, tenacious mucus, containing streptococci, staphylococci, and *Bacillus pyocyaneus*. The same organisms were found in her throat. The vaccine for this case contained 150,000,000 of each of these bacteria to the cubic centimeter. A satisfactory cure was made by twenty doses of vaccine.

Case III.—Miss D., a victim of rheumatic pains and aches, with chronic tonsillitis, and tenderness in the right ovary. There was a thick ropy discharge from the os uteri. Dr. Fisher prepared a vaccine for this patient containing 200,000,000 staphylococci and 100,000,000 colon bacilli, which in fifteen treatments permanently relieved the discharge and ovarian pains, and seemed to cure the tonsils.

Many authors have reported equally good results from autogenous vaccines, whether gonorrheal or not. One should remember that death does not occur from the number of bacteria in the blood, but from toxemia due to localized foci of infection. We must therefore limit this toxin absorption and favor its elimination. The difficulty in treating endocarditis, salpingitis, and endometritis with vaccines is, then, due to the difficulty in obtaining the bacteria which are causing the trouble, and the inaccessibility of the local focus of toxin absorption. Since the pus of a pyosalpinx is found to be sterile nine months after the acute symptoms appeared, it would seem that the patient must be continually revaccinating herself with the poisons from the dead bacteria. If this process can be hastened by an autogenous vaccine, so much the better for the patient; the primary focus of the infection must, however, be sought. The laity have always thought that "catarrh went through the system," and a recent report from the Johns Hopkins Hospital[39] calls attention to the large percentage of cases of chronic urethritis and ureteritis associated with tonsillitis and rheumatism. This once more warns us to treat the whole patient and not a part for the whole.

As for other local treatment to the genitourinary organs of the woman of middle-age, opinions differ as to the value of douches and tampons, etc., but in my own mind there is no doubt of the value of nitrate of silver and other silver salts, as well as of ichthyol, iodine, and red-salve, etc., in appropriate cases. It is possible that the French physicians and some others may use too much local treatment. Richelat, for instance, advises vaginal douches of hot mineral water, 26 gallons at a time, three times a day, at a temperature of 45° C. (113° F.); and this internal bath is extensively used at all the European water-cures. The rational treatment of such a case must, in fact, depend upon its character. The dried extracts of ductless glands have not taken the place in the treatment of diseases of the menopause that enthusiasts at first claimed for them. Ovarian extract, lutein extract, thyroids, and adrenalin have some place in special cases, while mechanical treatment by bandages, pessaries, and corsets, as well as gymnastics and rest-cures have great value. Surgery at its best can not restore organs or ligaments to exactly their former correct positions; its chief value is to remove diseased tissue and to aid in the diagnosis of an obscure case.

But whatever treatment we adopt for the improvement of the health of the gynecological patient let us save her from fads and whims when she reaches middle-age. She may need readjusting from the crown of her head to the soles of her feet. She needs treatment before she is born, continual watching and teaching while she is growing, and great care when she becomes a mother, as well as good advice when she has reached the menopause, whether she is conscious of any change or not. But if she is a victim of bad obstetrics and of unhygienic living there is much that can be done for her without surgery; if, however, she needs an operation, let us make that as psychologically easy as possible. Crile has demonstrated that every anesthetized patient is handicapped by shock although the memory of the pain is obliterated. Bloodgood maintains that if the pain of an operation could be effaced entirely the mortality would be cut in half and the convalescence made much shorter. When, therefore, shockless surgery becomes possible we shall more willingly resort to surgery for the woman of middle-age, and by a judicious choice of medicine, surgery, orthopedics, and nerve re-education we may hope to eliminate the discomforts of the menopause and vastly increase the efficiency of the patient who should be in her prime, as is the man of fifty.

THE MECHANISM OF IMMUNITY IN EXPERIMENTAL CANCER*

By ISAAC LEVIN, M.D.,

NEW YORK.

CHIEF OF THE DEPARTMENT OF CANCER RESEARCH AT THE MONTEFIORE HOME; ASSOCIATE IN CANCER RESEARCH, COLUMBIA UNIVERSITY.

MALIGNANT tumors occur in nearly every species of lower animals. These spontaneous tumors are identical in their clinical behavior, as well as morphologically, with human cancer. In certain species, principally in white mice and rats, the growth of a malignant tumor may be induced artificially by an inoculation into a previously healthy animal of a piece of tumor tissue.

Before I proceed with my thesis I may show that this experimentally produced malignant tumor in lower animals is analogous clinically and pathologically with human cancer, and that consequently results obtained from the study of these conditions

*Read at the XVII International Congress of Medicine, London, August 8, 1913.

may be used in elucidating phenomena in human cancer with the same caution that is required in all other subjects of experimental medicine.

The usual method of propagating the tumors of the white mice and rats consists in a subcutaneous inoculation of a small particle of tumor tissue. In most of my work, which serves as the basis for this report, the technique differed inasmuch that I inoculated the piece of tumor tissue directly into organs, *i.e.*, brain, kidney, liver, spleen, and testicle. My aim was to imitate as near as possible the conditions in the human. As will be seen later, I observed a number of interesting phenomena, which would have escaped the old method of subcutaneous inoculation.

The tumors which develop upon an inoculation of a piece of tumor tissue into a parenchymatous organ show all the characteristics of malignancy described in human cancer. The tumor cells infiltrate diffusely and replace the substance of the organ. Consequently symptoms of clinical malignancy must occur as soon as a sufficient amount of an organ substance has been destroyed by the tumor. Indeed, these animals do not live any longer than about ten weeks after the inoculation, and frequently die with much smaller tumors than are obtained on a subcutaneous inoculation. True metastases form with much greater frequency than after a subcutaneous inoculation and the tumors recur after an apparently complete operative removal.

The objection may still be raised that this experimental cancer in white mice and rats is not comparable with human cancer since what we are inducing experimentally is only a metastasis through the introduction of a group of cancer cells in a certain place of the animal. But the biological and clinical behavior of a primary and metastatic tumor is absolutely identical, provided they occur in the same place and contain the same kind of cancer cells. The real gravity and importance of the metastatic tumor lies in the fact that it occurs subsequently to the formation of the primary tumor and consequently increases the gravity of the condition of the host. In experimental cancer the animals used are normal and the inoculated tumor is the only one within the host and therefore cannot be considered a metastatic growth in the true meaning of the word.

The most important phenomenon observed in the study of experimental cancer consists in the so-called immunity or resistance of certain animals to the growth of the inoculated tumors. This resistance depends upon a number of various complex conditions, most of which present as yet no tangible explanation. The phenomenon is a resultant of two component parts, the power of the inoculated cancer cell to unlimited proliferation and the reactivity or counteraction of the organism of the host. When a spontaneous tumor is inoculated it grows successfully only in a small number of animals used, frequently in less than 10 per cent. In subsequent inoculations with material taken from the implanted tumors the success of the takes increases to nearly 100 per cent. This indicates that the implanted cancer cell increases its proliferating power—its virulence. The fact, on the other hand, that a certain number of animals retain their resistance to the growth of the tumor, shows the influence of the reactivity of the host. There is still another factor which complicates the condition of immunity in experimental cancer. Before the inoculated piece of tumor tissue can develop its virulence in the new host, it must become ingrafted.

This mechanism of ingrafting is common to tumor and normal tissue. When the grafting succeeds then the further development of the graft depends upon the character of the tissue used.

The percentage of animals which resist the development of experimental cancer may be increased artificially by a previous inoculation of tumor tissue, the virulence of which is known to be very low, or of normal tissue. In view of the fact that no passive immunity may be induced by treatment of a normal animal with the blood-serum of an immune one, and the further fact that living tissue seems to be required to immunize an animal against tumor growth, and that there is no specific relationship between the character of the tissues used for immunization and the tumors used for subsequent inoculation, many investigators considered this immunity to be due to a peculiar cellular activity of the organism of the host.

The most plausible of these theories is the one advanced by Ehrlich under the name of "athrepsia," which is based on the following considerations: Growth of inoculated cancer is due to cellular activity and indicates that tumor cells possess a great avidity for a certain specific foodstuff within the organism of the host and consequently obtain it from the normal tissue cells of the organism. When cancer fails to grow, then either the organism of the host does not possess the necessary specific foodstuff or else the avidity of the cancer cells for this food is not strong enough to deprive the normal tissue cells of it. When the organism of the host is immunized by treatment with a cell emulsion, these cells bind the specific food and consequently the cancer cells inoculated subsequently do not find the necessary nourishment and die.

My own investigations have indicated, as I shall show later, that while immunity in experimental cancer is not identical with bacterial immunity there exists an analogy between the two conditions. In the first place I have shown that it is possible to immunize an animal against a subsequent tumor inoculation not only by a previous injection of an emulsion of living cells but also by one of the autolyzed tissues: *i.e.*, of tissue in which the cells have suffered dissolution but in which the endocellular ferments apparently remain active. This fact militates against the supposition that immunity in experimental cancer is due to a peculiar cellular activity, but is due probably to action of ferments and hence is analogous to bacterial immunity. In collaboration with Zittenfield I have further shown that athrepsia may serve to explain solely the condition of the resistance and susceptibility of an animal to the grafting of tumor tissue, and that the success of such grafting of the inoculated cells may depend on the conditions of nutrition. On the other hand, the differences in nutrition cannot explain the reason why in one successful tumor graft there forms a small nodule which is subsequently absorbed, while in another the nodule grows into a large tumor and kills the animal.

I cannot give here the details of the work, but I shall describe one very striking experiment. Ehrlich based his hypothesis among other things on the fact that a mouse tumor when inoculated into a rat forms a small nodule which is absorbed in eight days, but if before absorption the nodule is reinoculated into a mouse a big tumor develops. The reason is supposed to be the fact that the cells of the mouse tumor do not find specific food in the rat, but find it when reinoculated into a mouse.

"Twenty mice were inoculated with pieces of *mouse sarcoma* taken from rats. Nineteen mice survived, and of these one took the tumor, which represents 5 per cent. of takes. The tumor from this mouse was inoculated in twenty other mice and the tumor took in fourteen mice, or 70 per cent." It appears from these experiments that while a mouse tumor after a sojourn in a rat still grows subsequently in a mouse, its virulence is greatly diminished. Consequently the organism of the rat must have not only failed to furnish food to the cells of mouse cancer, but also produced on it an active inhibitory influence.

Bashford in his conception of immunity in experimental cancer also considers it to be a kind of cellular activity and furthermore denies that there is any direct influence of the organism of the host on the inoculated cancer cells. According to his idea an inoculated piece of cancer tissue causes in the new host the formation of a specific connective-tissue and vascular scaffolding. This connective tissue stroma invades the graft and furnishes it with the mechanical support and nutrition necessary for its development. Immunity, then, consists in the failure of the organism of the host to supply the specific stroma reaction. The immune organism does not produce a direct deleterious effect on the cells of the inoculated cancer, but alters its own normal connective tissue cells so as to render them insusceptible to the chemiotactic properties of the inoculated cancer cells.

My own studies led me to believe that Bashford's theory of a specific connective-tissue scaffolding has no general application in the explanation of cancer immunity. The conditions appear to be quite different when in accordance with my method of work the tumor is inoculated directly into an organ instead of subcutaneously. In this case the first visible step is not the formation of a connective-tissue stroma, but the inoculated cells immediately begin to proliferate and invade diffusely the normal tissue.

On the other hand, in an immune animal the tumor cells inoculated into an organ do not grow but die and are invaded by an extensive connective tissue stroma like any other dead foreign body. Consequently the immune organism does not lack the capacity to form connective tissue scaffolding, and such an incapacity can no more be considered of a general importance in the elucidation of the phenomenon of immunity in experimental cancer than the lack of specific chemical food.

I shall now turn to the description of other phenomena in the immunity in experimental cancer which I observed and which could have only been detected through my method of inoculation into organs.

The inoculable tumors of the white mice and rats as a general rule grow just as well when inoculated into a parenchymatous organ as when inoculated subcutaneously. On the other hand, an animal resistant to a subcutaneous inoculation also resists an inoculation into an organ.

In my experiments with the Flexner-Jobling adenocarcinoma of the white rat I noticed that while the tumor grows when inoculated subcutaneously or into any other organ in a large percentage of animals used, it does not grow when inoculated into a normal testicle. But when a testicle is treated previous to the inoculation either with an emulsion of Scharlach R in oil or an emulsion of ether in water, there takes place in the organ an inflammation accompanied with a proliferation of the intertubular connective tissue, and then the inoculation of the same tumor into the organ becomes successful. The failure of the growth of the tumor in the normal testicle is not due to a general condition of the organism, but to a local action of the testicle on the tumor cells. The percentage of animals which are generally resistant to a subcutaneous inoculation is very small, and all the animals used for the inoculation into the testicle could not have been resistant to the growth of the tumor. Nor is it due to the mechanical influence of the tunica interfering with the expansion of the organ by the growing tumor, nor to the lack of specific food in the organism of the host. My investigations have shown that other inoculable tumors grow well in the testicle. The mechanism of this local resistance can be due only to an inhibitory action upon the cells of this tumor of the cells of the tubules of the testicle. This investigation shows also that it is possible to render the same testicle artificially susceptible to the growth of the tumor.

In another more recent investigation I have found again a striking proof of the possibility of a certain organ reacting differently toward the growth of an inoculable tumor than the rest of the organism. Uhlenhuth has shown that when a tumor inoculated subcutaneously is removed surgically, and then a piece of the same tumor is introduced into the subcutaneous tissue of another region, then the second inoculation will fail if the operation was radical. But if the tumor at the site of the operation recurred, then the second inoculation was also successful in the majority of cases. These experiments were repeated by many investigators and with the exception of Apolant they all received nearly identical results. I repeated the experiments with the difference that the second inoculation was done not subcutaneously but into an organ. The results obtained coincided well with the results of Uhlenhuth. I then varied the experiments so that the second inoculation was not done in one organ, but in two organs—liver and spleen—simultaneously. The results obtained were quite unexpected. When the operation was radical and the subcutaneous tumor did not recur, then the secondary inoculation was not successful in any organ. On the other hand, when the operated subcutaneous tumor recurred then in a certain number of cases the secondary inoculation succeeded in both organs; in another series of experiments the secondary inoculation succeeded in one organ and failed in another.

All these experiments of Uhlenhuth, myself and others show conclusively that the phenomena of immunity in experimental cancer cannot be explained by specific food relationship. When a large recurrent tumor grows at the site of the operation it should have taken up all the specific food of the organism and the secondary inoculation should have failed.

There must exist a certain as yet unknown kind of an active inhibitory influence of the organism of the host on the cancer cells. Furthermore, we see here again the possibility of a purely local organ resistance in an otherwise susceptible animal. The subcutaneous tumor for instance recurs and a subsequent inoculation into the spleen is successful, but a simultaneous inoculation into the liver fails.

It is interesting to note here that the spleen is

the organ in which the inoculation most frequently succeeds, and the spleen also is the organ which is most frequently found diseased in tumor animals. Again as in the experiments with the testicles we find an experimental proof of the supposition supported by the clinic that a diseased organ is more easily susceptible to the growth of cancer.

To recapitulate, then: the condition of immunity in experimental cancer, while not identical is very similar to the immunity in bacterial diseases, and is due to an active inhibitory influence of the organisms of the host upon the proliferative power of the cancer cells. Furthermore, such an inhibitory action may be produced locally by a certain organ in a generally susceptible animal. Such a local inhibitory influence of an organ is destroyed when it becomes diseased.

The phenomenon of general inhibitory activity or general immunity of the organism against the growth of cancer is undoubtedly of paramount importance from the theoretical standpoint, but for the practical application of our knowledge of the pathogenesis of the disease the factor of the local organ immunity and of the possibility of destroying this immunity artificially is of at least as much importance.

In men who reach the cancer age only about 10 per cent. die of cancer; it is possible that the rest, or fully 90 per cent., are immune against the development of cancer. The general active immunity, the nature of which we do not know as yet, is consequently of such general occurrence that it seems plausible to suppose that when the local irritation in a certain organ is great enough, then cancer may develop even in an organism which is generally immune against tumor growth. It is of the greatest importance then to study the conditions of local organ susceptibility or immunity. Not only will it be possible to learn ultimately in this manner the true pathogenesis of the disease, but also to find the correct methods for the prevention and treatment of the disease. It is possible to suppose, for instance, that the action of *chemotherapeutic measures* or of the *radioactive substances* is due not only to their deleterious effects upon the cancer cells but also to the purely local increase of the inhibitory action of the normal organ tissue surrounding the growing tumor.

119 West Seventy-first Street.

RESULTS OF TREATMENT OF SYPHILIS WITH SALVARSAN AND NEO-SALVARSAN.*

By Major Sanford H. Wadhams,

and

Captain Eben C. Hill,

Medical Corps, United States Army.

Salvarsan and neosalvarsan are still considered by many as a specific for syphilis. One injection was formerly deemed sufficient to effect a cure. As a consequence, the dread of this disease has lessened among the laity. The self-termed "men specialists" advertise permanent and immediate cures and one advertisement even goes so far as to state that one dose not only cleanses the system of this dread disease but prevents all future danger of infection! As a consequence men having the disease hasten to avail themselves of the wonderful remedy even at a charge of fifty dollars. Many of them undoubtedly marry on the assurance of this one expensive injection, believing themselves permanently cured. The after results of such a union are unpleasant to consider.

Such unbounded faith in the remedy has been based on the excellent and almost miraculous results achieved in treating primary lesions, secondary eruptions, and tertiary ulcers during their active stages. Mucous membranes heal rapidly and sores seem to disappear overnight. We have had syphilitic ulcers of the tonsils, face, nose, and body respond rapidly to this remedy. Three cases of amebic dysentery were seemingly cured by the drug. Men have gained weight and been greatly benefited physically and mentally. It is a wonderful remedy and as yet its field of usefulness is only beginning to be realized.

But, judging from our results and the Wassermann reactions, it is not a cure for syphilis when given in one, two, three, or even six full doses of .9 gram intravenously. If such prove to be the case amongst other observers, then it is dangerous and criminal to allow the laity to continue in their belief that one treatment alone will cure a disease which affects not only the patient himself but his family. No man should be allowed to marry on the assumption that his one injection of salvarsan or neosalvarsan has produced a permanent cure. One injection will probably produce a decided change in the Wassermann reaction when taken immediately after treatment with the drug. The test may show a negative reaction. This may have occasioned faith in the immediate cure after one dose of the remedy. But take other tests in a month or so when the patient has had no alcohol for forty-eight hours and has received no mercury and iodides for two weeks or more. What is the result then?

We have selected twenty cases from our records of men who have been under constant observation. In the military service we can follow our cases. We can control the men and know that they take treatment at regular times. Thrice a day each soldier is required to report at the post hospital for either the "H. S." or protoiodide tablets. The medicine is taken in the presence of a dispensary sergeant and checked in a treatment book. The men are questioned as to headache or signs of salivation. Frequently the dosages have to be reduced and in many cases only protoiodide is tolerated. All are started, however, with the "H. S." until it is definitely proved that there is danger of salivation or gastric disturbance from this mixed treatment.

With the intravenous injections of neosalvarsan we have had no untoward results. There is ordinarily a slight diarrhea for a day or so. Now and then there have been headache and slight elevation of temperature. These, however, are not usually noted if freshly distilled water and salt solutions are made up on the day of injection. The old theory that it took at least a year to effect a cure with iodides and mercury led us to expect a shorter period of treatment with neosalvarsan combined with the vigorous old-time remedies. Such optimism seems unwarranted in view of the following cases:

Date of first Wassermann report shows time treatment was started. All treatment was stopped on April 1, 1913. All Wassermann reactions retaken on May 23, 1913, and reported from Army

*Published with the consent of the Surgeon General, U. S. Army.

REPORTS OF TWENTY CASES OF SYPHILIS TREATED WITH NEOSALVARSAN AND MERCURY AND IODIDE

Number of Case	Time of Infection	Wassermann Tests Made at Army Medical School, Washington, D. C.	Treatment With Neoalvarsan All given Intravenously. Dates and Amounts of Dosage	Other Treatment Given Three Times Each Day. Men Compelled to report at Hospital for Each Dose	Results: Apparent and Subjective
1	1910	Dec. 11, 1912++ May 28, 1913+	July 24, 1911; given a dose of Salvarsan-intramuscular—dose unknown. Dec. 16, 1912, .9 gm. Feb. 17, 1913, .9 gm.	H. S. 4 c.c.; 8 c.c. No. 1 in Dec. and Jan., 1912-1913. H. S. 4 c.c. 8 c.c., t.i.d.p.c. No. 3.	Has been seemingly well, no change in weight. States he was well before and feels no different. Slightly enlarged glands.
2	1909	Sept. 23, 1912— Oct. 31, 1912+ Jan. 27, 1913— May 28, 1913+	Dec. 3, 1912, .9 gm. Mar. 14, 1913, .45 gm.	Protoiodide pills; 2 t.i.d.p.c.	Gained 15 pounds. Feels better stronger, has good appetite no longer anemic.
3	1912 July	Oct. 31, 1912++ May 28, 1913++	Dec. 3, 1912, .9 gm. Feb. 7, 1913, .9 gm. Mar. 14, 1913, .45 gm.	Protoiodide pills; 2, later 3 t.i.d.p.c.	Cured of amebic dysentery, gained 20 pounds. Feels like a "new man."
4	1912 March	Nov. 20, 1912++ May 28, 1913++	Dec. 1, 1912, .9 gm. Jan. 10, 1913, .9 gm. Mar. 14, 1913, .45 gm.	Protoiodide pills; 2 t.i.d.p.c.	Gained weight; feels better.
5	1912 July	Feb. 5, 1913++ May 28, 1913++	Feb. 14, 1913, .9 gm. Mar. 13, 1913, .45 gm.	H.S., 4 c.c.; 8 c.c. No.1; then 4 c.c. No. 2.	Greatly improved.
6	?	Feb. 5, 1913++ May 28, 1913++	Feb. 14, 1913, .9 gm. Mar. 13, 1913, .9 gm.	H. S. 4 c.c. No. 1; later Protoiodide 2.	No longer constipated, gained weight; no longer "dopey."
7	1912 June	June 26, 1912++ May 28, 1913++	June 26, 1912, .45 gm. Salvarsan Oct. 10, 1912, .45 gm. Dec. 3, 1912, .9 gm. Dec. 16, 1912, .9 gm. Jan. 12, 1913, .9 gm.	Can't tolerate H. S. Protoiodide pills 2 t.i.d.p.c. Salivates easily.	Gained 24 pounds. Greatly improved.
8	Denies	Oct. 31, 1912+ May 28, 1913++	May, 1912, .9 gm. (?) at Fort Slocum. Mar. 13, 1913, .9 gm.	H.S.; 4 c.c.; 8 c.c. No.1, then 8c.c. No. 2.	Feels better, condition hereditary bowels regular after 606, previously constipated.
9	1911	Jan. 4, 1913+ Jan. 15, 1913+ May 28, 1913+	Feb. 7, 1913, .9 gm. Mar. 14, 1913, .45 gm.	H. S. 4; 8; c.c. No. 1; 4 c.c. No. 2.	No change, splendid condition and health before treatment.
10	?	Nov. 20, 1912+ Dec. 14, 1912+ Jan. 4, 1913+ May 28, 1913++	Mar. 1911, Salvarsan intramuscular; dose?	4 c.c., 8 c.c., H. S. No. L.	No change, seems well. Heavy drinker.
11	1910	Dec. 11, 1912+ Provocative test Jan. 4, 1913+ Jan. 8, 1913+— Jan. 27, 1913— May 28, 913+	Mar. 11, 1911, Salvarsan, intramuscular; dose? Jan. 2, 1913, .9 gm.	H. S. 4 c.c. No. 1.	No change in feelings. Seems well. No indications of syphilis.
12	1911	Dec. 11, 1912— Jan. 15, 1913++ Feb. 5, 1913+ May 28, 1913++	Mar. 11, 1911, Salvarsan, ntramuscular, .6 gm.	4 c.c. No. 1; 8 c.c. No. 2.	Some slight gain in weight. No marked glandular enlargement nor other symptoms.
13	1898 ?	Oct. 31, 1912++ Nov. 29, 1912++ May 28, 1913++	Jan. 2, 1913, .9 gm. Jan. 4, 1913, .9 gm. Feb. 7, 1913, .9 gm.	Since October 31 been taking 8 c.c. No. 2.	Lost a testis from the disease, was in bad shape till Oct. 31. Could not be induced to take 606 till disease broke out on face in Jan. 1913. Has gained 40 pounds, feels well.
14	1911	Dec. 12, 1912++ May 28, 1913++	Dec. 14, 1912, .9 gm. Jan. 31, 1913, .9 gm.	6 c.c. No.1. Can't tolerate mercury	Somewhat improved.
15	1910	Dec. 14, 1912++ May 28, 1913++	Dec. 16, 1912, .9 gm. Mar. 13, 1913, .45 gm.	H. S. 6 c.c. No. 1.	No change.
16	?	Oct. 31, 1912++ May 28, 1913+	Dec. 11, 1912, .9 gm. Jan. 10, 1913, .9 gm.	8 c.c. No. 1; 4 c.c.-8 c.c. No. 2.	Great improvement; gain in weight.
17	Jan. 1912	Jan. 4, 1912++ May 28, 1913++	Feb. 14, 1913, .9 gm.	4 c.c.-8 c c. No. 1. 4 c.c. No. 2.	No change; heavy drinker.
18	1901	Jan. 4, 1913++ Mar. 10, 1913++	Jan. 12, 1913, .9 gm. Jan. 31, 1913, .9 gm. Mar. 13, 1913, .9 gm.	4 c.c.-8 c.c. No.1. 8 c.c.-10 c.c. No. 2.	Gained 30 pounds. Remarkable improvement.
19	1898 ?	June 12, 1912++ Dec. 26, 1912++ May 28, 1913++	Jan. 2, 1913, .9 gm. Jan. 31, 1913, .45 gm. Mar. 13, 1913, .45 gm. June 14, 1913, .9 gm.	Can't tolerate mercury except by inunctions.	Inunctions every other day. Protoiodide 1 tablet t.i.d.p.c.
20	? Denies	Dec. 2, 1912+ Dec. 12, 1912+ Jan. 4, 1913+ May 28, 1913+	Jan. 31, 1913, .45 gm. Feb. 21, 1913, .9 gm. Mar. 13, 1193, .45 gm.	6 c.c. No. 1.	Gained 16 pounds. Had a suspicious iritis although denied infection.

Medical School, Washington, D. C., on May 28, 1913. No alcohol was allowed before this test. H. S. No. 1 contained bichloride of mercury .2 gram, potassium iodide 65. grams, and water q. s. ad 800 c.c. H. S. No. 2 contained bichloride of mercury .4 grams; potassium iodide 90. grams, and water q. s. ad 800 c.c. Injections of various salts of mercury were tried, but for routine treatment proved too painful even when injected with cocaine in the solution.

Conclusions.—(1) Salvarsan and neosalvarsan in full doses given intravenously do not appear to cure syphilis. (2) They are of very great value in the active stages of the disease and are especially useful in patients who cannot tolerate mercury. (3) No harmful results have been noted from frequent injections. (4) No patient should be allowed to assume that he is cured after one or more injections of this drug unless the Wassermann reactions taken at definite intervals for a year or more are continually negative and the patient has abstained from alcohol for 48 hours previous to the test.

MORTALITY EXPERIENCE—TOTAL ABSTAINERS.*

By R. I. LOUNSBERRY, M.D.,

BINGHAMTON, N. Y.

MEDICAL DIRECTOR, SECURITY MUTUAL LIFE INSURANCE CO.

We have been requested many times to publish the Security Mutuals' mortality experience in its Total Abstinence Class. In view of the fact that the Department was not organized until September, 1900, we have been reluctant to furnish it, believing that our experience was too short and the exposure too small to prove of positive value; however, disregarding our personal feelings in this matter, we are giving you herewith the data.

Permit me to recite briefly the rules governing admission to the Total Abstinence Department:—First the man must be a total abstainer at the time of making application and must have been one for at least five years preceding date of his application. His statement that he is and has been a total abstainer has been corroborated by the statement of the agent submitting the case and by the inspector. No man is placed in this class unless he makes a special request and signs an application for membership to this class. Many abstainers decline to go into the class in view of the promise that they will forever abstain from the use of alcoholics, so this class is composed almost exclusively of men and women who are total abstainers or who are opposed to the sale of alcoholic liquors for principle's sake. This has in a way given to this particular department more or less of a fraternal spirit; possibly this may be a factor as influencing mortality.

So far as I am aware, the company I represent was the first one to organize a Total Abstinence Department and put into that Department only such risks as made application for entrance to it and whose statement that they were total abstainers was in every instance verified by an inspection.

This department's organization was due entirely to a man who is now in charge of it and has been, continuously, since it started. The gentleman referred to is a total abstainer and a Prohibitionist; he has been prominent in his political party (Prohibition), also in his church. With him it has been purely a matter of principle. He has, however, not passed upon the eligibility for membership, because he preferred to place that part of the work in the hands of people who could and would make the selection without any personal interest in the class. Such data as we have is herewith furnished you in table form.

44	398	2	4.31				
45	381	2	4.25	Tot.	23,058	77	224.84

The total number of entrants is 7,231. The total years of life exposed 24,725. Average duration of membership 3.42 years.

The average amount of policies terminated by death is considerably greater than the average amount of the policies in the class. This is due to the fact that the Department experienced losses under several policies for our maximum limit.

The occupation of the male entrants may be divided as follows:

Clergymen	273
Farmers	1,315
Clerks	1,006
Miscellaneous	4,160
Total	6,754

*Read at the twenty-fourth annual meeting of the Association of Life Insurance Medical Directors, Philadelphia, October 29-30, 1913.

The miscellaneous occupations are divided up among a very large class covering wage-earners averaging probably $15.00 to $25.00 per week. The classification of occupations is given for the reason that there is a very general impression that the class is made up largely of clergymen.

The actual passing upon the question of eligibility to membership in this class has been in the hands of the Company's Actuary, Mr. D. S. Dickenson, and myself. The necessary calculations for the formation of the tables herewith presented were made in our Actuarial Department and verified by the Actuary.

BENIGN TUMORS OF THE FEMALE BREAST; REPORT OF A CASE.

By WILLIS E. HARTSHORN, M.D.,

NEW HAVEN, CONN.,

INSTRUCTOR IN SURGERY, YALE UNIVERSITY.

THE writer's attention was drawn very forcibly to the problem presented by the benign tumors of the female breast by the following case, which was referred to him recently for operation.

The patient was 33 years of age, well developed, married, had borne three children, and had enjoyed excellent health. There was no history of abscess of the breast. No loss in weight. No history of previous serious illness or trauma. Seven years ago she first noticed a slight serous discharge from the right nipple. This had continued at various times and in gradually increasing quantity up to the present.

Physical examination.—This showed the heart, lungs, and kidneys normal. The left breast was normal. The right breast was not enlarged. The nipple was not retracted. An area 3 to 4 cm. in diameter on palpation felt somewhat indurated. There were no nodules palpable in the breast. The patient had complained of no pain until the question of pain had been suggested by one examiner a few weeks earlier. Since then she stated that at times she has noticed slight discomfort. Axillary palpation revealed the presence of several enlarged glands. There was no cervical glandular involvement nor affection of the left axilla.

A radical operation was performed, both pectorals being removed and the axilla carefully dissected, leaving the lower subscapular nerve to the latissimus dorsi and the long thoracic to the serratus magnus intact. The skin wound was closed completely without grafting. The question naturally arose as to the advisability of this complete dissection, but with a history of seven years' discharge from the nipple, a rather indurated mass around the nipple, and a glandular enlargement in the axilla no other course seemed justifiable.

A macroscopical examination of the specimen removed immediately after the operation proved very interesting. On incising the nipple and the region immediately posterior to it there was a free discharge of a clear straw-colored serum to the amount of 3 c.c. Cutting the specimen still further showed a rather hard indurated mass. One cyst 2 cm. in diameter was found in this mass. This contained what was apparently calcareous material. The tumor mass as a whole did not give the impression of malignancy. The lacteal ducts showed surrounding induration. The axillary glands removed were indurated.

Pathological report.—Dr. C. J. Bartlet, Pathologist at the Yale Medical School, gave the following report after sectioning: "Microscopically in addition to the inflammatory process there was found a papillomatous outgrowth into the ducts. These are adenofibroma in nature, the fibrous stroma behind being rather cellular, and numerous glands being present. I do not consider it malignant but it is sufficiently cellular to make me suspect that it might have later become malignant. The enlarged lymph nodes showed endothelial cell hyperplasia."

A brief statement regarding the lymphatic supply of the female breast should be made, as it is an extremely important consideration. This supply is a very profuse one and extends in many different directions. The following excellent classification has been suggested by Dr. John M. T. Finney of Baltimore.

Skin.—The lymphatics of the skin are made up of two superimposed networks; from each arise efferent trunks leading to the axilla.

Fat.—It is very nearly impossible to inject the lymph-vessels in this tissue. It is assumed that they accompany the corresponding blood vessels to enter the axilla and thorax.

Breast.—Arising in the substance of the breast itself the lymphatics run toward its surface, here being fused into efferent channels. The axillary are the main channels the more superficial accompanying the cutaneous lymphatics the deeper lying on the pectoral fascia. Smaller branches leave the lower surface of the breast, follow the perforating branches of the internal mammary artery, and empty into the glands of the anterior mediastinum and still others follow the intercostals to the spine.

Muscle.—One set of lymphatics run parallel to the muscular fibers toward the sternum, and close to its margin they perforate the intercostal spaces to enter the mediastinum.

The glands extend the entire length of the large blood vessels in close relation to the vein posteriorly in the cellular tissue between the anterior surface of the scapula and the serratus magnus muscle. Chains of glands also accompany the internal mammary perforating branches and others lie between the pectoralis major and minor.

In discussing a case presenting symptoms suggestive of a benign tumor of the female breast an important diagnostic problem outlines itself. It is one on many occasions difficult to solve. A recurrence of the growth after operation would be inexcusable. A frozen section is always an important aid in diagnosis. Preservation of the pectoral muscles is worthy of most serious consideration. Removal of this group of muscles weakens to a certain extent the function of the extremity, not seriously, but in a way which deserves attention. In the case reported it was the patient's right arm. No other than a radical operation was justified in this case owing to the long standing of the lesion and the great probability of malignant degeneration.

In the differential diagnosis of benign tumors of the breast several different types must be considered.

1. Periductal Fibromata.—In these tumors there is an increase in the connective tissue surrounding the ducts. They are small in size, firm on palpation, the connective tissue hyperplasia predominating over the epithelial. They occur between the ages of 18 and 40 and are perhaps the most common type of benign tumor of the breast. They may be single or multiple, are not adherent to the skin, are usually painless, and have no axillary involvement. These are more frequent than any other tumor in the breast tissue of young women. They may remain with no increase in size for years or they may have periods of growth and then periods of quiescence. There is no discharge from the nipple.

2. Periductal Myxomata.—On palpation these are softer tumors and may contain areas of tissue which has broken down. These growths are larger in size. There is not the well-rounded or nodulous feeling on palpation present in the case of the fibromata. They are apt to be more rapid in growth. There is no axillary involvement. Little pain and no discharge from the nipple. If associated with inflammatory changes they may be adherent to the skin.

3. Cystadenomata, particularly if papillary, are apt to show a discharge from the nipple. Simple cysts frequently occur in the breast. These are often difficult to diagnose. In these cases it is not uncommon for the patient to complain of sharp shooting pains in the breast. On palpation a cyst may present similar characteristics to the periductal myxomata. Aspiration of a cyst will frequently aid in the diagnosis. This has been recommended by some surgeons in place of excision. It is, of course, a very simple procedure and some good results have been reported. It cannot be considered the best type of surgical treatment. Dermoid cysts of the breast are rare.

4. Inflammatory Types.—The various types of chronic inflammatory processes in the breasts usually present more or less characteristic symptoms of the lesion, causing the primary inflammation. On careful questioning of the patient either the previous history, or, on examination, the clinical nature of the growth aided by careful laboratory tests will lead to a definite diagnosis. Axillary involvement is here common.

It is difficult to differentiate clinically from the fibrocystic tumors those combining with simply a fibrous hyperplasia a marked increase in the epithelial cells relegating them to the class of adenomata or fibrocystic adenomata. In all these tumors the type depends on the proportion present of fibrous tissue or epithelial cells, and they constantly merge one into another. Pain seems to be, as a rule, much more frequently present in the cystic type than in the fibrous. Why this is true is difficult to state, but clinically it is a fact. Regarding the danger of the tumor a safe statement would be that the greater the proportion of the epithelial element the greater the possibility of a serious outcome.

Paget's disease of the nipple should be mentioned at this point, though it belongs to the carcinomata. It usually commences as an eczematous inflammation at the base of the nipple often rather late in life. There is first an itching or burning sensation around the nipple. This gradually involves the areolar at its base and the adjacent skin. Retraction of the nipple occurs early in the course of the disease. There is induration of the skin. The primary condition may exist for a considerable time but eventually a carcinoma of the breast develops. The origin of this type of carcinoma is probably the epithelial cells of the lacteal ducts. In Paget's disease there is frequently a seropurulent discharge from the nipple. The treatment should be radical.

Benign tumors of the breast are best treated by complete excision, using this term to include removal of the breast. It is not necessary always to do a radical operation. Like the statement so frequently heard about appendicitis, "many appendices have been removed too late but none too early," so we have yet to hear of a breast removed too soon in these cases. The axiom should be complete excision, removal of the muscles, and a dissection of the axilla in all doubtful cases. The surgeon of wide experience might be justified in taking a chance which would be entirely unjustifiable in one of less ability. It is far wiser to be too radical than to risk the blame sure to follow a recurrence. Each case must be weighed as a clinical entity to be decided by itself. No general rule can be safely laid. Occasionally a transverse incision along the lower border of the breast will be found advisable. In any and all cases it is a wise precaution to secure from the patient permission to make the operative procedure as extensive as is deemed necessary, otherwise a weakened arm and prolonged convalescence may cause considerable inconvenience to the surgeon as well as to the patient.

RETROPERITONEAL RUPTURE OF THE DUODENUM.

ONE of the not uncommon though usually overlooked results of a severe contusion of the abdomen is retroperitoneal rupture of the duodenum. It is curious to note in this season of football enthusiasm that two cases of the above condition reported by R. Lawford Knaggs in the *Proceedings of the Royal Society of Medicine*, July, 1913, occurred in players during football games. Both of the victims were struck by another player's knee in the region of the umbilicus. A fatal outcome ensued in each instance despite operative interference. Three important facts stood out clearly in the study of these cases: first, the difficulty of reaching an early decision that the abdomen ought to be opened; second, the absence of peritonitis; and, third, the widespread character of the retroperitoneal extravasation. The difficulty of making a diagnosis of retroperitoneal rupture of the duodenum resides in the fact that peritonitis does not set in until a late stage, when leakage from the retroperitoneal extravasation may occur. This extravasation is the most important feature of retroperitoneal rupture of the duodenum. In both of the author's cases it constituted an abundant dark bile-stained fluid that permeated the retroperitoneal connective tissue on the right side of the spine, accumulating in the vicinity of the right kidney, and extending upward to the diaphragm and downward to the pelvis. The extravasation is mixed with pus. The peritoneum covering it may be stained yellow, or there may be large olive-green or black areas where the subjacent fluid or gangrenous subperitoneal tissue shows through the serous membrane. There is apt to be a cushion-like swelling on the right side of the spine, lifting up the ascending colon and cecum.

The fact is emphasized that in an exploratory operation following a severe abdominal contusion the retroperitoneal extravasation may escape recognition, owing to the fact that at first it is so small in amount. The only physical sign given by this effusion during life is a right-sided dullness continuous above with the liver dullness, gradually increasing from day to day, and not shifting. This is regarded as a sign of great value, but when it is elicited the condition of the patient is already practically helpless owing to the septic absorption from the effusion.

There are now on record sixteen cases of this condition, the first having been reported by Alexander Thomson in 1854. None of the patients recovered. The injuries constituted blows upon the abdomen from the kick of a horse or the knee of a human being, catching of the body between the buffers of two railway carriages, run-over accidents, etc. The condition of the peritoneum following retroperitoneal rupture of the duodenum may be as follows: there may be present a quantity of dark bile-stained fluid; there may be no peritonitis at all; there may be a localized plastic peritonitis in the neighborhood of the duodenum; or there may be a generalized peritonitis. Blood may be found beneath the peritoneum or in the substance of the mesocolon, mesentery, omentum, or adjacent parts to which it may have tracked from the wound in the duodenum. Emphysema of the retroperitoneal tissues or of the abdominal wall, if met with during an operation following abdominal contusion, is an important sign, for it indicates a retroperitoneal rupture of the duodenum or large intestine. Emphysema of the abdominal wall is regarded as of particularly grave omen, for it is associated with a widespread extravasation of duodenal contents.

Realization of the late onset in the symptoms of retroperitoneal rupture of the duodenum emphasizes the need of early exploratory operation whenever there is reason to suspect that this condition is present. The question arises: What is the correct surgical procedure if this suspicion is confirmed? The rent should be sutured if this is possible. But the real problem is how to deal with the retroperitoneal extravasation. Drainage from the front across the peritoneum is of no avail, as is also drainage by means of a tube inserted through the loin from inside the abdomen. Knaggs believes that so far as possible the extravasation should be dealt with on similar lines to those adopted in extravasation of urine. The retroperitoneal space should be opened up by a wide incision, like Morris's incision for exploration of the kidney, and incisions at right angles to the main one would help to open up effectually the infiltrated area. The use of large drainage tubes and a light gauze packing may crown with success this heroic procedure in a condition which up to the present time has been uniformly fatal.

BESREDKA'S METHOD OF ANTITYPHOID VACCINATION.

THERE is absolutely no doubt of the great value of the prophylactic vaccination against typhoid fever. The statement has recently been made that during the first nine months in the present year there was not a single case of typhoid in the United States Army, an achievement hitherto unapproached and attributable solely to the use of vaccines. The method in use has been the familiar one of Wright, that is the subcutaneous injection of an emulsion of killed typhoid bacilli. A few years ago Besredka devised the employment of sensitized instead of killed organisms and for the past two years has used them entirely. Theoretically the more nearly the organisms in the vaccine approach

the normal live bacteria, with the exception of the latter's ability to grow in the body, the more apt will the vaccine be to call forth the production of protective antibodies. When a bacterial emulsion is killed by heat it is probable that the bacterial protein suffers a certain amount of change and, therefore, it is argued the antibodies developed by its use will not be exactly adapted to the destruction of live virulent typhoid bacilli. Besredka robbed his organisms of their virulence by sensitizing them and thus hoped to bring about the production of more powerful antibodies.

In three articles by Metchnikoff and Besredka, Besredka and Ardin-Delteil, and Negre and Raynaud (*Annales de l'Institut Pasteur,* 1913, xxvii, 597, 607, 644), the work for the past two years is briefly summarized. It is found that this method produces immunity rather rapidly but that the dose should be as large as is that of the dead bacilli. The authors definitely determined that while living bacilli remained in the vicinity of the injection for about five days, the blood, urine, and feces at no time showed typhoid bacilli and that the individuals so treated were not in danger of becoming bacillus carriers. The percentage of marked reactions was apparently not greater than with the older form of vaccination. Further, this preparation has been used to a limited extent in the treatment of cases of the disease and the results have been apparently satisfactory. It has thus been shown that the sensitized bacilli may be administered without injury to the recipient and with results as beneficial as those obtained by the use of the killed vaccines. No distinct advantage has been shown for the proposed method, however, and, indeed, it would seem to be very difficult to improve upon the results which have been obtained in the Army by the present technique. The preparation of the sensitized vaccine is more difficult than that of the killed emulsion so that it is improbable that it will attain very general use.

SEX HYGIENE.

Probably nothing better illustrates the old adage that a little knowledge is dangerous than the present campaign for the teaching of the so-called sex hygiene in the public schools. The public has just been made to realize by the medical profession the direct as well as the indirect effects of sexual diseases, and the necessity for preventing them. But in its enthusiasm the public has failed to see the proper methods of application and the difficulties of application, as well as the profundity of the whole subject. The enthusiasts seem to think that the ones to be taught are the young, probably on the principle that if they are forewarned of the dangers long before they arise, they will be able to anticipate them. Were the latter a fact the campaign would be well advised. There is little doubt that, while sexual diseases are present in the young, the amount due to ignorance is very little and is negligible. The majority is due to non-sexual infections from adults. Sexual diseases usually have inception in adults and it is the adult who must be educated if he does not already know. It is he who has sufficient understanding to appreciate the real and not the analogous or illustrative value of sex teachings. It is he who must face the world where sex diseases must be counted as one of the adversities. And whether moral teaching of the adult will result in continence is still an ultra-medical question. Suffice it to note that merely a proper understanding of the dangers of incontinence alone does not always act as a check, as shown by the fact that infection among medical students is probably as large as among any other student class.

The sex maturity of children of the same mental and physical age varies so much that a general teaching of this subject cannot apply with equal force to all. The likelihood, then, that some will learn it in a hazy and vague manner is especially dangerous, for in discussing this among themselves the subject will become distorted, with an obvious tendency to work harm. Will not the children who have vicious sex habits have the best opportunity to impress them upon the others? It is a question how much children can learn by sex teaching with plants as objectives, and how far this will go to explain the human organism; or how far the explanation will prevent harm. It is quite possible that the natural propensity of children for experiment will open fields of abuse which ignorance at least would not.

Sex hygiene should be taught—but to the parents. It is too intricate a question for the young, when so many parents are ignorant regarding this subject. Parents should be taught sex hygiene, and they should be taught to impart that knowledge gradually and at the proper time according to the maturity of their own children. The child should get just as much of this knowledge as it is able to appreciate from its physical, sexual and environmental development. There will then be no danger of experiment and abuse from discussion of the subject between the children.

ECZEMA AND SUDDEN DEATH.

Although of rare occurrence the fatal outcome of a case of chronic eczema in a child has been observed a sufficient number of times to merit close attention and study. An important contribution in this subject is made by P. S. Hichens (*Proceedings of the Royal Society of Medicine,* July, 1913), who notes that of twenty-eight cases of eczema treated in the children's ward of the Northampton General Hospital for the past twelve years, no fewer than six ended fatally. The history of two of these cases was particularly interesting. One was a six-months' old child that was apparently recovering from an eczema of the face and head, when she suddenly became extremely pale, collapsed, and died in the course of a few hours. The other case was that of an infant of the same age in whom recovery from a similar eczema was much more gradual, but in whom the same symptoms of shock supervened though more slowly, and death was ushered in by symptoms of cerebral irritation.

No satisfactory explanation is forthcoming as

to the cause of the fatal outcome in these cases and in cases reported by others. There is an old popular saying about the danger of driving in an eruption. Gaucher used to warn his students against treating cases of eczema in children too energetically, owing to the possibility of sudden death. Hichens suggests that in these cases the cutaneous eruption is the evidence of a toxemia finding a vent on the surface of the body and that the healing of the skin forces an excess of the poison upon the vital centers. He also suggests that the fatal outcome may be due to a physical alteration in the balance of the fluids of the body with an excessive accumulation of fluids in the brain and pressure on the floor of the fourth ventricle.

In the discussion that followed the reading of the author's paper, G. Pernet referred to cases in which an irritable dermatitis alternated with attacks of asthma. The latter occurred whenever the cutaneous condition improved. Leonard Guthrie said that up to the end of the eighteenth century, people who had "issues" were careful not to heal these too soon lest death should result. In view of the clinical importance which is nowadays attached to anaphylaxis, the temptation is strong to attribute the death occurring in the course of a rapidly healing eczema to the latter phenomenon.

Symmetrical Gangrene and the Balkan Wars.

The recent wars in southeastern Europe provided a large number of data of considerable value in military surgery. These data have been reported in several interesting papers read at the German and French surgical congresses during the past summer. During the last four months of 1912 German surgeons, including Wieting, Lauenstein, and others, working with the Turkish army, observed an epidemic of gangrene affecting the extremities, and attributed it to the action of cold upon the blood vessels, although the weather was not particularly severe. During the same period of time A. Welcker, surgeon to the Dutch ambulance attached to the vanguard of the Bulgarian army before Tschorlu, observed 160 cases of a similar gangrene among the troops. In the *Zentralblatt für Chirurgie,* October 18, 1913, he reports his study of these cases. He notes that almost without exception in 115 of these cases there had been from seven to fourteen days preceding the onset of gangrene, recovery from an attack of cholera, diarrhea, or dysentery. In 45 cases the gangrene occurred in the second or third week of typhoid fever or during the convalescence from this disease. The conclusion is drawn that the above diseases were the cause of the symmetrical gangrene, and that the affection on both sides of the Chatalje lines was of identical nature. An important factor in the production of the gangrene was malnutrition resulting from the monotonous diet. Bread, vegetables, and rice constituted the chief meal for months. Another factor was the damp and depressing weather and the privations to which the troops were exposed. With few exceptions, however, a further factor was necessary, namely, the occurrence of cholera, diarrhea, or typhoid fever. The disease was recognized as distinct from that caused by frost, and as the same as that described by various clinicians as a rare vascular complication of typhoid fever, cholera, etc.

The Results of the Pasteur Treatment of Rabies.

It is a pleasure again to note the record of the Pasteur Institute of Paris attained in their antirabic inoculations. Dr. Viala's report for 1912 (*Annales de l'Institut Pasteur,* 1913, xxvii, 794) shows that 395 persons received the treatment during the year and that none of these died. Of these, 71 were bitten by animals which were proven to have rabies by inoculation tests, 145 by animals which were declared rabid by veterinarians and the remaining 179 by animals suspected of having the disease. One person who received the treatment in 1911 died from rabies in 1912 so that the mortality for 1911 was raised to one. During the past five years the Institute has administered the Pasteur treatment to 2128 persons with a mortality of three (0.14 per cent.). These figures scarcely demand comment. It is sufficient to say that they furnish additional confirmation, were it needed, of the high value of this method of treatment.

News of the Week.

City Death Rate.—For the week ending November 15, the number of deaths in New York City was 1,250, giving a death rate per thousand of 12.14, as compared with a total of 1,216 deaths in the corresponding week of 1912, when the rate was 12.26. The decrease in the rate shows that the increase in the total number of deaths was proportionately less than the increase in the population. For the first forty-six weeks of the year the death rate was 13.81 per thousand, as against 14.12 for the same period of 1912, a decrease of 0.31 of a point.

High Cancer Death Rate.—The Equitable Life Assurance Society of New York has recently issued a review of its statistics, showing that during the past ten years the indicated death rate from cancer has increased thirty per cent. among males, and twenty-two per cent. among females in the United States registration area. The increase has occurred in every age group, but is, of course, largely due to more exact diagnosis.

Brain Weight.—In accordance with the wish of Prince Katsura, the Japanese statesman who died recently from cancer, his body was dissected by Dr. Nagayo, and the brain removed. The weight of the brain was found to be 1,600 grams, or nearly 300 grams more than the average.

Harvey Lecture.—Prof. G. H. Parker of Harvard University will deliver a lecture before the Harvey Society at the New York Academy of Medicine on Saturday evening, November 29, at half-past eight. Professor Parker will speak on "The Nervous System; Its Origin and Evolution."

Surgical Clinics.—Dr. Parker Syms will hold a series of surgical clinics at the Lebanon Hospital, New York, on Wednesday afternoons at three o'clock, from November 1 to March 1, to which all physicians are cordially invited. The hospital is most conveniently reached by the Subway (West Farms Division) to the Jackson Avenue station. Details of the clinics will be announced on the bulletin board of the Academy of Medicine.

Railway Accidents in Pennsylvania.—According to statistics published by the Accidents Department of the Pennsylvania Public Service Commission, 312 persons were killed on the steam railways in the State during the months of July, August, and September. Of this number 105 were employees,

6 were passengers, and 167 trespassers; 26 persons were killed at grade crossings. During the same three months 3,060 persons were injured on the steam railways, and 53 persons were killed and 949 injured on the street railways.

Anniversary of the New York Laryngological Society.—The Laryngological Section of the New York Academy of Medicine celebrated on Tuesday evening of this week the fortieth anniversary of the foundation of the New York Laryngological Society, the first society of throat specialists in the world which is now a section of the Academy. Dr. W. W. Carter presided. Dr. Clinton Wagner delivered an address on the history of the organization, and Dr. D. Bryson Delavan presented a bronze tablet commemorating the founders of the Society, and also an historical collection of laryngological instruments and books.

Sterilization Unconstitutional.—The statute recently enacted in New Jersey, authorizing the sterilization of the feeble-minded, epileptics, criminals, and other defectives, has been declared unconstitutional by the Supreme Court of the State. The act is held to be contrary to the Fourteenth Amendment to the Constitution of the United States guaranteeing equal protection of the laws to all, and to exceed the police powers of the State. The Court points out the danger of permitting Legislatures to prescribe those upon whom the operation should be performed, since, if sanctioned, the penalty might be extended to include those regarded as undesirable by a majority of a prevailing Legislature.

Centenarians Dead.—Joseph Jackson, a negro inmate of the State Hospital at Binghamton, N. Y., died recently at the reputed age of 113 years.

Mrs. Charlotte Campbell of Vineland, N. J., said to be the oldest woman in Southern New Jersey, died on November 16 at the age of 104 years. She was the mother of ten children, and had never been outside of New Jersey, her native State.

Lepers in London.—Sir Malcolm Morris of London, presiding at a lecture on leprosy on November 19, in that city, surprised his hearers by the assertion that London contains many lepers, and that efforts are now being made to provide a small institution for their care. England has no law preventing the entrance of lepers to the country.

Health Officials Quarantined—The seven laboratory employees of the State Board of Health of Mississippi, at Jackson, were found on November 20 to be suffering with diphtheria, and all have been quarantined. It is believed that the infection resulted from cultures sent to the laboratory for examination.

Providence Hospital.—The new Providence Hospital for Surgery, Providence, R. I., was formally opened at noon on November 17. The institution, which will be devoted entirely to the care of surgical cases, has accommodations for twenty patients. The operating room is said to be the finest in the State, and the other appointments of the Hospital are in keeping with it.

Oklahoma Statistics.—The report of the Oklahoma State Board of Health shows that during the year ending October 1, 1913, there occurred in the State 9,272 deaths and 30,134 births. Of the total number of deaths 3,209 were of children under six years of age, and 525 of children between six and ten; 651 occurred between the ages of ten and twenty; 887 between twenty and thirty; 762 between thirty and forty; 693 between forty and fifty; and 2,181 between fifty and seventy years. Six hundred and two deaths were due to external causes, such as homicide, suicide, accident, etc., while the preventable diseases were responsible for the following deaths: Tuberculosis, 732; typhoid fever, 399; malaria, 173; diphtheria, 131; cerebro-spinal meningitis, 127; whooping-cough, 109; measles, 91; septicemia, 87; smallpox, 84; pellagra, 72; dysentery, 53; syphilis, 40; erysipelas, 27; scarlet fever, 18; hydrophobia, 2; glanders, 2; total, 2,128.

Montefiore Home.—On November 22, the new buildings of the Montefiore Home for Chronic Invalids, at 210th Street and Gun Hill Road, New York, were opened to its patients, and the transfer of the 300 invalids from the old building to the new was successfully accomplished. All of the hospitals in the city loaned their available ambulances to facilitate the removal of the patients, and private ambulances also were pressed into service. A formal reception will be held in the new home on Sunday afternoon, November 30.

Fire in Hospital.—A fire in the store-room of the Philanthropic Hospital, New York, on November 19, caused some alarm among the patients, but was successfully controlled with only about $500 damage. The hospital staff showed the results of good training and made preparations for removing the patients without confusion if it became necessary. Fortunately the fire was confined to a small area.

The Legal Status of the American Medical Association.—The Trustees of the A. M. A. announce in the *Journal* of November 22, that the decision of the Appellate Court of Illinois, recently referred to in this column, did not affect the Association directly but only ordered the State's attorney to bring quo warranto proceedings against the Trustees. The State's attorney has appealed against this decision, but if it is sustained by the Supreme Court he will be forced to bring an action for illegality against the Association as represented by the Trustees.

Personals.—Fräulein Rachel Hirsch of Berlin has recently received signal and unusual honors in being given the title of professor. She is the first woman in Berlin to be so honored. Prof. Dr. Hirsch has for several years been the chief assistant to Prof. Kraus and in this capacity has conducted clinics for both men and women in some of the Berlin hospitals.

Dr. Maria Montessori, whose new method of teaching has attracted great attention, has left Italy for a visit to this country. While here she will give a course of lectures on the Montessori method and will also study our system of education.

Professor Ettore Marchiafava, physician to Pope Pius X, has been created an Italian Senator.

Gift to Medical Library.—The Boston Medical Library is the residuary legatee of the estate of the Miss E. B. Wyman of Newburyport, Mass., who died in Italy last February. The bequest will, it is estimated, amount to about $86,000, and is to be known as the Samuel Wheeler Wyman Memorial Fund in honor of the testator's father, a graduate of the Harvard Medical School in 1818.

The Elliot Operation for Glaucoma.—Col. R. H. Elliot, formerly of Madras, India, and at present of London, will be in New York, December 5 to 11. He will operate according to his method for

glaucoma at the New York Eye and Ear Infirmary on Friday afternoon, December 5; at the Herman Knapp Memorial Hospital on Monday afternoon, December 8; at the Manhattan Eye and Ear Infirmary, Tuesday afternoon, December 9, and at the Post-Graduate Hospital on Wednesday afternoon, December 10. Colonel Elliot's address, while in New York, will be 46 West Fifty-third Street.

Dr. Porter Endorsed.—At the thirteenth annual conference of health officers of the State of New York, held in Utica on November 20, resolutions were passed endorsing the work of Dr. Eugene H. Porter, the present State Commissioner of Health.

Yale Medical School.—The New Haven Hospital and the Medical School of Yale University recently entered into an agreement by which the school obtains the privileges of the hospital for the instruction of its students provided that before July 1, 1914, it is able to secure the sum of $600,000, to be used for the erection and equipment of a clinical and pathological laboratory for the hospital, and for the endowment of the same. The University is now making efforts to obtain this sum, in order to consummate the arrangement, which is of the utmost importance in the proper development of the school.

Army Medical Corps Examination.—The Surgeon-General of the Army announces that preliminary examinations for appointment of first lieutenants in the Army Medical Corps will be held on January 19, 1914, at points to be hereafter designated. Full information concerning these examinations can be procured upon application to the "Surgeon-General, U. S. Army, Washington, D. C." The essential requirements are that the applicant shall be a citizen of the United States, between twenty and thirty years of age, a graduate of a recognized medical school, of good moral character and habits, and have had at least one year's hospital training after graduation. In order that all necessary arrangements for the examinations shall be perfected, applications must be sent in at least three weeks before the date of the examination, and early attention is therefore enjoined upon all intending applicants. There are at present twenty-six vacancies in the Medical Corps of the Army.

The American Society for the Study of Alcohol and Other Narcotics will hold its forty-third annual meeting at the Rittenhouse Hotel, Philadelphia, on December 3 and 4, 1913. Two sessions will be devoted to the practical work of hospitals and sanatoria for inebriates. Further particulars may be obtained from the secretary, Dr. T. D. Crothers, Hartford, Conn.

American Sanatorium Association.—The ninth midwinter meeting of this society will be held at Otisville, N. Y., on December 6 and 7, 1913, when the members will be the guests of the Department of Health of the City of New York at its Tuberculosis Sanatorium. Dr. Hermann M. Biggs will speak, by invitation, on "Some Desirable Features of a Large Municipal Sanatorium"; Dr. Charles W. Mills will present a paper on "Gastrointestinal Complications of Tuberculosis," and Dr. S. A. Knopf one on "Occupations for Afebrile Tuberculous Patients." Opportunity will be afforded for an inspection of the sanatorium building and the antitoxin laboratories.

Medical Society Elections.—Suffolk County (N. Y.) Medical Society.—At the annual meeting held on October 30, at Riverhead, the following officers were elected. *President*, Dr. S. R. Corwith, Bridgehampton; *Vice-President*, Dr. B. F. Many, Port Jefferson; *Secretary*, Dr. F. Overton, Patchogue: *Treasurer*, Dr. B. D. Skinner, Greenport.

Washington Society of Nervous and Mental Diseases.—At the annual session held recently the society reelected its officers, as follows, for the ensuing year: *President*, Dr. Tom A. Williams; *Vice-President*, Dr. W. M. Barton; *Secretary*, Dr. W. M. Hough.

Montgomery County (Ala.) Medical Society.—The annual meeting was held at Montgomery on November 8, officers for the ensuing year being elected as follows: *President*, Dr. Fred W. Wilkerson; *Vice-President*, Dr. J. Brannon Hubbard; *Secretary*, Dr. P. S. Mertins; *Treasurer*, Dr. C. G. Laslie.

Southern Illinois Medical Association.—At the annual meeting held in Duquoin, on November 6 and 7, officers were elected as follows: *President*, Dr. Charles W. Lillie, East St. Louis; *Secretary*, Dr. Alonzo B. Capel, Shawneetown; *Treasurer*, Dr. James W. Armstrong, Centralia.

Chickasaw County (Ia.) Medical Society.—The following officers were elected at the annual meeting on November 3: *President*, Dr. A. D. McKinley, Lawler; *Vice-President*, Dr. S. B. Zoller, Fredericksburg; *Secretary-treasurer*, Dr. Paul E. Gardner, New Hampton.

Scott County (Ia.) Medical Society.—The annual meeting was held at Davenport on November 4, officers being elected as follows: *President*, Dr. Peter A. Bendirsen; *Vice-President*, Dr. A. P. Donohoe; *Secretary*, Dr. J. V. Littig; *Treasurer*, Dr. T. W. Kemmerer, all of Davenport.

American Association of Clinical Research.—At the fifth annual meeting of this society, held in Chicago on November 8, the following officers were elected: *President*, Dr. Leonard K. Hirshberg, Baltimore; *Registrar*, Dr. Jefferson D. Gibson, Denver; *Secretary-Treasurer*, Dr. James Krauss, Boston.

Southern Homeopathic Medical Association.—The annual convention was held at Atlanta on November 13 and 14. The following officers were elected: *President*, Dr. Harry E. Koons, Danville, Va.; *Vice-Presidents*, Dr. S. D. Sloan, Atlanta, Ga., and Dr. Lee Norman, Louisville, Ky.; *Treasurer*, Dr. H. R. Stout, Jacksonville, Fla.

Obituary Notes.—Dr. Warren Oscar Plimpton of New York, a graduate of the College of Physicians and Surgeons, New York, in 1888, formerly professor of surgery in the New York Post-Graduate Medical School, attending surgeon to the Post-Graduate Hospital and the Daisy Field Hospital of Englewood, N. J., and consulting surgeon to the Tarrytown Hospital and the Mary Immaculate Hospital of Jamaica, and a member of the New York State and County Medical Societies and of the American Medical Association, died at his home in Westport, Conn., after a long illness, on November 19, aged 55 years.

Dr. James H. McClelland of Pittsburgh, Pa., a graduate of the Hahnemann Medical College and Hospital of Philadelphia in 1867, professor of surgery in the Hahnemann Medical College in 1876-77, president of the American Institute of Homeopathy in 1893-94, honorary president of the International Homeopathic Congress in Paris in 1900, and a former president of the Homeopathic Medical Society of Pennsylvania, died after a short illness at his home on November 14.

Dr. Edward Francis Denner of Paterson, N. J., a graduate of the College of Physicians and

Surgeons, New York, in 1894, a member of the Medical Society of New Jersey, the Passaic County Medical Society, and the Association of Physicians of New Jersey, and chief surgeon at St. Joseph's Hospital, Paterson, died in the hospital from typhoid fever, after a brief illness, on November 14, aged 41 years.

Dr. Philip X. Ryan of New York, a graduate of the College of Physicians and Surgeons, New York, in 1901, died at his home on November 17, aged 36 years.

Dr. Douglas Ayres of Fort Plain, N. Y., a graduate of the Albany Medical College, New York, in 1865, a member of the Medical Association and of the New York State and Montgomery County Medical Societies, having been first vice-president of the State society and at one time president of the county association, of which he was the oldest member at the time of his death, and for twenty-five years president of the Board of Education of Fort Plain, died at his home from heart disease, on November 20, aged 71 years.

Dr. Marion H. Jackson of Neely, Ark., died at his home suddenly, on November 7, aged 36 years.

Dr. William A. B. Treadway of Stamford, Conn., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1883, and a member of the American Medical Association and the Connecticut State and Fairfield County Medical Societies, died at the Stamford Hospital, from pneumonia, on November 17, aged 54 years.

Dr. Augustine C. Haub of Boston, Mass., a graduate of the Boston University School of Medicine in 1893, died on November 14, aged 33 years.

Dr. George Bassett Sawtelle of Malden, Mass., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1866, a member of the Massachusetts Homeopathic Medical Society, and formerly on the staff of the Malden Hospital, died suddenly at his home on November 14, aged 75 years.

Dr. Edgar Clarence Collins of Springfield, Mass., a graduate of the Albany Medical College, New York, in 1880, and a member of the Massachusetts Medical Society, the Hampden District Medical Society, and the Springfield Academy of Medicine, died suddenly at the Collins Emergency Hospital, Springfield, on November 14, aged 55 years.

Dr. Charles Sumner Collins of Nashua, N. H., a graduate of the Boston University School of Medicine in 1875, and for several years a member of the New Hampshire State Legislature, died at his home after a long illness on November 16, aged 60 years.

Dr. William Pennington Mullin of Chestnut Hill, Philadelphia, formerly a resident of Vineland, N. J., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1881, died at St. Luke's Hospital, Philadelphia, on November 14, aged 53 years.

Dr. John S. Walker of Philadelphia, a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1871, but never actively engaged in the practice of his profession, died at his home on November 15, aged 66 years.

Dr. Thomas Benjamin Amiss of Luray, Va., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1861, a member of the Medical Society of Virginia and of the District Medical Society, and a surgeon in the Confederate Army throughout the Civil War, died at his home on November 9, aged 75 years.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HYSTERIA IN SOME OF ITS ASPECTS—GRESHAM LECTURES—ASTROLOGY IN MEDICINE—OPEN-AIR SCHOOLS AND PREVENTIVE MEDICINE—OBITUARY.

London, Nov. 7, 1913.

The Bradshaw lecture at the College of Physicians was delivered on Tuesday by Dr. T. R. Glynn, professor of medicine of the University of Liverpool and consulting physician to the Infirmary. He selected for his subject "Hysteria in Some of Its Aspects," which he admitted at the outset was a little out of fashion, since hysteria is well-nigh incapable of definition, and is without pathology or pathognomonic symptoms. Modern research and speculation, far from showing light on it, he thought, rather rendered its problems more obscure and served to create doubt. Charcot's views have been subjected to vigorous criticism for these twenty years. Janet's theory of a restricted field of consciousness appealed to most. But the theory of Breuer and Freud, though very ingenious so far as a mental trauma went, was repellant as regards their contention concerning its being always related to a sexual disorder. He rather agreed with the view that the malady was concerned with the vasomotor system, and of a certainty was not entirely psychical. Paget pointed out the so-called bad circulation of some patients, and Dr. Savill amplified his observations, concluding that all the symptoms suggested the neurovascular system. Dr. Glynn supported these views and illustrated them by reference to numerous cases in which the stigmata of hysteria were associated with other disorders, particularly epilepsy, chorea, chlorosis, and gastric and cardiac diseases. So he continued recognized antecedents of hysteria were rheumatism, typhoid, influenza, tuberculosis, and other specific disorders, as to which he added that at times hysteria may develop during the course of any of these and complicate them. In concluding he said his chief object in selecting the subject of his lecture would be attained if he succeeded in rousing more interest in the study of hysteria, as is met with in association with other diseases.

Dr. F. M. Sandwith is this year the Gresham Professor of Physic, and has just given the course of lectures required by that office, in which he has discoursed discursively about Harvey, Darwin and Huxley.

As to the first he observed that at a time when ancient beliefs were blindly accepted Harvey made perhaps the greatest discovery ever made in physiology, approaching the problem from an astonishingly modern standpoint. He sought the truth by experiments extending over long years, accepting no fact till he had indisputable evidence. By a happy chance the manuscript notes of his Lumleian lectures on anatomy in 1616, in which he declared his discovery to the College of Physicians, were preserved in the British Museum. They were about one hundred pages written in a cramped hand on both sides. Harvey seemed as familiar with Latin as English, and expressed himself as easily in one as the other, and the two were mixed in a way quite quaint to modern readers. For twelve years he continued to lecture, but we have no evidence that he had much effect on medical teaching at that time. It was astonishing, in the light of mod-

ern investigation, to observe how accurate were Harvey's deductions, for the microscope then did not make it possible to follow the blood from the arteries into the capillaries and thence into the veins—this final proof being left for Malpighi, discoverer of the capillary system. At first Harvey's views were disapproved, especially abroad, and at home he declared his practice fell mightily. Aubrey wrote that the vulgar thought he was "crack brained," and all the physicians were against him. But in time the more enlightened adopted his doctrine and Harvey was one of the happy few who lived long enough to find the opinions for which he had fought almost universally accepted.

In considering Darwin the Gresham professor held that both desired to get at the truth, both were slow to publish their conclusions, and both lived to see their discoveries adopted. Darwin's dislike of seeing operations made him abandon the idea of studying medicine. He wasted some time at Cambridge, but got appointed naturalist to the *Beagle*, though his father thought it a useless undertaking. On his return he determined to devote himself to science. It was by slow and careful study that in a few years he reached his convictions on natural selection, but his minute labor would have gone for nothing without his unparalleled power of theorizing. The coincidence of Russell Wallace's discoveries led Darwin to publish earlier than he would have done and his book was received with furious but undeserved attacks. Even Lyell was slow to accept the ideas put forward in the "Origin of Species," but Hooker was an early convert, and Huxley wrote that he was "sharpening his teeth and claws" for the fight. When little more than a decade afterwards "The Descent of Man" was published the criticisms were not nearly so violent. In fact, Darwin's theories were then widely prevailing. In 1882 he died and was buried in Westminster Abbey.

Huxley, the Gresham professor described as a fine, incisive and convincing speaker, who early proclaimed himself an enemy of the ecclesiastical spirit which resisted science. He was greatly influenced by Carlyle. By the voyage on H. M. S. *Rattlesnake*, lasting four years, he learned discipline—"the facts of life," as he said. His first paper sent to the Royal Society was accepted, but he did not know it till long after it was published. When elected he had no money to publish books. "Science," said Huxley, "does everything but pay; one can earn praise but not pudding." He obtained a lectureship at the School of Mines. He took interest in the zoological position of man, disagreeing with Owen, but his views were supported by Darwin's doctrines. For them he fought the more as they were opposed by church authorities. He fell foul of Owen, who had said the structural differences between man and the ape were less marked than those between the gorilla and the lower types of ape. The fight between Huxley and Wilberforce was described by the lecturer as leaving the bishop without a word to reply. Huxley's power of work was remarkable; he served on ten Royal Commissions, and joined the London School Board where he was regarded at first as a materialist. But that prejudice passed. The professor declared he was not a materialist, though his religion was "undogmatical." To the day of his death he took the keenest interest in all branches of science, including medical science.

Dr. C. A. Mercier yesterday at the Royal College of Physicians delivered his first Fitz-Patrick lecture—his subject "Astrology in Medicine." The position of astrology among the sciences he thought quite unique, forming a part of the life of every nation which had passed beyond barbarism. It had been studied in unbroken effort for thousands of years, and occupied some of the greatest intellects all along the ages. The universal system of medicine set forth by Bacon was founded on astrology. Even now people talk of being born under a lucky star and speak of persons being jovial, saturnine, or mercurial. We retain the names, Saturday, Sunday, and Monday. Nevertheless, the lecturer pronounced astrology to be now utterly extinct, having begun to decay during the Renaissance, and languishing on in the seventeenth century. Its death blow he thought was given by Swift's biting humor. Its study having begun in Chaldea in 1800 B. C., it had a history of nearly 4,000 years. Its chief factors were the four elements, but in medical astrology there were many others relating to the humors of the body. Speaking of astrological terms the lecturer said they were so obscure and expressed in Latin so canine and abbreviated as to be well-nigh unintelligible. In preparing his lectures he had had the advantage of the assistance of a Latin scholar, a professor of astronomy, and a professor of ancient history, and all had been unable to solve some of the problems. This promises well for the interest of the remaining lectures.

Sir Alfred Pearce Gould presided at a lecture on the "Place of the Open-Air School in Preventive Medicine," delivered on Tuesday at the University of London by Sir George Newman, chief medical officer of the Board of Education. The lecturer said that to stem the tide of physical and mental defect in the childhood of the nation they must proceed along the lines of the open-air school. Some had regarded the movement as a fad rather than a system of organized treatment. To understand it they must adopt a larger conception and study infont mortality. The deaths under school age, *i.e.* under five, were many; during school age (five to fifteen) few, and were due to three or four groups of disease. Tubercle, heart disease, and pneumonia were the chief causes from five to fifteen, and the same prevailed up to thirty-five. The seeds were sown in childhood, and to lower the rate they must deal with their conditions from birth to fifteen. A great proportion were then remediable and should be grappled with during school age, and the open-air school was a process of preventive medicine, a process, too, of curative medicine, a process of liberal education, and a school of hygiene for both body and mind.

Mr. Edward Nettleship, consulting surgeon to the Royal London Ophthalmic Hospital, and consulting ophthalmic surgeon to St. Thomas' Hospital, died on October 30 at his country home. He had retired from active work for some years, and his health had failed latterly. He was at one time on the staff of the Children's Hospital. In 1875 he was appointed to report to the Government on ophthalmia in the public schools. His "Students' Guide to Diseases of the Eye" will be known to you, as there were several editions issued. He took the F.R.C.S. in 1870, after two years' membership, having previously (1867) been a member of the Veterinary College. He was elected F.R.S. last year.

Mr. A. Godson, formerly on the staff of the Royal Infirmary and the Royal School of Medicine

at Manchester, has died at Cheadle, where he has been Medical Officer of Health, at the age of seventy-seven. He took his M.B. in 1864. He has also served as president of the Stockport Medical Society and vice-president of the Medical Society of Manchester.

PITUITARY EXTRACT IN LABOR.

To the Editor of the Medical Record:

Sir:—Reports from many practitioners extol pituitary extract in labor for insufficient pains. Some claim to have avoided the low forceps operation in almost all cases where it seemed inevitable. We all know that the objection to ergot antepartum is that it induces tonic spasm of the uterus, endangering its integrity, delaying labor, and risking harm to the child by long-continued interference with its circulation. I deem it, therefore, important to report a case of tonic contraction induced by pituitary extract.

I. O., 26, primipara, went into labor Nov. 9, 1913, in the morning, with moderate pains. She had not slept well the two preceding nights. By 2 A.M., Nov. 10, dilatation was complete with the head still in the cervix. Shortly afterward the pains died out, and the patient went into a broken sleep, the best in two nights. 6 A.M., conditions were unchanged. Position L. O. A., membranes ruptured the previous day. No caput succedaneum. 8 A.M. the same. I gave a pituitary extract, 1 c.c., and within 10 minutes she was again actively in labor. In an hour pains were dying out, and 1 c.c. more of pituitary extract was injected. Almost immediately the uterus went into tonic contraction, lasting 10 to 15 minutes, then relaxed, and after that intermittent contractions appeared. After all, a low forceps operation was necessary. Child lived; mother doing well.

3. Artificial Pneumothorax.—C. Floyd is impressed with the relatively small number of those afflicted with pulmonary tuberculosis who are really suitable cases for treatment by means of artificial pneumothorax. Well marked or advanced strictly unilateral cases are not especially common even in large clinics for pulmonary tuberculosis, and some observers believe that such cases are always bilateral. If this type of cases is strictly adhered to the results obtained in cases in which the method is carried out conscientiously will be uniformly good, and the percentage of patients markedly improved or even arrested will be as large as 40 or 50 per cent. If, on the other hand, as is the tendency with most men, almost any otherwise hopeless case in which satisfactory compression can be obtained, is given a chance of obtaining relief at least from persistent symptoms, the results will not be brilliant, and not more than 5 or 10 per cent. possibly of such cases will be arrested. Artificial pneumothorax is of real aid in the chronically recurring tuberculous pleural effusion, and in some cases of bronchiectasis and pulmonary abscess in which the inflammatory conditions to be met are not too extensive. But even if this group of diseases may be benefited by the use of this method, its field in the treatment of diseases of the chest is still relatively a narrow one. It is most applicable when the patient is under the supervision of hospital or sanatorium management, and has failed to do well with the older and well established methods.

5. Orthostatic Albuminuria Treated by Exercise.—H. J. FitzSimmons reports the case of a girl nine years old who was apparently normal except that when she assumed her usual erect position her kidneys excreted albumin. From the observations made upon children with chronic constipation, where the condition was cured by exercise, the author had noticed that decrease in the lumbar lordosis was coincident with a lessening of the complaint. Exercises were, therefore, commenced and carried on vigorously. All muscular exertion which tended to lessen the lumbar lordosis was encouraged, while all positions which increased it were forbidden. These exercises were definitely arranged, first to increase the muscle power of the abdominal walls. Particular attention was paid to the recti, the superior and inferior obliques and the transversalis. These exercises for muscle power were carried on simultaneously with instructions in "muscle control." Muscle control is very important, since by this means the patient has not only the power to hold a given position, but assumes this position first consciously during the training of certain muscles, then unconsciously. From this unconscious assumption of this position she passes into a condition in which she assumes a proper attitude. This condition was obtained by insisting during all the exercises, of a concentration upon the exercises, and the absolute exclusion of all other thoughts or actions.

9. Clinical Observations on Cancer; Its Treatment and Cure by Chemicals Alone. K. F. Junor.

1. Fliess and His Theory of the Family Substance.—B. Holmes discusses the theory propounded in 1906 by Wilhelm Fliess as to certain biological rhythms, and characterizes this theory as the most remarkable mystical, mathematical, and biological compilation of modern times. It appears that Fliess discovered that women menstruate regularly once in twenty-eight days and that many of them have irregular menstruations, which can be easily made to correspond with nodes produced by the coincident, or aggregated, or interfering rhythms of twenty-eight and twenty-three days. From such a system of examining irregular menstruations Fliess comes to the conclusion that there is in each individual a family substance having a male and a female manifestation, the rhythm of the former being twenty-three days from node to node, while the latter is twenty-eight days. He shows further that the eruption of the teeth in the children, the appearance of menstruation in the girls, and the various sicknesses of both the boys and the girls stand in a remarkable coincidence to the menstruation of the mother. The period of gestation is shown by Fliess to be a multiple of twenty-eight and twenty-three, and furthermore, that the appearance of the next pregnancy, the next gestation, and the next birth correspond similarly with these mystic numbers. Holmes regards the above theory as the flower of modern mysticism, as the sublimation of Freud's neo-phallicism.

2. Medical Care of the Aged.—I. L. Nascher states that much can be done to overcome the mental depression of the aged. One should induce the old man to make the effort to improve his appearance, stimulate his sense of pride and let those around him tell him how young he looks. The psychic effect is instantaneous. Association with the young has a rejuvenating effect, and if the young people treat the aged as one of themselves, it will arouse a youthful spirit in the old folks. One must make an effort to keep their minds pleasantly occupied. If they have nothing to do they think of their past and the future, and they brood. The action and appearance of the aged individual are more certain indications of the condition of his health than his statements. The family should know that there may be fever in spite of a cool forehead, that mumbling in sleep is often delirium, that when the old man or woman shows a disinclination to get out of bed at the usual hour it usually means a serious disease, though the patient does not complain of pain or other discomfort than weakness. Every symptom arising suddenly, even the sudden relief from a symptom, as sudden relief from dyspnea, is a grave omen. The family should know that the absence of pain does not exclude a disease which is usually painful, the absence of surface elevation of temperature does not exclude fever, the absence of cough does not exclude pneumonia, the absence of the accustomed snore does not exclude a coma from which the patient will never awake. The physician in dealing with the aged should apply to them sympathy and science; sympathy, to relieve distress wherever he may find it; science, to study life and how to prolong it. But the aged need more than these. They need the support of the humanitarian, who will help and cheer them.

2. Acute Acid Intoxication in Children.—By T. C. McCleave. (See MEDICAL RECORD, June 28, 1913, page 1187.)

5. Osteochondritis Dissecans.—John Ridlon reports three cases of this condition in otherwise healthy young men in whom the disorder gave little trouble except for a slight swelling and a lack of full extension at times from the contracted hamstring muscles. These cases may go on for years and give comparatively little trouble. Our present knowledge of the condition would not warrant discussion of its relations to other loose and partially detached bodies in the knee-joint or of its possible relation to arthritis.

7. Charcot Joints as Early Symptom of Tabes.—H. L. Taylor presents the history of twenty-three cases of tabes in which Charcot joints and spontaneous fractures were prominent symptoms, in some instances the earliest symptoms observed. In eleven of the cases lues was denied, but in the most of these it was extremely probable from the clinical evidence that syphilis was the underlying cause. The author concludes that Charcot joints and spontaneous fractures are often initial or early symptoms of tabes dorsalis. They often precede the ataxic gait, and are of diagnostic importance in calling attention to the underlying tabes. Charcot joints are frequently of traumatic origin and often follow fractures and lesser injuries. The results of orthopedic treatment in early or moderately advanced cases of Charcot joint are extremely satisfactory. Orthopedic treatment by protective splinting should also be used in the loose joints of tabes due to hypotonus before the appearance of swelling and effusion. As ataxia is frequently one of the later symptoms to appear the term "locomotor ataxia" to designate the affection is misleading and should be discarded. The term tabes dorsalis should be used in its stead.

10. Gastric Ulcer and Gastric Cancer.—F. Smithies analyzes a series of 566 consecutive cases of cancer of the stomach, demonstrated by operation and also pathologically. Many cases admitting only a clinical diagnosis of ulcer are shown by operation to be malignant, and the object of his study has been to determine how frequently chronic ulcer precedes cancer. The set ratio in gastric cancer is approximately that of chronic gastric ulcer (3.33 males to 1 female) and the age relations are similar. Precancerous history indicates that 41.8 per cent. of proved cases of cancer presented early symptoms of gastric ulcer; 16.7 per cent. presented the early symptomatology of "irregular" gastric ulcer, and 32.1 per cent. had the symptom complex of gastric cancer without a previous gastric disturbance. Thus over 60 per cent. of the cases of gastric cancer had early dyspeptic symptoms, usually of chronic ulcer. The length of time of all the symptoms of the primary cancerous group (162 cases) was 7.1 months. The average duration of the precancerous dyspeptic periods was 11.4 years in 239 cases. In this group the duration of evident malignancy averaged 6.1 months. The development of a precancerous history permits laparotomy in more than one-half the cases at a stage in which the surgical advantages of a localized process are available. Periodicity was observed in the preliminary dyspeptic symptoms in 81 per cent., while it was absent in 99 per cent. after the process became evidently malignant. Relief of pain by eating was experienced in more than one-fifth of the cases in which malignancy followed a clinical gastric ulcer and in 3 per cent. of the primary cancer group. The analysis of other symptoms such as hemorrhage, vomiting, occult blood, etc., is given in detail. In about 10 per cent. of the cases of a gastric cancer the roentgenogram and fluoroscope were of value in enabling one to make an absolute diagnosis. More than 98 per cent. of the gastric cancers were adenocarcinomas. Sarcoma was seen but once. There is a group of cases of chronic ulcer in which examination reveals cellular or intracellular variations warranting the designation of precancerous ulcer. It is often impossible to distinguish stages of simple and malignant hyperplasia histologically. Benign duodenal or gastric ulcers may coexist with cancer in the same person.

12. Etiological Study of Hodgkin's Disease.—C. H. Bunting and J. L. Yates refer to a previous publication in which they described a diphtheroid organism obtained in pure culture in four cases of Hodgkin's disease and observed in three others. They report experiments on monkeys by the inoculation of the cultures of this organ-

ism, and while they cannot claim as yet that they have produced Hodgkin's disease in the animals they state that by repeated injections they have produced progressive enlargement of a single group of lymph nodes which show histological changes identical with those observed in the lymph nodes in human beings in whom the disease is of the same duration

2. Specific Differences Among Bacteria.—F. W. Andrewes notes that much more variability is to be seen in some genera of bacteria than in others, and the general rule may be laid down that small genera, containing only one or two forms, show much more constancy than the large genera. Thus the anthrax bacillus has few or no close allies; it is almost a genus to itself and it shows hardly any variability. This is true also of *Micrococcus melitensis* and *Bacillus mallei*. In contrast to these we find such genera as the streptococci, the diphtheroids, and the coli-typhoid group, which are excessively abundant in nature, rich in the number of their forms, and present the highest degree of variability. It is in such genera as these latter that the chief disputes have arisen among bacteriologists as to what are species and what merely varieties. In such genera as the streptococci or the *Bacillus coli* group, one perceives a mass of variable forms, representing, as it were, the melting-pot in which species are made, and from which even now species are emerging. One may actually trace the process of emergence by the application of suitable methods, and all the stages of the process can be watched. Thus, from the *Bacillus coli* group we see the typhoid bacillus already emerged as a species almost fully fixed and defined, while in Salmonella we have a subgroup of coliform organisms struggling upwards into differentiation, separable as a subgroup, but with specific limits recognizable only by the doubtful criteria of serology. There is an aspect of the subject which is at the present day largely conjectural, but which is beginning to attract the attention of many workers, and which has recently been discussed by Eccles in the MEDICAL RECORD. This is the idea of "chemical evolution." The protein molecule is essentially built up of amino-acids, limited in number to some 20 or more. The different specific proteins owe their characters to the proportions of these different amino-acids present, and to their relative positions in the configuration of the molecule, affording an infinite variety of combinations. These minute structural differences in the configuration of the protein molecule have arisen by natural selection—as a result of the survival of the chemically fittest molecules in the struggle for existence of the organisms to which they belong. The conception of chemical differences between species is a relatively novel one, and although precipitin reactions are applied in distinguishing between the blood of one known animal and another, no one has yet dared to define species on chemical grounds alone. The author closes with the confession that he does not know by what criteria one can judge of actual specificity among bacteria.

3. Two Years' Experience with Salvarsan.—Sir Malcolm Morris and H. MacCormac state that in all their primary cases the disease has been immediately arrested, and in none which they have been able to follow up have secondary symptoms developed, with the exception of sore throat. In secondary and tertiary cases the skin lesions, without a single exception, have rapidly disappeared. The authors did not rely solely upon salvarsan, but supplemented it with mercury wherever patients could be prevailed upon to take a course of that drug. Even then their cases have not been free from recrudescence. In a few instances the patients have returned after two or in some cases three injections, with a complete relapse. In all of the secondary cases there has been a rapid disappearance not only of cutaneous but also of mucous membrane lesions. The rash has quickly faded, but some pigmentation has usually persisted for a considerable time. The general condition also has greatly benefited, the appetite improving, and the patients putting on weight and gaining color. In the group of tertiary cases, even in case that had proved obdurate to mercury and iodide of potassium vigorously and perseveringly administered, the authors have not had a single failure where the integumentary system was attacked. Almost as much may be said of lesions of the tongue. As between the salvarsan and neosalvarsan, the results inclined the authors to give the preference to the earlier one. Neosalvarsan is not only less stable than salvarsan, so that unless it be used at once its toxicity may be intensified to the danger point, but it is less rapid in its effects, lesions disappearing less readily under its influence, and the Wassermann reaction remaining positive longer. Although salvarsan may in some cases abort the disease in the primary stage, and may effect a permanent cure in later stages, these results cannot be confidently counted upon, and prudence dictates that in every case this remedy should be supplemented by a course of mercury. On the other hand, that salvarsan has a more rapid and powerful effect upon the spirochæte than mercury seems indisputable. In some of the authors' cases malignant and less severe types of syphilis that had proved absolutely resistant to mercury, or to mercury plus potassium iodide, have promptly yielded to salvarsan. With mercury alone, however administered, lesions are much more persistent, and in nearly all cases the Wassermann reaction remains positive during the first year and in about a third of the cases for over two years.

5. Visceral Complications Met with in Hysterectomy for Fibroids.—Sir John Bland Sutton discusses the manner in which surgeons deal with certain visceral lesions which occasionally complicate fibroids, such as cancer of the colon, injury of the ureters, and gall-stones. The author has had careful observations made on the cardiac condition of women with fibroids, and there is nothing which can be described as peculiar to the influence of these tumors. On three occasions the author has removed a uterus containing fibroids from women who at the time of the operation possessed goiters. He has been surprised on seeing the patients six months after the hysterectomy to notice a marked diminution in the size of the goitrous thyroids. The presence of sugar in the urine is as a rule a contraindication to hysterectomy for fibroids. The urine of patients with a large cervical fibroid, or a fibroid of the body of the uterus impacted in the pelvis, often contains slight traces of albumin. This is not a contra-

indication to operation, and the albumin quickly disappears after the tumor has been removed. One of the most serious accidents that happens in the course of hysterectomy is an injury to both ureters. It has happened to the author on several occasions in the course of removing the uterus for fibroids to find cancer of the sigmoid flexure. After completing the hysterectomy he excised the cancer in the colon and joined the cut ends of the bowel by an end-to-end anastomosis. As regards the coexistence of fibroids and gallstones the author lays down a general rule, as follows: If a woman deeply jaundiced in consequence of a stone impacted in the common duct also suffers from a uterine fibroid, which so troubles her as to make it desirable to remove the uterus, it is preferable to remove the stone from the common duct first because it is well known that cholemia predisposes to hemorrhage. Hysterectomy in a woman with persistent jaundice is an operation which would place her life in the gravest peril from postoperative bleeding.

7. Heredity and Inheritance as They Concern the Physician.—C. Mercier points out that breeders of animals breed for single qualities or for simple combinations of qualities, but the controllers of eugenics in the human race would breed for a vast number of complex qualities and would breed for them all at once. They would breed for physical robustness and capacity to resist disease, for physical beauty, for moral elevation, for intellectual genius and for manual dexterity. The author believes that neither biometrics nor Mendelism is of the slightest value to the practising physician. Moreover he does not believe that insanity is ever inherited. What is inherited when nervous disorder of this and other kinds appears in successive generations, is a certain instability or vulnerability of the nervous structure in the highest regions of the brain, such that they readily become disorganized when exceptional demands are made upon them, or even when demands are made upon them that are not exceptional.

8. Hysteria.—T. R. Glynn notes that the stigmata of hysteria are present in about 20 per cent. of epileptics. Some of the stigmata were found in 25 out of 96 cases of chorea. The infective diseases may provoke hysteria. Chlorosis is very frequently attended with hysteria. In Graves' disease the hysterical stigmata are present in 35 per cent. of cases. There was evidence of hysteria in three-fourths of the cases of simple gastralgia in young women. The relation of hysteria to heart disease is of special interest. Such hysterical affections as pseudo-angina, or simple pain over the heart, palpitation, dyspnea, and syncope, when the heart is normal arouse fears of cardiac disease in the patient, and worry the medical attendant till he lights on the explanation of the symptoms, and when these hysterical accidents occur in cases in which there are signs of organic heart disease they are likely to cause the patient's condition to appear more serious than it is.

12. Sensitized Virus Vaccination in Gonorrhea.—L. Cruveilhier employed sensitized living gonococcus vaccines in the treatment of gonorrhea and more particularly, of its complications. Cases of epididymitis were greatly benefited. This was also true of adnexal complications of gonorrhea in women. In acute gonorrheal rheumatism the action of sensitized virus vaccination was very rapid. In a refractory case of chronic gonorrheal arthritis great improvement was noted as the result of this treatment.

13. Nerve Surgery.—A. H. Tubby states that brachial plexus lesions, if traumatic, are hopeful, if the loss of power has not existed for years. If due to other causes the outlook is not so good. However, one should not despair of a case recovering, even five years after the operation, provided that the improvement has set in within three months after the operation and is continuous. Popliteal neuroplasty for infantile paralysis has proved disappointing for the reasons given previously. Injuries about the wrist should never be sewn up until the continuity of the nerves has been ascertained, and until all the electrical reactions have been tested. If the lesion of the nerve is compression by a scar the outlook after operation is most hopeful. If the nerve has been severed primary operation is very hopeful, but secondary suture rarely permits a complete recovery. No case, however, of traumatic nerve lesion should be regarded as hopeless, in view of the achievements of neuroplasty.

14. Public Antituberculosis Measures.—N. Raw discussed the general measures for the control of tuberculosis, which are as follows: (1) Voluntary and compulsory notification; (2) removal of affected children from school and home; (3) treatment of children in special children's sanatoria; (4) education of the general public with regard to the disease; (5) provision of municipal dispensaries in every community; (6) provision of sanatoria for the cure of early cases; (7) institutions for advanced cases; (8) home training and supervision among the working classes; (9) rigorous supervision of the milk supply; (10) extermination of tuberculosis among cattle; (11) assistance to family in the absence of the breadwinner; and (12) provision of suitable employment for cured cases and those in whom the disease is arrested.

16. The Amino-Acids in the Urine in Diabetes.—P. J. Cammidge has found that the urine in simple cases of glycosuria shows no amino-acid nitrogen excepting when there is evidence of a gouty condition or serious hepatic derangement; there may then be as much as 0.5 gram in 24 hours. In such cases the urine may contain traces of acetone, but it is free from aceto-acetic and oxybutyric acids. When secondary disturbances of metabolism occur and the patient has reached the third stage, the amino-acid nitrogen is small in amount at first, 0.05 gram or less, but as the disease progresses, and especially if it is not controlled by suitable treatment, it generally increases rapidly, often much more rapidly than the acetone bodies, until 2 grams or more are being excreted daily. Finally, the amino acids may be present in such abundance that the relatively insoluble tyrosine crystallizes out and can be recognized in the urinary sediment with the microscope. In some cases the excretion of amino-acids and acetone bodies run parallel, but this is not always the case, and one sometimes meets with a high excretion of acetone bodies and a low amino-acid nitrogen, while other cases show the reverse condition. The former often do surprisingly well, but the latter frequently die suddenly, with symptoms of heart failure, so that as a rule the author places more reliance on the amino-acid content of the urine in giving a prognosis, particularly in cases in which amino-acids are found in the urine. It is now generally recognized that many diabetics, and more particularly those of a severe type, do better when the amount of meat taken is strictly limited and intervals of meat-free diet are interposed. This is the basis of the "oatmeal cure," the "potato cure," and similar methods of treatment, and of the vegetable days which are prescribed for most diabetics who are being treated by modern methods. The reason for their use is often not appreciated, however, and they are consequently prescribed in a haphazard manner. The common policy of allowing patients with glycosuria an unlimited amount of meat is pernicious in all cases, for even when no amino-acids are being excreted in the urine, and it is evident that they are being utilized by the organism, one should remember the high specific dynamic effect of protein foods, and bear in mind that it has been proved experimentally that a purely protein diet stimulates metabolism 40 per cent. over the fasting standard, as compared with 6 per cent. for carbohydrates and 14 per cent.

for fats. The appearance of amino-acids in the urine in recognizable amounts is usually a sign that too much protein food is being taken, just as the presence of sugar is an indication that more carbohydrate is being consumed than the patient can deal with efficiently. Their persistent increase, in spite of careful dieting, is of bad prognostic significance, but a steady diminution following a regulation of the protein intake suggests that, with care, the life of the patient may be prolonged for months or even years.

17. **The Mortality of Children from Burning.**—W. A. Brend presents the following table which is compiled from the reports of deaths in England from 1906 to 1911 of infants and children caused by burning, chiefly from ignition of clothing:

Ages.	Boys.	Girls.
0 to 1	214	234
1 to 2	443	466
2 to 3	840	623
3 to 4	580	729
4 to 5	368	775
5 to 10	389	1427
10 to 15	47	369
15 to 20	33	261

It will be seen that there is a very marked difference between the mortality of boys and girls. In the case of boys the figures increase rapidly up to the age of 3, drop nearly as quickly to the age of 6, and then gradually fall away to almost nothing. The mortality of girls continues to increase up to the age of 5, and then declines, though to not nearly the same extent as among boys. It remains higher through the ages of adolescence, being between the ages of 15 and 20 about eight times as great. This remarkable difference in the mortality is probably due to the difference in the style of clothing worn by the two sexes. Up to about the age of 3 boys are dressed in the same way as girls. From 3 to 4 they are put into male attire and there is an abrupt and marked fall in the mortality from burning. With girls it is not until the age is reached at which they are better able to take care of themselves than the figures show a decline. The generally greater mortality of girls from burning is to be attributed to the loose and inflammable nature of their clothing. Flannelette is particularly pernicious in this respect.

5. Hereditary Transmission of Sarcoma. J. S. Manson.
6. A New Method of Dealing with Scars by Multiple Incision and Thiosinamin. By A. H. Tubby.

1. **Chronic Intestinal Stasis.**—Sir W. Arbuthnot Lane points out that the symptoms that result directly from the autointoxication of chronic intestinal stasis are (1) loss of fat; (2) wasting of the voluntary and involuntary muscles; (3) degenerative changes in the skin; (4) reduction of body temperature and particularly that of the limbs; (5) an apathetic mental condition; (6) pains in the muscles, joints, and skin; (7) wasting of the thyroid; (8)increase or decrease of blood pressure; (9) degenerative changes in the breast; (11) dyspnea on exertion; (12) degenerative changes in the heart; (13) chronic nephritis; (14) canities and alopecia; (15) indurative, inflammatory, and malignant changes in the pancreas; (16) diseases of the liver and biliary tract; (17) degenerative diseases of the eye. The indirect changes, or those that result from the lowered resisting power of the tissues to the invasion of organisms produced by autointoxication, can hardly be separated abruptly from all those conditions described as being caused directly by it. The most obvious are: (1) Infection of the gums causing the condition commonly described as pyorrhœa alveolaris. (2) Tuberculous infection, when not produced by direct inoculation. (3) Rheumatoid arthritis. This, like tubercle, cannot develop except in the presence of defective drainage of the gastro-intestinal tract. (4) Infection of the genitourinary tract, either directly or indirectly, through the blood stream, by organisms other than tubercle, producing nephritis, cystitis, pyelitis, endometritis, salpingitis, etc. (5) Development of changes in the thyroid gland, whether as adenomatous tumors, general enlargement of the thyroid, or exophthalmic goiter. (6) Still's disease. (7) Infections of the skin of a pustular nature. (8)Infection of the large intestine by organisms which produce the several varieties of mucous and ulcerative colitis. (8) Ulcerative endocarditis.

6. **A New Method of Dealing with Scars.**—A. H. Tubby describes a method which he has employed in the ment of scars of very considerable dimensions, in the axillæ, in the groin, about the neck, at the wrist, and on the fingers. Having frequently failed to obtain any satisfactory result by excision of scar tissue, even if followed by extensive skin grafting, he devised the following original method: With a fine and strong-backed tenotomy knife a large number of multiple incisions are made transversely to the bands of keloid material. The incisions are placed close together, not more than one-tenth of an inch apart; and great care is taken that they should penetrate not only into the subcutaneous fat, but also extend one-quarter or half an inch into the neighboring healthy skin. No attempt is made to arrest the hemorrhage except by pressure, and when bleeding has ceased, a solution of thiosinamine is vigorously rubbed in; and, if the scar tissue is very thick, a few drops are injected into the most prominent bands. The author has had no hesitation in injecting, in children, 15 minims at a time, and in adults 20 minims; in only one case was there any effect on the heart. In that instance some slight cardiac collapse occurred for a few minutes; the patient, however, was over sixty years of age, and, happily, no permanent ill results followed. After the operation the part is put up on a splint, in as much extension as possible, without tearing the soft parts, and is allowed to heal. This is accompanied by no excessive reaction and very little pain. The author believes that the absence of those signs is due to the fact that the thiosinamine is not pent up within the tissues, but freely exudes through the incision. After ten or fourteen days the wound will be healed, and the mobility of the part is increased by 50 per cent. The operation is then repeated, and it rarely may be required three or four times. The result is most satisfactory; scars which have been tough, resistant, and, in the case of the fingers, wire-like, have become soft and supple, the part has regained its mobility, and its usefulness has been restored.

Berliner klinische Wochenschrift.

October 20, 1913.

Cultivation of the Exciter of Rabies.—Noguchi mentions in succession the labors of Gattier, Pasteur, and associates Negri, Babes, J. Koch, and others, concluding with Proescher, a recent writer. The discovery of "Negri's bodies" in the ganglion cells was of critical importance, while other men found minute granules in the central nervous system. Finally Proescher's minutest, pleomorphic organisms were found in the nervous substance of rabbits killed with fixed virus. But not one of these bodies has been accepted as the cause of the disease. All are probably reactive phenomena of the virus of the dis-

ease which is filtrable in character. The author has been attempting to obtain serial cultures without absolute isolation of the germ, such as is commonly practised in diseases due to an invisible, unknown microorganism. He began his studies in 1912. The first or infective material was the sterile brain of an animal dead of rabies. This was passed through cultures of all kinds, and in different animals, causing an epidemic of experimental rabies. After eighteen months it was learned that many cultures had died out, and that no organisms could be brought to view. Minute chromatin corpuscles were visible and these could be carried through many generations. They corresponded to living formations, and in certain cases to Negri's bodies. Very small chromatin granules answered to Negri's spores. Thus far nerve substance containing these bodies caused typical rabies.

Pathology of Shock.—Henderson does not agree wholly with the Crile school as to the nature of this phenomenon. He believes that shock is a collective term and that we should study its individual phases. Sudden deaths were once supposed to be shock deaths, and while the mechanism was usually visible there was in many cases no trauma. Anaphylaxis to-day explains some of these instances. Psychic shock leading to death is also partially understood. Sudden death from electricity is commonly spoken of as due to electric shock, although these deaths may differ much among themselves. Death in chloroform narcosis (chloroform death) is regarded as due to a cardiac shock. Death from drowning is more or less a shock death, in cases in which resuscitation is impossible even after but two or three minutes of immersion. For the gynecologist shock is the result chiefly of hemorrhage; for the surgeon shock means a strong depression of all of life's functions not conditioned by loss of blood; for the military surgeon shock is due largely to the depression produced by prolonged operations. The phenomenon of acapina is discussed very fully and it is questioned whether or not it should be included under shock. It at least seems to be visible in the course of certain shock deaths. This relationship will doubtless be a great problem for the future. The relation of various functions to shock constitute problems of equal significance. Thus the question of circulatory shock must first involve the status of each structural component as venous pressure, the blood supply of the right heart, the influence of the nervous system (vasomotor). The venous pressure is not disturbed by an injection of adrenalin which causes a marked rise of arterial pressure. The author closes in recapitulation the extremely obscure nature of circulatory shock.

Münchener medizinische Wochenshrift.

October 28, 1913.

New Viewpoints for the Therapeutic Application of Camphor.—Leo has recently injected a watery solution of camphor having a high content of the latter, and finds it much superior to camphor oil. It stimulates the cortex and respiratory centre and under certain conditions raises the blood pressure. Camphor has long been known as of value in fevers, although the rationale has never been understood. It has recently been claimed that the drug acts as a bactericide in the circulation, with a quasi-specific action in pneumonia and pneumococcus sepsis. In animal experiment it has been found that the drug inhibits the development of pneumococci. Recent work at the Ehrlich Institute has shown that camphor oil exerts an undoubted prophylactic action on pneumococcus sepsis in rabbits and guinea pigs, while in mice it shows beyond doubt still greater possibilities suggesting cure. In croupous pneumonia in man we have either a localized process with a general reaction or a generalized sepsis such as occurs in animals. Nevertheless in croupous pneumonia in man there are always pneumococci in the blood, even if sepsis does not develop. In all of the different phases in man and animals there seems to be an indication for camphor. A study of history shows a marked germicidal power of camphor in infectious diseases. Thus Pirogoff praised it highly in erysipelas. At present much effort is being devoted to seek out the best preparations and methods of exhibition. We cannot rely on camphor alone, for in each disease the best general treatment must be followed up. In pneumococcus infection we should doubtless combine it with serotherapy and ethyhydrocuprein. Camphor should be used as a last resort by the intravenous route.

Traumatic Delayed Apoplexy.—Schuster refers to cases in which a cerebral lesion or vascular injury is the first step towards an apoplexy. The nature of the injury is apparent from the symptoms of focal irritation. A period of latency now sets in, of from 1 to 6 weeks on the average, with the maximum of nine months (Mendel). Cases no doubt occur not under medical control in which the interval may be years. Sooner or later apoplexy is certain to supervene. A case is described at great length. An injury had occurred in the floor of the fourth ventricle, a place of predilection, and the focal symptom was abducens paresis. Just what followed at the site of injury is problematical. There may have developed a focus of softening involving the vessels secondarily or the opposed condition may have ensued. In any case the vessels must have been damaged sufficiently in the fifth week for a rupture to occur. Under slight muscular overexertion a blood vessel ruptured in the left ventricle. The patient had a modified Graves' disease and the thyreotoxicosis may have injured the blood vessels, but such a sequence has never been established.

Deutsche medizinische Wochenschrift.

October 23, 1913.

New Principles in the Treatment of Gonorrhea.—The three first papers in this number deal with certain trademarked substances for the prophylaxis or cure of gonorrhea, the names of which need not be given but only the principles involved. Bruck has attempted to obtain combinations of silver with other substances intended to secure diffusibility and deep action with special regard to prophylaxis, where they are applicable in the form of bougies after intercourse. Sommer discusses the use of these in the clinic, while Glück studies the behavior of gonococci in the presence of the solution. The principal diffusive substance united with silver is uranin.

Benzol Treatment of Leucemia.—Mühlmann sums up as follows the results of treatment of a case of lymphatic leucemia with benzol. The patient died and extensive necroses were found in the liver. Neumann's find in a case of myelogenous leucemia was the same. Pappenheim gave benzol internally to rabbits with the same result. While we cannot say that benzol was responsible for the hepatic lesions in these cases, we must henceforth be cautious in the use of benzol for leucemia, giving small doses and strictly controlling the state of the hepatic functions by appropriate tests.

Complement Deviation in Whooping Cough.—A. Netter and M. P. Weil as the result of a systematic examination of the blood serum in children suffering from whooping cough, which examination was conducted at different stages of the disease, find that the specific amboceptor appears only during a relatively late period of the disease, *i.e.* in the second, and principally in the latter half of the second, week. On the fifteenth day the reaction was regularly positive. The complement-deviation reaction is therefore of little diagnostic value in whooping-cough.—*Comptes Rendus Hebdom. de la Société de Biologie.*

Insurance Medicine.

Educational Value of Cancer Statistics to Insurance Companies.—Before the Clinical Congress of Surgeons of North America, Mr. Frederick L. Hoffman read a paper on the educational value of cancer statistics to insurance companies. The opinion was expressed that the cancer death rate in the United States is unquestionably on the increase among both sexes at all ages over forty and for all important organs and parts.

From the standpoint of life insurance cancer presented itself in a threefold aspect: *first*, as a problem in selection in insurance medicine; *second*, as an element in insurance experience; and *third*, as a question of state medicine, with special regard to the educational value of cancer statistics and the feasibility of cancer control. The speaker briefly reviewed the literature of cancer in insurance medicine during the past half century. He thought that over-emphasis had been placed upon the alleged hereditary tendency in cancer, which theory had only been slowly given up in the view of increasing statistical and other evidence to the contrary.

The earliest data on insurance company mortality were of the London Equitable, for the period 1800-1821, in which, out of 1,930 deaths from all causes only 25, or 1.5 per cent., were deaths from cancer. The early experience of other English companies were all to the same effect, of an apparently low proportionate mortality from cancerous affections. Making allowance then for defects of registration, it was quite apparent that there had been an actual increase in the cancer mortality of life insurance companies.

The speaker reviewed the investigations of Messrs. King and Newsholme on the alleged increase of cancer, based in part upon the experience of the Scottish Widows' Fund. The conclusions of King and Newsholme to the effect that cancer was only apparently, and not actually, on the increase, were subsequently set aside by the still more thorough investigations by the medical officer of the Scottish Widows' Fund, Dr. Claud Muirhead, published in 1902. He concluded that there had been a slight decrease in the deaths from internal cancer and a distinct increase in the deaths from external cancer.

After reviewing the mortality experience of the Prudential Assurance Company, London, in its industrial branch, exhibiting a very low proportionate mortality from cancer as possibly typical of the working class, Hoffman reviewed the early experience of the Mutual Life of New York, the Washington Life, and subsequently the Clergy Mutual of England, the Northwestern Mutual of Milwaukee, the Gotha Life of Germany, and certain other German companies, all exhibiting a relatively high proportionate mortality from cancer during the most recent years of experience, and confirming to this extent the conclusion that cancer was actually on the increase in this as well as in other civilized countries.

According to the speaker, the most important contribution to the study of cancer as an insurance problem was the results of the recent medico-actuarial investigation of American companies for the period 1885-1908. The experience gained from these investigations, conclusively sustained the view occasionally expressed by writers on the subject of cancer occurrence, that the disease is more common among persons of overweight than among underweights, and by inference among the well-to-do and over-nourished, than among the less prosperous element but of more normal physique. The medico-actuarial investigation also considered the mortality from cancer according to conjugal conditions, proving quite conclusively that the death rate from cancer was distinctly less among unmarried women than among the married and the widows at every divisional period of life. Unfortunately, the investigation had not been carried far enough to disclose the variation in the cancer liability of married and unmarried women according to organs or parts of bodies affected, but possibly such an investigation may be made in the future, when a still larger amount of material will be available. The results of the numerous investigations seemed to lend force to the argument that the excess in the death rate from cancer among the well-to-do might be largely attributable to over-nutrition as a possible primary cause or irritant in the production of cancerous affections.

Hoffman recommended an educational propaganda, and also suggested that the Clinical Congress of Surgeons order a collective inquiry to be made into the facts of American surgical experience with regard to the immediate and after-effects of surgical operations for malignant and non-malignant tumors.

Mr. Hoffman concluded by saying that "There are the strongest possible reasons for believing that if the cancer facts, including medical and surgical experience, were brought together in authoritative form, they would not only materially aid the work of the American Society for the Control of Cancer, but the various cancer research funds, as well as the individual practitioner in his relations to his patients and the public at large. With this end in view, however, it is necessary that there should be intelligent and active cooperation between the laity and the profession, on the one hand, and the life insurance companies, and the Federal and State governments on the other. If by means of such cooperation the present upward tendency of the cancer death rate is only halted, and if by indefatigable efforts even a slight reduction in the rate from any or several forms of cancerous affections is brought about, the results will be well worth while, and the work done will be a genuine contribution to the well-being of civilized mankind."

Misrepresentations in Life Insurance.—An applicant for life insurance must act "in the utmost good faith" in disclosing to the insurer all things material to the risk about which information is sought. A misrepresentation in reference to any matter which materially affects the nature, extent, or character of the risk will void the policy; and the willful concealment of a material fact will have the same effect. Where an applicant for life insurance willfully conceals from the insurer the fact of a previous illness, such concealment will void the policy, if the disease was of such a character as to enhance the risk. The fact that the insured may have died a short time after the policy was issued, from a disease with which he was not afflicted when the policy was issued, does not conclusively show that the fact of the previous illness was not material, within the meaning of the general rule stated above.—Ætna Life Ins. Co. *v.* Conway, Georgia Court of Appeals, 75 S. E., 915.

Book Reviews.

A Text-Book on Gonorrhea and Its Complications. By Dr. Georges Luys, late assistant to the Urological Clinique, Hôspital Lariboisière, Paris; Prizeman of the Faculté de Médecine, Paris. Translated and edited by Arthur Foerster, M.R.C.S., L.R.C.P. (London); late Resident Medical Officer, London Dock Hospital. With 200 illustrations and three Colored Plates. Price $4.50 net. New York: William Wood & Company, 1913.

Books on genitourinary diseases are not lacking and there are several excellent ones in this country describing fully and satisfactorily the American methods of dealing with these affections. Methods differ somewhat, however, in different countries and for this reason a translation bringing new ideas and descriptions of new or at least not well known procedures is often to be welcomed. The French urologists are justly celebrated for their skill and therapeutic success, and high among the French urologists stands the author of this book. His "Traité de la Blurnorrhagic et de en Complications," which was reviewed in these columns nearly two years ago, achieved an instant success in France and among French-speaking genitourinary surgeons, and appeared in a second edition within a year. This well made translation by Mr. Foerster, himself no mean authority in venereal diseases, is of the second edition, with, however, some few changes, chiefly in the matter of illustrations.

Dr. Luys is an optimist as regards the therapy of gonorrhea for he holds that it is no longer "permissible for a medical man to allow a case of gonorrheal urethritis to go on without curing it." His optimism is justified for it is founded upon the results of the modern methods, aided by the urethroscope and other instruments, which he has obtained. The work consists of twelve sections, opening with an interesting chapter on the history of gonorrhea and its therapeutics. Then follow chapters on etiology and bacteriology, and one on the non-gonococcal forms of urethritis. The pathology is satisfactorily dealt with in a separate chapter, and following this are two excellent chapters treating of diagnosis and urotherapy. The numerous complications, including rheumatism and the other organic affections, are then reviewed, and a chapter is devoted to gonorrhea in women and children. The last two chapters are concerned with the treatment of acute and chronic gonorrhea.

The illustration are deserving of special commendation; they are numerous, well executed, and elucidative, making clear many points that are more or less unfamiliar to those who have not made a special study of genitorurinary surgery.

Ionic Medication. The Principles of the Method and an Account of the Clinical Results Obtained. By H. Lewis Jones, M.D., Fellow of the Royal College of Physicians of London; Consulting Medical Officer to the Electrical Department in St. Batholomew's Hospital, etc. Price $1.50. Philadelphia: P. Blakiston's Son & Co., 1913.

The author of this volume is evidently an enthusiastic believer in the efficacy of medication when introduced into the body in the form of ions by means of the electric current, and like most enthusiasts is inclined to go further in his advocacy than the average sceptical reader is willing to follow. The statement has been frequently made that the Americans are far behind Europe in the application of ionic treatment and it is perhaps well that an enthusiast has chosen to persuade them. An adequate discussion of the method is followed by a detailed consideration of the individual ions and their clinical application. The results reported are on the whole almost "too good to be true," but are evidently drawn from a rather wide experience.

Laboratory Methods in Agricultural Bacteriology. By F. Löhnis, Ph.D., Professor of Agricultural Bacteriology in the University of Leipzig. Translated by William Stevenson, B.Sc., N.D.A., N.D.D., Lecturer on Dairying and Bacteriology to the West of Scotland Agricultural College, and J. Hunter Smith, B.Sc., N.D.A., N.D.D., Lecturer on Agricultural Chemistry and Bacteriology to the University College of South Wales and Monmouthshire, and Revised by the Author. Price $1.75 net. London: Charles Green and Co.; Philadelphia: J. B. Lippincott Company, 1913.

With the introduction and development of courses in bacteriology in the agricultural schools came a demand for a laboratory book of methods adapted to such courses. Such a work is provided in Professor Löhnis' book and its translation will render it available for use in this country. It has been translated rather literally but still clearly, and its users will find it well suited to their demands. It is strictly a book of methods and a very good one.

The Microtomist's Vade-Mecum.—A Handbook of the Methods of Microscopic Anatomy. By Arthur Bolles Lee. Seventh Edition. Price $4.00 net. Philadelphia: P. Blakiston's Son & Co., 1913.

During the twenty-eight years since the first edition of this book appeared, the "Microtomist's Vade-Mecum" has been an indispensable aid in the histological and pathological laboratories. The numerous additions that have been made within recent years to histological technique are all included in the present edition, as may be concluded from the seven hundred new entries in its index. Among the recent methods described may be mentioned Gilson's new mounting media of camsal balsam and euparal, and the silver fibril stains of Bielschowsky and Ramón y Cajal.

Reports from the Laboratory of the Royal College of Physicians, Edinburgh. Edited by George Lovell Gulland, M.D., and James Ritchie, M.D. Vol. XII. Edinburgh: Oliver & Boyd, 1913.

This volume contains reprints of twenty-six papers on anatomy, pharmacology, pathology, and bacteriology, and represents the published work of the year. The articles cover a wide range of interesting subjects. Those of Wilkie on the omentum and retrograde venous embolism in the causation of gastric ulcer appear to be the most important, and those of Fraser on tuberculosis of the bone are scarcely less so. It is altogether a collection of unusually excellent articles.

The Relation of the Lachrymal Organs to the Nose and Nasal Accessory Sinuses. By Prof. Dr. A. Onodi, Director of the Rhino-Laryngological Clinic in the University of Budapest. With Photographic Reproductions, in natural size, of Forty-five Preparations. English Translation by Dr. Dan McKenzie, London. Price $4.25. New York: Wm. Wood & Co., 1913.

In the first section of this book, Professor Onodi describes the topographical anatomy of the lacrymal organs and their relations to the nose and the nasal accessory sinuses, with the aid of forty-five illustrations of preparations of adult and infant skulls. This supplies a gap left in most textbooks on anatomy and rhinology. Onodi reviews in the second section the different operations for the cure of diseases of the lacrymal efferent organs and concludes that Toti's operation should be performed when, together with obstruction to the passage of tears, there is great distention of the lacrymal sac. West's endonasal window-resection above the inferior turbinal is indicated when there is stenosis of the nasal duct without distention of the lacrymal sac; and von Eicken's operation of opening the nasal duct through the maxillary antrum is imperative in empyema of the antrum or in extensive complete occlusion of the nasal duct. The last named operation should also be preferred when preliminary interventions, such as removal of hypertrophied turbinals, spurs, deviations of the nasal septum, etc., are necessary, or when there is a destruction of the bony wall of the nasal duct. Illustrations are given of these operations and technical details are lucidly explained by the distinguished Director of the Rhino-Laryngological Clinic in the Budapest University. Dr. Bellin of Paris and Dr. Dan McKenzie of London have rendered into French and English the German original text.

Die Rassenhygiene in den Vereinigten Staaten von Nordamerika. Von Geza von Hofmann, k. k. österr-ungar. Vizekonsul mit einer Figur im Text. Price, 4 marks. Munich: J. F. Lehmann, 1913.

There have hitherto been no researches as to whether the State laws on eugenics are carried out with any rigor, and one of the Austro-Hungarian vice consuls in Chicago has now investigated the question and issued in German a book embracing information on the spread of eugenics in America, private and public enterprises for eugenic reform, the regulation of marriage, and the sterilization of the unfit. Herr von Hofmann believes that through the immigration restrictions America is now receiving practically the best of the European peasant and laboring classes, and warns Europe to redouble her energy in race hygiene, since she is thus depleted of the marrow of her lower social strata. There is a bibliography designed to give foreign students an idea of American eugenic literature.

Die Geschlechtskrankheiten und die Ärztliche Verantwortlichkeit. Von Dr. Gerhard Hahn, Breslau. Price, 1 mark. Halle a. S.: Carl Marhold, 1913.

Practitioners who through ignorance or carelessness neglect their venereal patients, should read this philosophic gem of ten thousand words. It contains much good advice and many well merited rebukes.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION

Thirty-ninth Annual Meeting, Held at New Orleans, La. October 23, 24, and 25, 1913.

THE PRESIDENT, DR. ALBERT E. STERNE, INDIANAPOLIS, INDIANA, IN THE CHAIR.

Jackson's Membrane in Children.—Dr. JOSEPH RILUS EASTMAN of Indianapolis stated that pericolic membranes had been observed during abdominal operations upon young children by many surgeons, among whom were Roux, Stiles, Czerny, Willy Meyer, C. H. Mayo, M. L. Harris, Flint, Binnie, Coffey, Connell, Finney, Eisendrath, Gerster, McArthur, and Seelig. Often in young persons Professor Roux had observed a veil of new and almost free peritoneum containing young bloodvessels disposed transversely. The symptoms in these children were like those in chronic appendicitis. Roux observed these membranes at various levels upon the ascending colon. Stiles of Edinburgh had observed pericolic membranes in children from a few years of age upwards. Czerny had frequently seen anomalous peritoneal membranes upon the colon in children. M. L. Harris observed a typical Jackson's parietocolic membrane in a boy of twelve. Flint observed the membrane in children of eight, ten, twelve and sixteen years, and believed that they occurred in the same incidence in children as in adults, the reason that they were not more frequently seen being due to the fact that we operated upon adults ten times more frequently than upon children. Dr. Samuel Harvey, instructor of pathology in Columbia University, did 108 autopsies on infants from one to two years of age. In 16.6 per cent. of the cases he found membranes of the parietocolic type. In 13.9 per cent. of cases he found a membrane covering the *caput coli*. Lane's band or Reid's genitomesenteric fold was found in 9.3 per cent. of cases. For the convenience of study anomalous pericolic membranes may be divided as follows:

Group 1.—Those peritoneal sheets or ribbons which, because of their position and attachments, seemed to represent exaggerations of normal anatomical folds or ligaments; for example. (*a*) Those representing in an exaggerated or modified form the phenocolic ligament of Toldt, the costacolic ligament, the hepatocolic ligament, the nephrocolic ligament, etc. (*b*) Those representing in an enlarged or modified form the bloodless fold of Treves. (*c*) Those representing in amplified form the fold of Reid (genitomesenteric), Lane's band. (*d*) Those representing in amplified form the crescentric upfoldings of serosa which divide the space lateral to the ascending and descending colon into peritoneal fossæ. (*e*) Those representing in amplified form the attachments of the great omentum to the colon occasionally resulting in fusion of the omental serosa to the peritoneum of the colon throughout its length.

Group 2.—Peritonic membranes which corresponded in form and position to anomalous peritoneal folds which appeared occasionally in the fetus, as the: (*a*) Parietocolic fold of Jonnesco. (*b*) The several so-called root folds. (*c*) Nondescript peritoneal folds about the appendix and *caput coli*. (*d*) Adhesion of the peritoneum of the colon to the upfolding peritoneum of its own mesentery (Robinson and Reid).

Group 3.—A blanketing of the colon by the fused anterior and posterior peritoneal laminæ of the great omentum. The fat of the omentum was replaced by an abundance of young parallel coursing bloodvessels which vessels were disposed, as a rule, transversely to the colon.

Group 4.—Membraniform adhesions occurring about the colon the result of mild recurring peritonitis often secondary to chronic colitis (Gerster). These were similar to the pseudoperitoneums seen occasionally upon the broad ligament, the fundus uteri, and the uterine adnexæ. Such formations were essentially different from congenital membranes, although the two forms were frequently associated.

Group 5.—Changes in the peritoneum of the colon due to pathology of the circulation; as hyperemia or variocosities (Hertzler).

All of the varieties of pericolic membranes enumerated above had been observed in the fetus, and, whatever the fundamental processes of pathology which caused these fusions and adhesions might be, it seemed reasonably certain that those processes were often active in fetal life, and that all forms of pericolic membranes, with the possible exception of those embraced in groups 4 and 5, could be traced to fetal fusion.

Dr. F. DENEGRE MARTIN of New Orleans stated that from his experience with the Jackson membrane he was today more inclined to let it alone than to attempt to correct the condition. He had not yet found a case where the Jackson membrane was so situated—and so far he had had but nine cases—that did not have unmistakable signs of appendicitis. In the beginning he tried in several cases to correct the condition by doing what was suggested, severing the membrane and connecting it at some place if he could, but those cases in which that was done gave him more trouble than if he removed the cause and allowed the membrane to remain.

Dr. DANIEL N. EISENDRATH of Chicago said this subject was attracting considerable attention in the surgical world, because a great many clinical pictures had been described of this membrane, and a great deal of harm had been done by misinterpreting the membrane as pathological, when really it was nothing but a normal structure. In dissecting a number of fetuses he had found the membrane existed in the left side as well as on the right; it had the same character of vascularity, the same attachment from the splenic flexure to the sigmoid, and it was a sort of membrane which corresponded to the veil of Treves. A girl on whom he operated for appendicitis came back three years later with symptoms and he found what was known as a double barrel shotgun constriction of the membrane, causing the colon to become kinked. These cases called for cecosigmoidoscopy.

Dr. W. D. HAINES of Cincinnati said that his work in connection with children had been confined largely to perforated appendices, to traumatic perforation or ileus. It was emergency work that did not give much time for carefully looking about for anatomical anomalies.

Dr. RICHARD A. BARR of Nashville could not understand how a membraneous process could cut much figure except in two ways: First, by causing actual mechanical obstruction, which would give us the pathology of either acute or chronic intestinal obstruction. If we had symptoms of either acute or chronic, ordinary mechanical intestinal obstruction, we knew what to do, but, second, where we had what appeared to be obstruction with pathology behind it, what were we going to do with it? It seemed to him reasonable to suppose in these cases the obstruction was apparent rather than actual, and that the gut had lost its tone, hanging over or from the peritoneum, showing some constriction, where there were connective tissue bands, and causing almost obstruction. Was that actual obstruction? If so, why didn't we have the pathology of obstruction behind it?

Dr. LOUIS GREENSFELDER of Chicago said it had been his fortune in the past year to have charge of the service at the Michael Reese Hospital, where the cases admitted to his service were all under thirteen years of age, so that he had had an excellent opportunity to observe in these children the absence or presence of Jackson's membrane. He had taken particular pains in nearly every laparotomy to observe whether in these younger children such a membrane existed. In nearly every case he was able to demonstrate the presence of such a membrane. Likewise, in cases where there were evidences of constriction the membrane was removed and some surgical procedure for its relief was undertaken.

Dr. WILLIAM FULLER of Chicago thought we would have to study this subject in adult patients in preference to the child at the operating table. He believed the surgery of most men in connection with children was emergency work, and there was no time for trying to find the existence or absence of this membrane high up in the abdomen. In acute suppurative conditions in children one was glad to get in and get out in the shortest possible time. He had never felt justified in such cases in going high up with a view to determining whether the Jackson membrane existed or not.

Some Phases of Kidney Surgery.—Dr. HENRY J. SCHERCK of St. Louis, Missouri, said that in his early work, like many others, he was inclined to suture back by one of the several methods those kidneys which were very movable. A review of the work done by him for the relief of floating kidney had been extremely unsatisfactory, and he now believed that it was indicated in but a very few cases. The objections to the operation were that we fix rigidly an organ which normally had considerable motion and further, as he had indicated, we seldom removed the symptoms for which the operation was done, for in so many patients the kidney was only one expression of a general enteroptosis, so that less benefit was derived from the operation than would have been the case had the patient been given a rest cure, fattening process and suitable binder. Perhaps in England the opinion was very different, if we were to judge by the statements

made by two English physicians who recently visited this country and who read papers on dropped kidney in a number of cities. They attributed to this condition every manner of ill from a mild neurasthenia to a pronounced insanity. An enlarged gallbladder was once mistaken by him, both anatomically and symptomatically for a dropped kidney. Nephropexy was not a popular operation among American surgeons. He did not believe that every case of stone in the kidney should be operated upon. How often had we seen at autopsy kidneys removed in which stones had probably existed without producing symptoms for many years, and the death of the patient in nowise connected with their presence? We should have, at least, some other indication and no pronounced contraindications before performing a nephrotomy. Railroad hospitals furnished more opportunities for the observation of traumatisms of the kidney than did general hospitals. While serving on the staff of the Missouri Pacific Hospital, for many years he had been called in all cases of traumatism to the kidneys. His present practice was to wait, and to be governed by the subsequent indications before operating. The majority of these cases did well and recovered without operation, provided infection did not take place. The operation could be delayed unless the patient showed symptoms due to continued loss of blood. His remarks in regard to ruptured kidney referred entirely to extraperitoneal conditions. He had never seen an intraperitoneal rupture, in which the patient was not so badly shocked and the condition associated with so much other intraabdominal injury that an operation was not to be thought of. Hematuria occurred in all cases that he had seen, with the exception of one, and in this instance the ureter was ruptured and discovered on opening a large hematoma over the kidney. Of the tumors that affected the kidney he mentioned only one, that of hypernephroma. He had had occasion to operate on quite a number. Unfortunately, in the majority of the cases the diagnosis was made rather late, and the records showed recurrences and metastases in the majority of those operated on. Clinically hypernephormata had always shown a much slower course than was usually the case with malignant disease elsewhere in the body, and unless they produced an intermittent hematuria and were perhaps discoverable by palpation, they were difficult of recognition. Practically, however, a sufficient percentage of cases operated on showed results which warranted operating as soon as we could make a diagnosis, either from symptoms or by exclusion. Persistent hematuria, either intermittent or constant, without evident explanation, had determined him in many cases, and was his present indication for an exploration, suspecting, in the presence of such symptoms hypernephroma. He had noted in many cases the predilection of hypernephroma for bone metastases. Recently a patient presented himself at the City Hospital with a growth on the frontal bone, a section of which when examined proved to be a tumor resembling hypernephroma. Palpation revealed a kidney tumor in this case. The technique he now followed in exposing the kidney was much simplified, due to the leg rest suggested by Dr. Eisendrath of Chicago, which held the patient fixed in the lumbar nephrectomy position, and to Kernig's incision, which consisted of a vertical cut by the edge of the erector spinae carried almost to the iliac crest, from which point it was curved forward towards the umbilicus and sometimes even through the rectus muscle. This incision gave much room and facilitated every step of a kidney operation. Clamps, instead of ligatures, he seldom used if they could possibly be avoided, but if used they must not remain on the pedicle too long. In dividing the kidney the silver wire passed through the kidney by means of a sliver needle and sawed through its structure undoubtedly minimized hemorrhage.

Anent the So-Called White-Slave Law.—Dr. J. T. WINDELL of Louisville stated that in the majority of the writings of those who had hitherto commented upon the Mann Act, the terms white slave and prostitute had been made to serve a synonymous and interchangeable purpose, whereas literally there existed an extremely wide divergence in the signification of each. The term prostitute was used to denote a female who, of her own volition, and for monetary consideration, promiscuously offered herself as a means for the sexual gratification of others. The word gratification was utilized in this connection instead of the more common expression sexual intercourse, the significance of which was limited to the sexual act normally performed, since the fact was well known that the activities of the average professional prostitute were not strictly confined to normal coitus, her customers being offered when occasion demanded the choice of devious other methods by which gratification might be obtained. In contradistinction to the foregoing, the word slave contained no meaning, which, by the most liberal interpretation, could be construed to indicate that the individual should be either a prostitute or a female. Literally the term slave was used to represent a person in bondage and wholly subject to the will of another, or who was held as a chattel with no freedom of independent action, and whose service was entirely under the direction and control of another. A slave, therefore, need necessarily be neither a prostitute nor a woman. A prostitute, however, must necessarily be a female, and to a certain degree her enslavement by another was possible. The combined designation white slave appeared to the writer as being exceedingly unfortunate and misleading, utterly failing to convey clearly the meaning evidently intended by those responsible for its origin, since the individual in question might be neither white nor a slave. Literally construed, however, the inference was obvious that unless the individual be white and also an undoubted slave, the protective aid of the Mann Act could not be invoked; and that a person of any other shade or color might be abducted or transported and held in abject slavery for an indefinite period without the perpetrator of the alleged crime being amenable to the provisions of the law. In the absence of mature consideration, the perusal of current so-called white slave literature invariably produced the unfortunate impression that the primary and essential object of the Mann Act was the suppression or limitation of prostitution. It was believed, however, further study would demonstrate that such an impression was at distinct variance with the facts, and that the original intent of the law was to prevent the further importation of alien women and girls into this country to be virtually sold into slavery. It was a matter of common knowledge that not many years ago the international traffic in women reached such enormous proportions, and the evil became so pernicious, that, as there existed no law by which it could be controlled, regulated, or suppressed, one became imperative for the protection of the unfortunate creatures whose lives were being bartered and enslaved. The number of young girls who had been imported into this country and ultimately sold into slavery could never be even approximately estimated, and this, too, in a presumably free country which boasted of the superior grade of intelligence, the high moral standing, and the ultra civilization of its its people. The emoluments accruing to those engaged in the international traffic became so attractive and alluring to a certain class of individuals in this country that the evil extended into practically every urban and suburban community of the United States, *i.e.* the interstate and interurban traffic in human life became so extensive that the importance was recognized of enacting an enforcible law by which, not only such international, but also the interstate traffic could be suppressed. The outcome of the deliberations of those having the matter in charge was the enactment of the present Mann Act, the ultimate purpose of which, in brief, was the eradication from the face of the earth of the interstate traffic in so-called white slaves. The number of convictions already secured amply testified to the fact that the law was being enforced by the Department of Justice. According to the literal interpretation of the law, any person who defrayed the expenses of transportation for a female from the boundaries of one country or State to another shall be deemed guilty of a felony, and may be fined or imprisoned, or both, provided the female testified before the proper authorities that she was induced or persuaded to migrate from her native country or State by the person whose money paid for her transportation, or that it was at his instigation that her transportation was effected. In not a few instances the evidence upon which conviction was secured for alleged violations of the Mann Act demonstrated that the female was a confirmed prostitute, yet this fact was considered by the court neither competent, pertinent, nor admissible, the man having been instrumental in securing interstate transportation for the woman being sufficient. An equally strange miscarriage of justice occurred in a case where two men were placed in penal servitude for accompanying a married woman to another State, and there remaining in her company for a brief period. It was difficult of understanding and appreciation how the provisions of the Mann Act could be so construed by the court as to be applicable under such circumstances. Certainly no married woman, unless she be feeble minded, or the subject of insanity, should be granted protection of the law in such a case, and especially in view of the fact that she left home of her own volition. In another case the man who secured the transportation for the woman from her native State was convicted, while the other who paid the return transportation was not even prosecuted

Social Factors in the Prevention of Insanity.—Dr. Frank P. Norbury of Springfield, Illinois, said it was through education, through the warfare of science against disease as shown in invention, research, and discovery, that the perils of physical environment were being lessened. Now let us through education—through the opportunities of disseminated knowledge—aid in the preferential social conditions which would lessen, first, the breeding of the unfit; second, develop social environments which add to and develop the moralization of mankind, develop humanitarianism, and the recognition of the social rights of others. Surely, as Baldwin says, "it is high time for society, as it becomes conscious of the principles of its own development and of its resources of control, to address itself directly to the problems of eugenics." Again, he believed concurrent with this eugenics movement we should extend the propaganda to all social conditions which were factors in the prevention of biological and sociological disorganization. The child not only had the right to be born right, but it had an inalienable right to live right, in an environment where the pursuit of happiness might be guaranteed, and where society was in duty bound to make his life compatible with the things that were worth while. "Society and the individual are not two entities, two forces acting separately, two enemies making forced and grudging concessions." No, "on the contrary, they are two sides of a growing whole, in which the welfare and advance of the one, ministers to the welfare and progress of the other. There is but one human interest, when all is said, and this is both individual and social." Our duty was to combat all social conditions which contributed to and were a part of the determining factors in the cause of mental disorders. People were what they were by virtue of inheritance and social experience. The insane were what they were by inheritance, social experience, and the exigencies of disease and accident. Man's entire being was social, and he invaded the life of others and was himself invaded by them. The physician's duty was to bear this in mind, and in his altruism, which was inherent to his profession, remember it was a vital demand of our nature to love our neighbor as ourself. This meant the growth of social consciousness—the greatest factor in the prevention of mental disease.

The Medical Profession and Race Betterment.—Dr. John D. Trawick of Louisville, Kentucky, said we could have no quarrel with those who contended that environment was the essential to development simply because there were mental, physical, and moral potentialities within every nature which had never been called into use. Use and necessity had developed what might otherwise have been latent and undeveloped, but there could have been nothing developed spontaneously by environment had nothing been given in the inheritance. Since the enthusiasm was subsiding which met the first enactment of the law calling for vasectomy we were beginning to see that undoubtedly some good was being accomplished, namely, in the actual prevention of the power for procreation of that element of unfit upon whom vasectomy had been done, but there arose an ethical social error that was fearfully significant, that same individual mutilated though he be, was still a potential active carrier of venereal disease now absolutely cut loose from moral restraint by the knowledge taught him at the time the operation was done that he might indulge in all his libertine passion without fear of procreation. Disease, and crime, and immorality were so clearly related in their biological, sociological aspects that it was no wonder the enthusiast might sometimes hope to check all together by one sweeping mandate of the law. He was convinced that with the thorough awakening referred to of the eugenic conscience of the physicians of the land, the statutes already enacted would be found sufficient for the present need, and more time and money would be devoted to investigation, to research, to education, and less to the maintenance of legislators who in the very nature of things could not be expected to be comprehensively informed. The physician had it within his power to help create a moral tone in society which was a stronger force for good than all law, because law that was effective was law that society demanded for its own protection. These "legislative inroads into the realms of morals" must continue to be effective *only in part* until we had learned to resist immorality with morality. Not only must we teach the young man the danger to health that lies in the venereal diseases, but deeper and more abiding must the social ethical principle be stressed. In fact, were this new science of eugenics limited to its biological phase, dependent merely upon the principles of heredity for application to human development, it was doubtful if much could be predicted from the study. There would be a clearer line drawn between necessary knowledge and indiscreet, hurtful anticipation. If we stood, therefore, for the best there was to be perpetuated in the generations to come we must teach the teachers, instruct those who must instruct, that our children may not merely escape the perils of immorality, but more, may have a high eugenical ideal so that their loving could not be base.

Medical Ethics and Social Hygiene.—Dr. Hugh Cabot of Boston, Massachusetts, uttered a word of warning about the effect of laws passed to this end. He had seen of late a flood of ill advised legislation requiring medical certificates which physicians knew to be wholly worthless. The average practitioner was not, and perhaps never would be, competent to diagnose with certainty the cure of a gonococcus infection or syphilis. It required, and might always require, the services of an expert. To require certificates was to foster fraud. The individual who wanted to know could always get the facts from the public clinic or the private expert. No contracting party to a marriage need remain in doubt on this question if he or she wanted an answer. There was one other phase of this question which often put the physician in a difficult position. What was his duty when he found a married woman infected with one of these diseases? It had been the custom to conceal from her the facts. If we communicated them we might disrupt a household and bring great suffering on children who should be protected. We had often, therefore, accepted what seemed the lesser evil and deceived the wife. This course he believed to be unsound and unethical. The woman came to us in good faith asking for the truth, and to the truth she was entitled. We might refuse to treat her, but we might not refuse the facts. They must be the facts beyond peradventure and we were not required to guess as to the origin of the infection. On this point we might have but little evidence. The responsibility for the result was not on our shoulders, and we could not assume it if we would. In the past we had been parties to a crime. An enlightened public opinion would not tolerate quibbling in this matter, and would demand that all be treated alike. No longer could the women in this country be treated as children. We must hew to the line, let the chips fall where they might. His tale was done. He had offered what he believed to be a sound answer to the riddle. The dignity of the profession demanded that the doctrine of privileged communications be rigidly adhered to. We must regard each individual as equally entitled to the facts if he wanted them. Justice could know no sex. Our knowledge of the damage wrought by these diseases we must hold to be a public trust which it was our duty to administer so that an enlightened public opinion might apply the remedy.

Various Aspects of the Social Hygiene Movement.—Dr. R. S. Yarros of Chicago said first of all, as physicains we had been rather tardy in furnishing the instructions that the public required and was clamoring for. If we wanted to meet this situation fairly we must give the public the necessary information. It was up to us to instruct the people of the dangers of venereal diseases. The women had the task of spreading the information in trying to solve this very complex problem. Our aim was to abolish this most ancient of evils, prostitution, and its consequent diseases. We must make a beginning if we expect to ever accomplish an ending. In the city of New York there were about 100,000 cases, and about the same in Chicago. In Vienna and the larger cities of the world there were probably more. It was not the exact number of cases of gonorrhea that concerned us most, but its increasing prevalence in all cities, large and small. It should be the duty of parents to instruct their children of the dangers of these diseases, but first we, as physicians, must instruct the parents. These diseases attacked young men 18 to 25 years of age, mainly, at which time the self-control and disease-resisting powers were at the lowest point. This was of social importance. There was a general tendency to think that this disease was mainly confined to women of the lower classes, but this was not true. It was very important for every one of us, men and women, to enlighten the public in every possible way. Half of the operations on women in hospitals could be traced to gonorrhea. Hospitals, insane asylums, institutions were filled with patients suffering from these diseases, and we had not sufficiently awakened to it. Where did these diseases come from? We had traced the sources of typhoid, malaria, tuberculosis, but we had not taken up the work of discovering the sources of gonorrhea and syphilis, which unfortunately were not simple. Physicians were prone to touch lightly on it. We must study the source of prostitution and be ready sooner or later to suggest methods of eradication. Another thing facing the women was to do away with the white slave traffic. Poverty meant poor living, poor everything, and we must

teach them the importance of understanding these conditions. We must have certain laws to guide us. Laws were passed requiring people to put up placards showing the presence in their homes of typhoid, etc. It was thought at that time the people would not do it, and that the physicians would lie, but we all knew the importance of it. We had to take up some such measures in this question. If a man married a woman of fine character he should have a certificate showing he was clean. The law should be an essential point.

Dr. Henry B. Favill of Chicago agreed with Dr. Yarros that we should never end unless we began. In the study of psychology there were two divisions, the complex psychology of the monkey and that of children. This question of instinct was so closely related to the question of social life and social hygiene that until we had studied it in its fundamental conditions we could not be considered as efficient on the relationship of sex to society. The special subject of heredity, at present, was only reasonably tangible. The results from biological studies at this time were comparatively negative. There would be a wider chasm between the various grades in human society in the future than there was today. Therefore, we should not have the idea that eugenics were going to be crowned with universal perfection. All sorts of questions arose in this connection. The question of marriage was the most frequent question before the physician. A man had such and such a family history and went to a physician he knew, and who knew of mental aberrations in his past, and what was his attitude? The physician essayed an adjustment on that marriage. What was his right based on such intelligence? It was a question which we dealt with casually on the whole. Again, we should find in connection with this movement that there must be a reaction of the progress which we were apparently making as a result of our enthusiasm. We were going faster than good judgment dictated. But even amongst the people of thoroughly definite purpose and of strong intellectual acumen, we were going to see a reaction against the tenor which we had adopted. There had been recited here the fact that vasectomy, which was thought to be a great achievement in sociological studies, was now in disrepute. He alone refused to sign this law when it was first proposed. He only foresaw the present situation. And something was going to take place with the Mann law. The Mann law had a legislative and highly moral purpose, and we all marveled about it. It was an instrument of good in so far as certain phases went, but in so far as conditions went in this country it was merely an instrument of blackleg. He knew of so many instances, that it was perfectly astounding what it could do as a pernicious influence. It was going to be nullified or reconstructed.

Dr. C. B. Burr of Flint, Michigan, said that readjustment would come to pass when the people considered means which were reformatory and when the people realized that they were in reality. Just as when the people got together for economical reasons, as in the home, municipalities, federation, etc., so would they resolve themselves into a unit to bring about these ends. Just as soon as they realized the gravity of it, the effectiveness would be greater than just one or two going alone. There were miscarriages of the laws, but the laws should not be condemned on that account. That it should be called a "White Slave Law" was rather strange, and that no provision should have been extended to cover other colors than white, was also strange. The law implied that it covered all women of whatever color or condition, but it did not.

Dr. Albert E. Sterne of Indianapolis said the time to begin this educational movement was at the time when the individual composition of the community was manifested where nature pointed the way, at the period when education was easiest attained; that was when nature passed from homo- to hetero-sex. Nearly all of us in our earlier years were homo-sex. Later we learned what we should do and what we should not do. This knowledge was not acquired through instinct. When we changed from homo- to hetero-sex was the time to tell the child what it all meant. It was easily done in the home and school. In later years it was entirely too late. If that were done, it seemed to him that we could bring about in the future generations a new viewpoint. The dual condition of morality in society was due to the good women; they permitted the young men to walk along different paths. If the good women said that they all should walk along this line, they would all do it.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 6, 1913.

The President, Dr. William M. Polk, in the Chair.

The scientific session was under the auspices of the Section on Laryngology and Rhinology.

Intracranial Complications of Accessory Sinus Suppuration.—Dr. John McCoy read this paper, the only one of the evening. He discussed the subject under the following general headings: bacteriology, suppuration of the sinuses, and extension to the endocranium, methods of extension, types of endocranial suppuration, the types from individual accessory sinuses, diagnosis, symptoms and treatment of types, and closed with general conclusions. The accessory sinuses of the nose consisted of three fairly large sized bone cavities, and one series of small bone cavities, accessory to the nasal cavity of each side. These were known respectively as the maxillary sinus or antrum of Highmore, the frontal sinus, the sphenoidal sinus, and the ethmoid bone cells. The last three were directly under and separated from the cavity of the cranium in a good portion of their situation by a thin plate of bone and, in some cases, even this thin plate of bone was not present in certain places. These sinuses were lined throughout with a mucous membrane periosteum which was continuous with that of the nasal cavity and which furnished nourishment to the bony structures. In three of the accessory sinuses under consideration this was an important factor to be considered. The blood supply of the mucosa of the maxillary sinus and antrum was furnished from a branch of the nasal artery. The walls of the antrum received a double blood supply as both sides were covered with periosteum. The frontal sinus received its blood supply through the ostium from branches of the sphenopalatine artery. The venous circulation anastomosed in several directions. Dr. McCoy told of the arterial blood supply of the sphenoid sinus, of the ethmoid cells, etc., and stated that a study of the position and blood supply of these sinuses would give them an idea of the method and ease with which infection could penetrate the endocranium, as shown by schematic illustrations. It had been found on examination of specimens from normal nasal cavities that there was present a variety of germs, such as the pneumococcus and the micrococcus pyogenes, the bacillus of Friedlander, the bacillus proteus and the bacillus aurens. In acute and chronic catarrhal conditions of the nose there were found the micrococcus catarrhalis, the bacillus coryza, and the bacillus of Friedlander. It had been found impossible to examine the normal accessory sinuses without contamination of the swab, but on examination of the accessory sinuses of 36 cadavers, made within two and a half hours after death, all of these sinuses were found to be sterile. In another series of cases, on examination of 28 cadavers, within eight to twenty-four hours after death, thirteen were found quite sterile. In the others the pneumococcus and micrococcus pyogenes were found. In an examination of the secretion from 22 cases of acute and chronic inflammation of the nasal accessory sinuses, pneumococci were found in 36 per cent., streptococcus pyogenes in 40 per cent. and the micrococcus pyogenes in 45 per cent. In 43 cases of maxillary sinusitis the pneumococcus was found in 13, the streptococcus in 33, the micrococcus pyogenes in 34, the bacillus influenza in one, tubercle bacillus in one, and the micrococcus catarrhalis in two. It was evident, therefore, that a variety of organisms might be found in the healthy nasal cavities of most individuals, and in the nasal accessory sinuses of persons otherwise healthy, but who had chronic catarrh or muco-purulent inflammation of the mucous membranes. The chief organisms which demanded their attention were the pyogenic cocci, the pneumococcus, the micrococcus catarrhalis, the influenza bacillus, and the meningococcus. Suppurative inflammations of the accessory sinuses were the direct result of bacterial invasion which was usually purely local, but it had been demonstrated that in scarlet fever an infection might result through the blood or lymph channels. The spread of the suppuration from the accessory sinuses to the endocranium was dependent upon several factors, among which might be mentioned deficient drainage from the accessory sinus due to absolute or relative impermeability of its excretory duct, the virulence of the enclosed pus, or congenital defects in the bony walls of the accessory sinuses. The avennes by which the infection traveled to the endocranium were in general by direct extension as the result of carious or a cario-necrotic condition of the bony walls, or complete destruction and perforation of the same, or by way of the venous channels

which passed directly from the mucosa of the sinuses through the bony walls to the dura, or indirectly from the veins of the sinuses to the orbit, then by way of the ophthalmic veins to the cavernous sinus, and possibly by way of the lymph vessels. Before considering the individual sinuses, Dr McCoy took up the subject of the nasal etiology of cerebrospinal meningitis. He spoke of the epidemic, the pneumococcal and influenzal meningitis, as well as of the pyogenic and suppurative meningitis. In epidemic cerebrospinal meningitis, and in sporadic cases of this disease, due to the meningococcus, it was generally accepted that the infection reached the central nervous system by way of the lymphatics from the nasopharynx. In influenzal pneumococcal meningitis, it was probable that the infection was carried to the central nervous system from an infected condition of the nasopharynx. There was a possibility that in some cases the infection was carried by the lymphatics of the nasal mucosa through the cribriform plate. In the pyogenic cases, and some of the pneumococcal and influenzal cases, the infection found entrance to the meninges by way of direct extension through caries of the bony plate of the suppurating accessory sinus or by way of the blood supply in the suppurating accessory sinuses.

Types of Intracranial Infection from the Individual Accessory Sinuses.—The antrum was less likely to produce intracranial suppuration and when it did it was usually as a result of extension of the infection into the orbit, into the ophthalmic vein and thence into the cavernous sinus. Following suppuration in the frontal sinus there had been a number of well authenticated cases reported of intracranial involvement. Brain abscess was the most common intracranial complication of frontal sinus infection; the next most common was a purulent leptomeningitis, the next was extradural abscess, and the next was sinus thrombosis. Direct extension through carious perforation of the posterior wall was the most common avenue of infection, and the next common method of extension to the endocranium was by way of a thrombophlebitis, extending from the sinus mucosa through the bone and anastomosing with the dural veins.

Special Consideration of the Ethmoid Cells.—In a series of 25 cases of intracranial complication, by way of the ethmoid cells, there were found abscess of the brain in 11 cases. Suppurative meningitis was found in 12 cases. Uncomplicated ethmoid suppuration in these cases was very uncommon, and mostly combined with suppuration of the frontal and maxillary sinuses. The avenue of infection was mostly by direct extension. Eleven out of the 25 of the intracranial complications followed acute ethmoiditis, whereas the endocranial complications from the frontal were mostly from chronic suppuration. The intracranial complications following sphenoid suppuration were, in a large proportion of cases meningitis and thrombosis of the cavernous sinus.

Abscess of the frontal lobe he divided into latent and manifest stages. There were no symptoms which indicated the incipiency of pus foci in the brain. In the manifest stage the symptoms were at first general, anemia, loss of weight, loss of appetite and psychic depression, later followed by pronounced brain symptoms, such as headache, vomiting, dullness and drowsiness. Two cases of this condition were reported in detail. After considering the four stages of thrombosis of the superior longitudinal sinus (Killian) and cavernous sinus thrombosis, Dr. McCoy said that the treatment of these conditions accomplished but little, and he referred to the operative cases of Dwight and Hartley. In conclusion he said that he felt, in looking over the reports of the older cases, that incomplete surgery was probably the cause in many of these cases. They had progressed to a very large extent in their present radical measures and that the pendulum had swung to a point where too complete surgery might be responsible for some of these cases. He felt that they were just opening the door leading to the hitherto dark closet of intracranial suppurations, and that a short time perhaps would suffice to throw a flood of light in this recess, and would make it another bright spot added to the illustrious accomplishments of rhinological and otological surgery.

Dr. Ross H. Skillern of Philadelphia said that a comprehensive discussion of the admirable essay that they had just heard lent itself to such a broad scope that it would be presumptious for him to even attempt it. There was however one phase which to the general medical man must excite more or less interest and that was the possibility of successfully combating these intracranial complications after they had once occurred. Now in the very beginning it must be stated that cases rarely ran the same course being dependent upon many extingencies such as the general condition of the patient, the virulence of the infecting microorganisms, the duration of the affection, etc., etc., but despite these, in the eventuality of a cerebral complication it was always possible to at least formulate a definite line of treatment. With this statement in mind he asked them to consider the sinuses from their individual standpoints.

The Maxillary Sinus.—This was the only accessory nasal cavity that did not border directly upon the brain; consequently one heard little of cerebral affections resulting from diseases of this structure. Despite this fact cases had occasionally been reported and occurred in the following manner: The bony walls became affected and the disease spread by continuity up the ascending process of the superior maxillary until the frontal, ethmoid and finally the meninges were reached. As far as he was able to learn this form had invariably started in the root of a decaying tooth. Cerebral complications might also occur indirectly through the medium of the orbital structures, first causing a thrombophlebitis of the ophthalmic vein which spread to the cavernous sinus. In the first instance any therapeutic procedure was practically hopeless as it was impossible to resect so much bone with any degree of success. The condition had advanced too far for surgical interference but could easily have been prevented when it was limited to the walls of the sinus. The orbital condition offered more hope by an immediate operation.

The Frontal Sinus.—All varieties of intracranial complications had followed both the acute and chronic form of frontal sinusitis and until comparatively recently with fatal terminations. Mortality might be from the following: 1. Thrombophlebitis. 2. Pachymeningitis, 3. Serous meningitis. 4. Extradural abcess. 5. Brain abcess. Thrombophlebitis had the least percentages of cure in those operated upon and brain abscess the greatest after surgical intervention. One prodromal symptom was of the greatest diagnostic importance, that was, the sudden appearance of edema of the upper eye lid during the course of a chronic frontal sinusitis. According to von Eichen this denoted the beginning of cerebral invasion and demanded instant surgical intervention. Regarding the condition of the patient as to the advisability of an operation, if they recalled the well known case of Killian in which the patient was unconscious with Cheyne-Stokes breathing, absolute left sided paralysis, and all the symptoms of being in extremis, the operation showing an abscess in the frontal lobe containing 5 oz. of fetid pus, the patient recovering with normal faculties, it would be seen that even a late operation was not without hope. The ethmoid labyrinth played rather a peculiar rôle as far as intracranial complications were concerned. On account of the foramina in the cerebral plate, infection could occur either by primary direct extension through these channels along the sheaths of the olfactory nerves or indirectly as in the true sinuses. Despite this portal of double entry complications arising in this structure alone were rare judging from the paucity of reported cases. In the event, however, of its occurence particularly if the progress of infection be slow as from a pyocele, a complete exenteration of the ethmoid labyrinth either intra or extranasally would offer the only hope of a cure.

The Sphenoid Sinus.—One would be inclined to think that on account of the deep anatomical situation of this sinus, once a complication occurred, nothing further could be done. Such however, was far from being the truth as the reports of several apparently hopeless cases which were operated on with prompt recovery had proven. He had had the opportunity of seeing several with beginning meningeal symptoms completely recover after the sphenoid on the affected side was opened intranasally to its fullest extent. Taking a brief retrospect of the entire subject it was plain that the only hope of successful treatment lay in the early recognition of impending complications with the earliest possible appropriate surgical intervention.

Dr. Wolff Freudenthal, said that the subject of endocranial infection from sinus disease was perhaps the most important one in the whole domain of rhinology. He agreed with the speaker that an infection from the antrum was very rare, but when it did occur, it was invariably fatal. He had seen, however, quite a number of infections, perhaps half a dozen, that occurred after the extraction of teeth. Invariably the infection could be traced to a lack of asepsis on the part of the dentist. Here they could differentiate two kinds of infection, viz., the one spreading by way of the lymphatics directly to the cranial cavity, and the other causing a purulent sinusitis in the antrum and thence spreading upward. The region from which endocranial involvement most often occurred was the frontal sinus, and it was generally the vicinty of the frontal lobe that was affected. In order to prevent fatalities they had

to decide when to operate. That was the salient point which might occasionally prove to be a difficult task. He gave a few examples. The first case was published in a paper read before the International Medical Congress at Budapest, five years ago. The patient was a woman of twenty-five, with acute suppuration of the frontal sinus. There was retention of pus, headache, etc. The middle turbinate body was not removed because her family physician objected. Several weeks afterward she returned with edema of the eye and cheek, vomiting, high fever, etc. She was operated upon, and an abscess of the frontal sinus was found. She died four days later. This patient's life could have been saved by an early operation on the frontal sinus, or perhaps by the simple removal of the turbinal. On the other hand, they should think twice before recommending a radical operation, for a radical operation did not always mean a radical cure, and fatalities would occur when one least expected them. Last year he demonstrated before a local medical Society ten consecutive cases operated upon for empyema of the frontal sinus. All had healed in the most satisfactory way. The next patient, a strong healthy woman of twenty-seven, died of postoperative meningitis. It was true that an operation had been advised by him a year and a half before consent was given for the operation to be performed. But the question arose: would not the patient have survived if the operation had been performed at the time suggested, or could she have lived on for years to come with the defect of the cerebral wall of the frontal sinus found at the operation? There were possibilities in each direction. In regard to the propagation of the infection, they were often at a loss to explain it. Thus, Hansberg published a case in which the right frontal sinus was affected (pus). The patient died, and it was expected that an abscess would be found in the right frontal lobe. Instead, an old abscess was present in the *left* lobe. The history of a similar case was given to him by Professor Herzfeld of Berlin. A man of fifty-seven who had repeatedly received traumas at the inner angle of the right eye, was operated upon by Herzfeld for a long-standing fistula. The frontal sinuses were exposed and a defect of the inner wall of the *left* frontal sinus was detected, i. e., the side affected only secondarily. In closing, he wanted to repeat that he had operated on a large number of cases of frontal sinusitis with a remarkably low death rate. The operation was a most satisfactory one, and yet it was his firm conviction that radical operations on the frontal sinus should be undertaken only after very careful deliberation.

Dr. Cornelius G. Coakley reported two cases of extradural abscess. He had no cases of intradural abscess to report. Among his cases of serous meningitis but one recovered; this was a border line case between a serous meningitis and a true meningitis. He had seen two cases of brain abscess and both resulted fatally. He had seen three cases of sinus thrombosis; two were of the septic type and died, the other making a recovery. He had seen at least 50 cases of leptomeningtis and, in many cases, there were no evidences of suppuration in the ear. True cases of meningitis as determined by the clowdy fluid under pressure, with large number of cells, with the pneumococcus, streptococcus, or staphylococcus, in his experience never got well. These cases ran a course of about five days and terminated fatally. Some of these patients have a slow pulse, about 40, with a temperature of 102° or 103° F., headaches and these cases sometimes do get well. The slow pulse was due to the pressure, and often was associated with orbital abscesses. Before any of this operative work it was his custom to place the patient on seven and half grains of urotropin, four times a day. This seemed to lessen the chances of the infection traveling up into the brain and also lessened cerebral complications.

Dr. Harmon Smith said that he was greatly interested in the statistics given in the paper both as regards the frequency of meningeal disturbance incident to sinusitis, also in the paths of infection and in the variety of the microorganisms producing it. While this was of peculiar interest it afforded no solution to the problem by suggesting treatment or the means of prevention. He believed that the majority of meningeal disturbances followed the radical disturbance of a chronic sinusitis where the resistance of the tissues nearest the brain had been lowered by long contact with pus and that drainage was insufficient to bring away the pus collected between the congested tissues and the dura. Extensive operative procedures opened up new avenues of infection and disturbed too extensive an area for the resistance of the superimposed tissues to withstand. He believed that just sufficient operative procedure should be instituted to drain away the pus to prevent pressure symptoms and thereby permit the thin lamina of bone intermediate between the frontal, ethmoidal and sphenoidal sinuses and the brain to regain some of its resistance before a radical operation was performed. The bony structure would rehabilitate itself after pressure had been reduced just as a great many of the mastoid cells distant from the focus of infection regain their healthful condition, even when long subjected to contact with pus. Dr. Smith said that the dura frequently withstood contact with pus for a long while without meningeal disturbances, as had been demonstrated in numerous instances in mastoid cases where necrotic bone was removed exposing a comparatively large area of dura. If the neurologist or the rhinologist could determine the exact area of the meninges exposed to the purulent condition that area could be successfully relieved by operative procedure and no subsequent trouble would result any more than happened in the case of the dura exposed in mastoid conditions, but the difficulty had been to determine at what point the dura was in contact with pus, whether in the frontal, ethmoidal, or sphenoidal regions. Wherever a frontal sinus had been of sufficiently long standing to warrant extensive operative procedure the anterior ethmoidal cells were always involved and in the majority of instances the posterior ethmoidal and sphenoidal cells as well. Dr. Smith reported four fatalities, three of which followed radical external sinus operation, in all of which there had been necrosis of the ethmoidal cells into the orbit as well as of the floor of the frontal sinus and he believed in each of these instances the meningitis which followed was due to too radical operative procedure at the time and that if he had given only sufficient drainage to withdraw the pus away from the meninges, permitting that area to re-establish its health and had followed this at some subsequent time by a radical operation, his patients would have escaped fatal meningitis. In another instance there had been an abscess of the frontal lobe of the brain in a child as the result of injury, and a probe could be passed up between the frontal lobes into the abscess through the cribriform plate, which had been destroyed. The child lived for many weeks with this abscess present and ultimately died of pneumonia, although there had been free drainage from the abscess through the cribiform plate, which showed conclusively that the dura could withstand the presence of pus for a long period without producing fatal meningitis.

STATE BOARD EXAMINATION QUESTIONS.

Alabama State Board of Medical Examiners.

July 8, 9 10, *and* 11, 1913.

ANATOMY.

1. How are cervical, thoracic, and lumbar vertebræ distinguished? Give the characteristics of the seventh cervical vertebra.
2. To what class of joints does the elbow belong? What bones enter into its formation and name three of its ligaments.
3. Name the muscles of the anterior tibial region, and describe the tibialis anticus.
4. Describe a nerve fiber.
5. Give the origin and course of the musculospiral nerve.
6. Describe briefly the structure of arteries and veins.
7. Name the branches of the external carotid artery. Give the origin, course, and distribution of the lingual artery.
8. Give in a general way the flow of blood through the systemic veins.
9. Name the terminal lymphatic vessels, and locate and describe the receptaculum chyli.
10. Give the structure of the stomach.

PHYSIOLOGY.

1. Discuss at length the means and methods employed by the human organism in protecting itself against infectious diseases.
2. What phenomena follow injury to and section of the pneumogastric nerve?
3. Discuss the function of the mucosa of the respiratory tract.
4. Discuss the distribution and function of the cerebrospinal fluid.
5. Discuss aphasia.
6. Discuss hunger and thirst.
7. How is the automatic action of the heart muscle supposed to be maintained?
8. Discuss the absorption of ingested fats.
9. What gneral conditions influence blood-pressure and blood-velocity?
10. Discuss the origin and significance of urea.

CHEMISTRY.

1. Define "chemical change" and "physical change."
2. Name, describe, and give source of two elements used in their elementary forms in medicine.
3. Describe hydrogen—how does it occur and how may it be prepared?
4. Describe carbon dioxide—give formula and state what relation it bears to the respiratory changes.
5. What is phenol—give properties and source?
6. In what tissue is iron an important constituent, and how is it combined therein?
7. Define "proteid" and name three proteids found in the human body.
8. Describe the method for the quantitative determination of urea.
9. How may occult blood be detected in the feces?
10. What are ptomaines and how may they be introduced into the body?

ANSWERS.

ANATOMY.

1. The *cervical vertebræ* are distinguished by possessing a foramen in the transverse process. Further, they are smaller than those in the other regions; they have no facets for the ribs; the spinous processes are generally short and bifid; the spinal foramen is large and triangular; the superior articular process is directed upward and backward, and the inferior articular process is directed downward and forward.

The *thoracic vertebræ* have a heart-shaped body with a facet or demi-facet on each side for articulation with a rib; the laminæ are broad and deep; the spinous process is long and points downward; the transverse processes are long and articulate with the tubercle of a rib; the superior articular process is directed backward and slightly outward; the inferior articulate process is directed forward and slightly inward; the spinal foramen is smaller and circular.

The *dorsal vertebræ* have a large body, wider transversely, and with no facet or demi-facet; the laminæ are short and thick; the spinous process is horizontal; the transverse processes are "rudimentary"; the superior articular process is directed inward and slightly backward; the inferior articular process is directed outward and slightly forward; the spinal foramen is larger, and triangular.

The *seventh cervical vertebra* is characterized by possessing a very long and prominent spinous process which is thick, not bifurcated, and is nearly horizontal.

2. The *elbow-joint* is a ginglimus or hinge-joint. The *bones* which enter into its formation are the trochlea of the humerus, the greater sigmoid of the ulna, and the head of the radius. *Three of its ligaments* are: Anterior, posterior, and internal lateral.

3. *Muscles of the anterior tibial region* are: Tibialis anticus, Extensor proprius hallucis, Extensor longus digitorum, and the Peroneus tertius.

The *Tibialis Anticus* is situated on the outer side of the tibia. It arises from the outer tuberosity and upper two-thirds of the external surface of the shaft of the tibia, from the interosseous membrane and from the intermuscular septum; it is inserted into the inner and under surface of the internal cuneiform bone and the base of the metatarsal bone of the great toe. It is supplied by the anterior tibial nerve; it flexes the foot at the ankle-joint.

4. NERVE FIBERS.—1. *Medullated Fibers.*—"Medullated nerve fibers usually consist of three parts: (*a*) axis cylinder, (*b*) medullary sheath, (*c*) neurilemma. An *axis cylinder* is a cell process that carries an impulse away from the nerve cell. It is a slender cytoplasmic process and may be very long, as is the case with the motor fibers that come from nerve cells in the anterior horn of the spinal cord and extend, without interruption, to muscles in the distal parts of the limbs. The axis cylinder presents a longitudinal striation, a fibrillar structure, that is supposed to be continuous with the cytoplasmic striation of the cell body. The fibrils are imbedded in a fluid protoplasmic substance, the neuroplasm, and the whole surrounded by a delicate membrane, the exolemma. Implantation cone is an elevation that is sometimes present at the junction of the axis cylinder and cell body. The *medullary sheath* (white sheath of Schwann) is a covering to the axis cylinder. This sheath never extends to the nerve cell, but begins a little distance from it. Nodes of Ranvier are constrictions of this sheath at regular intervals. The smaller the fiber the greater the distance between these nodes. Long fibers are slender, with long distance between the nodes; short fibers are coarse, with short distance between nodes. The *neurilemma* is a thin structureless membrane that surrounds the medullary sheath. An oval nucleus is present in this sheath, midway between the nodes of Ranvier. At each node the neurilemma is constricted and touches the axis cylinder, which in turn may be slightly thickened at this point and may give off a collateral. Medullated nerve fibers with a neurillemma are found in the cranial and spinal nerves. Medullated fibers without a neurilemma are found in the brain and spinal cord. The neurilemma gives great strength to the fibers. Its absence in the brain and cord accounts for the pulpy soft nature of this tissue."

"*Non-medullated nerve fibers* with a neurilemma, but without a medullary sheath, mingle with the medullated fibers. The sympathetic system consists largely of non-medullated fibers. Terminal branched endings of an axis cylinder, called neuropodia, have neither medullary sheath nor neurilemma. The axis cylinder, just as it leaves its nerve cell, is likewise uncovered." (Hill's *Histology.*)

5. The *musculospiral nerve* is derived from the posterior cord of the brachial plexus, and originates from the sixth, seventh, and eighth cranial nerves. At first it is behind the axillary and brachial arteries; it winds around the humerus in the musculospiral groove with the superior profunda artery; it pierces the triceps muscle. At the elbow joint it divides into the radial and posterior interosseous nerves. It supplies the Triceps, Anconeus, Supinator longus, Brachialis anticus, and Extensor carpi radialis longior muscles.

6. An *artery* consists of three coats: The tunica interna, or internal coat; the tunica media, or middle coat, and the tunica adventitia, or external coat. The internal coat consists of a basement membrane, on which is a layer of endothelial cells. The middle coat consists of involuntary muscle fibers, between the layers of which are some elastic fibers. The external coat consists of connective tissue (white fibrous and yellow elastic). Between the two outer coats is an elastic membrane.

The *veins* also have three coats, but the external coat is thicker than the middle coat (the opposite condition prevails in the arteries); the veins often have valves.

7. *The branches of the external carotid artery* are: Superior thyroid, lingual, facial, occipital, posterior auricular, ascending pharyngeal, superficial temporal, and internal maxillary.

The *lingual artery* arises from the external carotid artery; it runs upward and inward to the great cornu of the hyoid bone, then downward and forward beneath the hyoglossus muscle; it then runs perpendicularly to the tongue, and turns forward on the under surface of the tongue, going almost to the tip of the tongue under the name of the ranine artery.

8. "The *systemic veins* return blood to the right auricle of the heart through the superior vena cava, the inferior vena cava, and the coronary sinus. The two first named receive blood from the veins of the body and limbs and from most of the solid viscera. The coronary sinus receives blood from the veins of the walls of the heart alone. The veins of the body wall and limbs form two groups—(1) the superficial veins; (2) the deep veins. The *superficial veins*, which commence in the capillaries of the skin and subcutaneous tissues, lie in the superficial fascia, and are very numerous. They frequently anastomose with one another, and they also communicate with the deep veins, in which, after piercing the deep fascia, they terminate. They may or may not accompany superficial arteries. The *deep veins* accompany arteries, and are known as venæ comites. The large arteries have only one accompanying vein, but with the medium-sized and small arteries there are usually two venæ comites, which freely anastomose with each other by short transverse branches of communication. *Visceral veins* usually accompany the arteries which supply viscera in the head, neck, thorax, and abdomen. As a rule there is only one vein with each visceral artery, and, with the exception of those which enter into the formation of the portal system they terminate in the deep systemic veins." (Cunningham's *Anatomy.*)

9. The *terminal lymphatic vessels* are the thoracic duct and the right lymphatic duct.

The *receptaculum chyli* is a triangular pouch-like structure which forms the commencement of the thoracic duct. It is situated on the front of the bodies of the first and second lumbar vertebræ, to the right of and a little behind the aorta, and by the side of the right crus of the diaphragm.

10. "The *wall of the stomach* consists of four coats, which, enumerated from without in, are: serous, muscular,

areolar, or submucous, and mucous membrane. The *serous coat* is a layer which is derived from the peritoneum. It is deficient only along the lines of the lesser and greater curvatures. The *muscular coat* consists of three layers of plain muscular fibers. Of these the bundles of the outer layer run longitudinally, those of the middle layer circularly, and those of the inner layer obliquely. The longitudinal and circular bundles become thicker and stronger toward the pylorus, at which they pass into the corresponding layers of the small intestine; at the pylorus itself the circular layer is greatly thickened to form the sphincter muscle. The oblique fibers are only present in the left or cardiac part of the stomach. The *areolar or submucous* coat is a layer of areolar tissue, which serves to unite the mucous membrane loosely to the muscular coat; in it ramify the larger branches of the blood vessels and lymphatics. The *mucous membrane* is a soft thick layer, generally somewhat corrugated in the empty condition of the organ. Its inner surface is covered by long columnar epithelium cells, all of which secrete mucus. They are prolonged into the ducts of the glands, but when these divide to form the tubules the cells become shorter (cubical). The thickness of the mucous membrane is due to the fact that it is largely made up of long tubular glands the mucous membrane is formed of retiform with glands, which open upon the inner surface. Between the some lymphoid tissue. Externally it is bounded by the muscularis mucosæ, which consists of an external longitudinal and an inner circular layer of plain muscular fibers." (Schäfer's *Essentials of Histology.*)

PHYSIOLOGY.

1. The acidity of the gastric juice, the urine, and the vaginal secretion; the alkalinity of the blood; the bactericidal action of the blood and lymph; the agglutinating action of the blood; and the general power of the body to produce antitoxins.

2. *Injury to or irritation of the pneumogastric nerve* may cause: Palpitation, vomiting, coughing, a sense of suffocation, hoarseness, aphonia, laryngeal paralysis. *Division of one pneumogastric nerve* may cause few or no symptoms; but division of both nerves is followed by death due to paralysis of the laryngeal muscles.

3. The *mucosa of the respiratory tract* serves: To warm the inspired air, to moisten the inspired air, to remove injurious substances from the inspired air.

4. The *cerebrospinal fluid* is present in the ventricles of the brain, in the central canal of the spinal cord, and in the subarachnoid space surrounding the brain and the spinal cord. Its *function* is to protect the brain from injury and the circle of Willis from compression; it forms a water cushion on which the middle and posterior parts of the brain may rest; it minimizes shocks.

5. "The speech areas, four in number and in kind, are in the left hemisphere in righthanded persons and in the right in lefthanded persons. There are two types of aphasia, which is the loss of the power of speech, known as motor and sensory aphasia. The motor speech center lies in the posterior part of the third frontal convolution (Broca's convolution), just in front of the center of the muscles of speech (hypoglossal and facial nerve centers). A lesion of the motor speech center causes motor aphasia, in which there is a loss of the word-forming power, although the tongue is movable and the patient may understand spoken and written language and knows what he wants to say. It is as if memory of the motor combinations essential to produce speech were lost.

"The power of writing is usually lost with motor speech. The probable location of its cortical center is in the posterior two-thirds of the first, and perhaps in the second, temporal convolution. A lesion here causes 'word deafness,' a sensory aphasia in which the memory of the sounds of words is lost so that they are not understood, though hearing may be normal.

"The visual speech center lies in the posterior part of the angular gyrus in the outskirts of the higher visual or the visuopsychic field. Word-blindness (alexia), or the loss of memory of printed or written language is caused by a lesion here, though sight itself may be normal.

"Thus the basis of language is a series of memory pictures (1) of the sound of words; (2) of their appearance; (3) of the effort necessary to enunciate them, and (4) to write their symbols. As these memory pictures are connected with each other and with others that make up the concept by subcortical association fibers passing between them, a lesion in any of these association tracts also leads to a defect of speech." (Woolsey, *Applied Surgical Anatomy.*)

6. *Hunger and Thirst.* "The seat of sensations of hunger is located in the epigastrium. The seat of sensations of thirst is located in the pharynx, and is quieted by intravenous injections of water. In every case it is admitted that hunger and thirst are but localized expressions of a general need of the blood for food and drink. The true seat of hunger and thirst is not known. In all cases it is acknowledged that thirst is more painful than hunger, and it is more urgent to satisfy thirst than hunger. A dog without food but supplied with water lives twice as long as a dog deprived of both food and water." (Ott's *Physiology.*)

7. *Automaticity of the Heart.*—"The question of the cause or causes of the automatic rhythmical contractions must be sought for whether the phenomenon turns out to be a property of the muscular tissue or of the nervous tissue of the heart. When we say that a given tissue is automatic we mean that the stimuli which excite it to activity arise within the tissue itself, and are not brought to it through extrinsic nerves. In the heart, therefore, we assume that a stimulus is continually being produced, and we speak of it as the *inner stimulus.* Experiment and speculation have been directed toward unraveling the nature of this inner stimulus. Most of the physiologists who have expressed an opinion upon the subject have sought an explanation in the composition of the blood or lymph bathing the heart tissue, or in the products of metabolism of the tissue itself. Regarding this latter view there is nothing of the nature of direct experimental evidence in its favor. No product of the metabolism of the heart tissue capable of exerting this stimulating effect has been isolated. In regard to the former view, that the inner stimulus is connected with a definite composition of the blood or lymph, there has been considerable experimental work which is of fundamental significance. While the older physiologists paid attention mainly to the organic substances in the blood, it has been shown in recent years that the inorganic salts are the elements whose influence upon the heart beat is most striking. These salts are in solution in the liquid of the tissue, and are therefore probably more or less completely dissociated. Attention has been directed mainly to the influence of the cations, of which three are especially important, namely, the sodium, the calcium, and the potassium." (Howell's *Physiology.*)

8. *Absorption of fat.* "Fat is not absorbed as fat, but as glycerin and fatty acid or soap. It is generally accepted that the fatty acid set free in the intestine is dissolved by the bile salts, and in this way, together with the glycerin, is absorbed by the columnar cells, but that during absorption a lipase which is contained in the columnar cells re-synthesizes, by reverse action, the glycerin and fatty acid. In this way minute fat particles are found near the bases of the columnar cells, and these may be demonstrated by staining with a 1 per cent. solution of osmic acid. The fat globules are further taken up from the columnar cells by some of the lymphocytes, which are capable of exhibiting ameboid movements, and which are found in the lymphoid tissue between the columnar cells and the central lacteal. The fat is then deposited in the central lacteal by these ameboid cells, and in this way it gets into the general lacteal stream, and thence into the thoracic duct. The bile salts, which have been absorbed by the columnar cells, in all probability get into the portal vein radical, and in this way are taken back to the liver to be excreted again in the bile. After a fatty meal minute globules of fat may be demonstrated in the blood plasma of an animal; but they disappear rapidly, possibly existing in a solution and invisible form adsorbed to the blood proteins before they are deposited in the fat depots of the body." (Lyle's *Physiology.*)

9. *Blood-pressure* is influenced by several factors, such as: The quantity of blood in the circulation, the force of the ventricular systole, the elasticity of the arterial walls, and the peripheral resistance.

HEART.	ARTERIOLES.	BLOOD-PRESSURE	BLOOD-FLOW.
Force constant . .	Resistance increased	+	—
Force constant . .	Resistance diminished	—	+
Force increased. .	Resistance constant	+	+
Force diminished	Resistance constant	—	—
Force increased. .	Resistance diminished	+ —	+ +
Force diminished	Resistance increased	— +	— —
Force increased. .	Resistance increased	+ +	+ —
Force diminished	Resistance diminished	— —	— +

The *velocity of the blood flow* is largely influenced by the same factors as the blood-pressure, particularly the force of the ventricular systole and the peripheral resist-

ance. The possibilities of the variations in these factors are shown in the preceding table from Waller, in which the plus sign denotes an increase, and the minus sign a decrease in effect.

10. *Urea* is the end-product of proteid metabolism, and is the most important of the nitrogenous excreta of the body. The quantity of urea excreted is an index of the amount of protein which has been broken down in the body. Most of the urea is formed in the liver, from (1) the amino acids which have been absorbed from the small intestine, and which are not needed by the body; and (2) from the ammonium carbonate which is derived from the tissues, and from the action of a uricolytic enzyme upon uric acid. These two sources give respectively what is known as *exogenous* urea and *endogenous* urea.

CHEMISTRY.

1. In a *physical change* the composition of the matter acted upon is not altered; in a *chemical change* the composition of the matter acted upon is altered.

2. *Two elements used in their elementary form in medicine:* (1) *Iodine* is a bluish gray solid occurring in scales; it is volatile, the vapor has a violet color and a peculiar odor. It may be prepared by burning kelp, extracting the ashes with water, removing the other salts and removing the iodine from the compounds in the mother liquor by chlorine. (2) *Iron*, when pure, is a silver white, soft solid, and crystallizes in cubes or octahedra. Reduced iron is prepared by heating ferric oxide in hydrogen:

$$Fe_2O_3 + 3H_2 = Fe_2 + 3H_2O.$$

3. *Hydrogen* is a colorless, odorless, tasteless gas; it is the lightest substance known, and is a good conductor of heat and electricity; it does not support combustion or respiration. It occurs free in volcanic gases and in the gases of the stomach and intestines; also in combination in water, ammoniacal compounds, and many organic substances. It can be prepared by the action of diluted sulphuric acid on zinc:

$$Zn + H_2SO_4 + x\ H_2O = x\ H_2O + ZnSO_4 + H_2.$$

4. Carbon dioxide is a colorless, suffocating gas, with a faintly acid taste. It will neither burn nor support combustion; it is soluble in water. Its formula is CO_2. There is 0.04 per cent. of it in atmospheric air; but in expired air this is increased to 4.4 per cent.

5. *Phenol.* C_6H_5OH, is commonly called carbolic acid. It is a crystalline solid, occurring in long, colorless needles. It has a peculiar odor, and a burning taste; it is soluble in water, alcohol, and ether. It occurs in coal and wood-tar. It is made by heating phenyl iodide with potassium hydroxide:

$$C_6H_5I + KHO = KI + C_6H_5OH.$$

6. Iron is an important constituent of the blood; it is found in the hemoglobin of the red corpuscles.

7. Proteids are nitrogenous organic substances of very complex composition and of unknown constitution. They all contain carbon, hydrogen, oxygen, and nitrogen; and some contain, in addition, sulphur, iron, phosphorus, or some other element.

Three proteids found in the body: Hemoglobin, keratin, and mucin.

8. *Quantitative determination of urea:* "The specific gravity of the urine is carefully determined, as well as that of the liquor sodæ chlorinatæ. One volume of the urine is then mixed with exactly seven volumes of the liqvor sodæ chlorinatæ, and, after the first violence of the reaction has subsided, the mixture is shaken from time to time during an hour, when the decomposition is complete; the specific gravity of the mixture is then determined. As the reaction begins instantaneously when the urine and reagent are mixed, the specific gravity of the mixture must be calculated by adding together once the specific gravity of the urine and seven times the specific gravity of the liquor sodæ chlorinatæ, and dividing the sum by eight. From the quotient so obtained the specific gravity of the mixture after decomposition is subtracted; every degree of loss in specific gravity indicates 0.7791 gram of urea in 100 c.c. of urine. The specific gravity determinations must all be made at the same temperature; and that of the mixture only when the evolution of gas has ceased entirely." (Witthaus' *Manual of Chemistry.*)

9. *Detection of occult blood in the feces:* "Soften a portion of the stool with water, shake with an equal volume of ether to remove fat, and discard the ether. Treat the remaining material with about one-third of its volume of glacial acetic acid and extract with ether. Then apply the guaiac test (mix equal parts of ozonized turpentine and fresh tincture of guaiac which has been diluted with alcohol to a light sherry-wine color. In a test tube or conical glass overlay the liquid to be tested with this mixture. A bright blue ring will appear at the zone of contact within a few minutes if hemoglobin be present)." (Todd's *Clinical Diagnosis.*)

10. *Ptomaines* are basic, nitrogenous compounds produced from protein material body by the bacteria which cause putrefaction. They are generally introduced into the body as food.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†
Alabama*	W. H. Sanders, Montgomery	Montgomery, Jan. 3
Arizona*	J. W. Thomas, Phoenix	Phoenix, Jan. 3
Arkansas	F. T. Murphy, Brinkley	Little Rock
California*	C. B. Pinkham, 929 Butler Building, San Francisco	Sacramento, Jan. 13
Colorado	David A. Strickler, Empire Building, Denver	Denver, Jan. 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven, March 10

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Septic Dermatitis.—W. M. Robson reports a case of this condition in a male, aged 4½ years, who began to have blisters on his body three years ago; they were never profuse. In July, 1912, a more profuse eruption began on the legs and gradually spread to the abdomen, arms, face, and neck, and lastly, to the back. The groins and axillæ have been more affected than the rest of the body. Other children of the same family were normal. Some of the bullæ were small and contained clear fluid, others were opaque. Some of the bullæ became septic and the temperature rose to 101° to 102° F. A culture taken from an apparently non-pustular blister gave a pure culture of *Staphylococcus aureus.* Treatment has been increasing doses of Fowler's solution, boracic baths, and injections of *Staphylococcus aureus.*—*Proceedings of the Royal Society of Medicine.*

Congenital Spastic Paraplegia, with Congenital Optic Atrophy.—P. S. Hichens reports the case of a girl aged 6 years who, according to the mother, though backward, was a normal child till she was 3 years old. She was then frightened by a Salvation Army band, and had two convulsions and developed paralysis of the right arm and leg, and paresis of the left leg. The child appears to be slightly microcephalic. She has congenital optic atrophy and spastic paraplegia of the right arm and leg, and, to a less extent, of the left leg. Despite the history the case is probably one of congenital spastic paraplegia.—*Proceedings of the Royal Society of Medicine.*

THE SEROLOGICAL TESTS IN CEREBRAL HEMIPLEGIA.*

By CHARLES L. DANA, M.D.,

NEW YORK.

For the last two years I have been having the patients with cerebral hemiplegia, who came into my service at Bellevue, submitted to serological tests for the purpose of determining whether there was a syphilitic or inflammatory element in the case.

The attempt was made to have four tests in all cases. A Wassermann test was made of the blood serum and of the cerebrospinal fluid; a globulin test was made of the spinal fluid, and a cell-count of this fluid. Either complete or partial tests were made in twenty-eight cases of acute cerebral hemiplegia, and a similar series of complete or partial tests were made in twenty-six cases of old hemiplegia—that is to say, of cases in which the patient had had the paralysis for six months or over.

In the cases of acute cerebral hemiplegia a practically complete series of tests was made in 11 cases, and an incomplete series in 16 more. In the 11 complete series the blood serum was positive in 6; the spinal fluid in 4; and there was cell excess in 6. In the whole series of 27 cases the blood-serum was positive in 11 out of 22 cases tested. In 8 cases out of 13 at least two of the 4 tests were positive. In 10 out of 14 cases in which cell counts were made the number of cells was in slight or great excess.

Serum Wassermann	+=11 −=11
Cerebro-spinal Fluid Wassermann	+=6 −=11
Cells	+=10 −=4

*Paper read at a meeting of the Practitioners' Society of New York, October 10, 1913.

The conclusion was that in the hospital cases of acute cerebral hemiplegia there was a luetic infection in about 50 per cent. The positive findings were nearly all in persons under 55 or 60. All the cases of hemorrhage were males except two. This percentage of lues in hemorrhage of the brain was surely much higher than in the non-hospital classes, and the figures were not extensive enough to draw final conclusions. Probably in some cases the infection was incidental and had nothing to do with the lesion. Still it was worth noting that one-half of 22 consecutive cases of acute cerebral hemorrhage responded to two or more of a series of tests for lues.

Chronic Hemiplegia.—A series of 4 tests was made in 11 cases of chronic hemiplegia of 3 months or more duration. The serum Wassermann was postive in 4 out of 9 tested; the cerebrospinal fluid was positive in 2 out of 11 tested. A positive reaction of one or other types was present in 7 out of 15 tested. The spinal fluid cell count was never high, but was above 6, in 7 out of 10 counts. Evidence of lues by two tests or more was found in 6 out of 15 cases. The reactions were much less marked than in acute hemiplegia, and this might, in part, be due to the fact that nearly all such cases received iodides and mercury after their seizures. It would not be unfair to conclude from a study of these 37 consecutive cases that in nearly half of hospital hemiplegia there was a luetic infection present.

CHRONIC HEMIPLEGIA

	Sex	Age	S.W.	C.S.F.W.	G.	Cells

12	M.	58	?	?	+	10
13	M.	28	−	?	?	?
14	F	34	−	−	?	?
15	M.	32		−	?	?

Serum Wassermann	+=4 −=9
Cerebro-spinal Fluid Wassermann	+=2 −=11
Cells	+=6 −=4

If such was the case it seemed to me that it would be of interest and importance to apply intensive antiluetic treatment in a more definite and routine way in cases of apoplexy which are brought into the hospital and which respond positively to the tests.

Cerebrospinal Lues.—The table below presented shows the results of 4 tests in 12 cases of what were diagnosticated as syphilis of the meninges or arteries of the brain. The greater intensity of the reaction

was so marked as to need no comment. Where there were no reactions the patients had been under vigorous treatment, or something was wrong with the diagnosis or the laboratory.

SYPHILIS OF BRAIN

Serum Wassermann	+ = 7 - = 4
Cerebrospinal Fluid Wassermann	+ = 8 - = 4
Cells	+ = 7 - = 4

At the same time that these examinations were made, tests were made in cases of tabes, and paresis. A complete serological formula was obtained in 16 cases of tabes and 8 cases of paresis. My findings in these cases did not differ from those that have been obtained by other observers. It is generally agreed everywhere that the most positive findings are in the cases of paresis. Next in frequency come the findings in cerebrospinal lues, while the most irregular formulæ are those connected with tabes. In the four items of the series the most important finding was the increase in the cells of the cerebrospinal fluid. It is practically impossible to lay down any definite formula with which cases suffering from different forms of lues that are brought into an active hospital service will agree. The formulæ differ, depending upon the age of the case, upon the past therapeutic experiences of the patient, and upon conditions of alcoholism and complicating infections. We cannot make a diagnosis between tabes, paresis, tabo-paresis and nervous syphilis with any certainty, upon the serological formulæ alone. It is my conviction that there is now no longer any definite line which separates cerebral lues from paresis, and not always spinal lues from tabes. That which has in the past been called "paresis" is sometimes now a curable type of lues. While cerebrospinal lues is supposed to be especially an exudative disease, and one which affects the blood vessels and meninges, causing physical symptoms more than mental, yet it is not rare for this form of lues to present nearly all the typical mental, as well as physical symptoms, of paresis, especially when the malady has a somewhat acute onset. I think it is demonstrated and generally accepted that (as I asserted ten years ago) early paresis can sometimes be cured.

53 West Fifty-third Street.

COLDS AND THEIR RELATION TO THE PHYSICS OF THE ATMOSPHERE.*

By C. M. RICHTER, M.D.,
SAN FRANCISCO.

I shall confine myself to discussing acute affections of the mucous membrane of the upper air-passages, when not due primarily to infections. They are generally given the name "colds," and especially whenever their immediate cause can be traced to a low temperature, principally a moist, cold temperature, or to exposure to draughts of such air. Such affections form a distinct clinical aggregation of symptoms, and they are more or less feared as leading to much more severe affections, as pneumonia, nephritis, etc. The proof that cold temperature is the cause and an acute inflammation the effect has never been given by the inductive method, but still this tradition of "colds" continues to infect every modern textbook on medicine.

It would seem natural that such a question should call for a most painstaking scrutiny of the different meteorological factors that might produce, or appear to produce, singly or in combination, an acute catarrhal inflammation of the upper air passages. But where is the research work that brings light on this subject?

I take from Reik[1] the following in reference to the *Anatomy and Physiology of the Mucous Membrane of the Upper Air Passages*:—"The turbinate bones are covered with a mucous membrane, but contain beneath a basement membrane, a mass of lymphoid and erectile tissue and collapsible venous channels capable of great distention (swell bodies). Beneath the epithelium are many mucous glands, which open upon the free surface. These turbinate bodies pour out a great quantity of serum, which serves to thin the mucous secretion and to humidify the inspired air. By greatly increasing the extent of mucous surface over which the air passes, and by their peculiar function of bringing a large supply of venous blood near the surface, they also serve to bring the temperature of the inspired air up to that of the body. The air is thus warmed and humidified for its reception by the lower respiratory tract."

Reik adds: "Although the nasal mucosa is under normal conditions constantly bathed in a slightly alkaline, watery secretion, there is no visible appearance of such secretion—and the individual is not conscious that it exists."

It is true that we have no special sense to put a proper estimate on the amount of moisture in the air inside or outside our body, except in so far as the temperature of such air is of assistance. Prof. W. M. Davis[2] puts it this way: "The humidity of the atmosphere exercises a strong control over our bodily sensation of the temperature of the air."

Prof. M. W. Harrington,[3] summer of 1894, called the temperature shown by the wet-bulb thermometer the "sensible" temperature —*i. e.*, the temperature felt at the surface of the skin. The sensation of warm and cold is an attribute of the mucous membrane of the mouth, throat, and the front part of the nose, of the floor of the nose and of the back part of the soft palate. It is exaggerated by a quick change of temperature. It is to be noted that when keeping the mouth open the air we breathe is *not* passing through the nose.[4] Besides the sensation of heat and cold, we are conscious of only two other sensations in the area just mentioned, that of tickling and that of pain. Killian[5] asserts that the effect of electricity, of change in temperature, of chemical excitation is felt as one of these two sensations. These sensations are very similar on outer skin and mucosa. One would expect the hair on either to communicate simultaneously the sense of touch and perhaps of tickling. The vibrissæ that grow in the nostrils, and which, "guarding the atrium of the nostrils, act as a coarse filter,"[6] are, of course, more or less hygroscopic. They

*Read before the San Francisco County Medical Society, May 13, 1913.

change their relative position inside the nose in conformity with relative humidity, get longer, when moisture increases. By their movements undoubtedly they often cause a tickling, provocative of sneezing. I may note here that Chinamen prefer to have these vibrissæ pulled out by their barbers, and I learn that Chinamen are relatively immune to colds.

Killian (*l. c.*) found that "four points in the front part of the nose and perhaps some in the back part are affected by tickling, but only by extensive and intensive tickling. Some noses are hyperesthetic and they respond to even light tickling by relatively severe hyperemia, increased secretion, swelling of the mucosa, coughing, sneezing, etc. Heat and dryness of the air affect a hyperesthetic mucosa differently from cold and moisture. As the anterior area of the nasal mucosa depends on the nervus ethmoidalis and the posterior on the nervus sphenopalatinus, the physiological and clinical behavior of the two areas is as different as the peculiar actions of these two nerves. Sneezing seems to be entirely due to the ethmoidal nerve's action. One of the neuroses of this nerve is called the vasomotor rhinitis."

The reflex action inside the mouth and throat in its relation to the ever-changing physical and chemical condition of the air we breathe is still rather obscure. We experience a certain sense of dryness at the posterior part of the tongue and at the soft palate and the posterior wall of the throat when very dry and relatively hot air has affected those parts for some time. This is the only symptom experienced. The amount of saliva is of great consequence.

The effect of aqueous vapor on the mucosa is direct and indirect. Our mucosa is a hygroscopic organic substance, principally by virtue of the surface cells and the hair, resembling in this way the epidermis. The amount of hygroscopic water the mucosa contains changes constantly in proportion to the relative humidity of the air next to it. Its ability to conduct heat, its volume, etc., prove this, and it does not differ greatly from any other organic substance, as wood, for instance, in this respect. Of course, every activity of the protoplasm in our mucosa creates heat and increases thereby its temperature. The temperature of our protoplasm has to be kept within definite limits to prevent damage to its activity and existence. The heat in the nasal mucosa has a constant outflow into the nasal cavity.

What induces us to speak of "colds" as if air temperature was the principal factor to be considered? Is not *air humidity* in a more direct relation to "colds"? Rubner's[7] conclusions in regard to the effect of dry and moist air on the human being are as follows: "At a lower air temperature the increase of moisture increases the sensation of cold. At a mean temperature of 14° to 15° C. (57° to 59°F.) dry air appears to give more comfort than moist air, especially between 24° and 30°C. (75° and 86°F.). In dry air, without wind, perspiration is not in evidence unless a temperature of 30°C. (86°F.) is reached, with about 22 per cent. relative humidity. Air of 80 per cent. relative humidity becomes extremely hot at 24°C. (75°F.), even when we are at rest, with perspiration not material, but more so with higher percentage of humidity. Adiposity will increase these effects. Excessive dryness of air is not concomitant with decrease of comfort, but excessive humidity is! The delivery of aqueous vapor depends greatly on relative humidity, but is likewise a function of the air temperature. It is lowest between 15° and 20°C. (59° and 68°F.), but will vary with rest or work, adiposity, nutrition, blood supply of the individual. This varying condition of the organism is paramount and more so than the existing temperature. The export of moisture at a mean temperature and humidity of the room air by the lungs of an adult per hour amounts to 17 gm. when resting, 19 gm. when deep breathing, 34 gm. when singing. The importance of the evaporation value by the lungs is given in this table (one hour for the adult):

Temperature	Dry Air			Moist Air		
	Rel. Hum. Per Cent.	Resp. Org.	Skin	Rel. Hum. Per Cent.	Resp. Org.	Skin
15°C. (59°F.)....	8	16.8 g.	9.5	89	9 g.	....
20°C. (68°F.)....	5	17	37.1	82	11.7	3.6
25°C. (77°F.)....	6	18.4	57.0	81	10.9	13.

Suppose we breathe on a cool winter day air of 0°C. (32°F.); it will contain at perfect saturation 4.89 gm. water to a cubic meter. Its temperature will be raised to normal body temperature quickly by our nasal mucosa. As air should contain 39.4 gm. water to 1 cm.³ at perfect saturation, the relative humidity of air heated from 0° to 35°C. (95°F.) sinks to 12.4 per cent.

Hann[8] gives other examples of extreme dryness, which do not affect our comfort materially. However, the reverse is our sensation when, for instance, at a summer temperature of 20°C. (68°F.) we experience a relative humidity of 28.5 per cent. In this instance we suffer rather intensely from the dryness. The keynote to a proper understanding lies in the regulatory function of our mucosa. The export of heat by hyperemia is the first process, the export of aqueous vapor by the blood represents the second process in insuring equilibrium of temperature and moisture. Whenever by excessive humidity a transport of moisture into such air is impossible, the transport of heat seems to be the first remedy. Of course, there is no normal relative humidity for our mucosa; it is always relative to a certain temperature, to absence of wind, to nutrition, to rest or work.

It is well to remember that dry air will always be preferable at high or low temperature to excessively moist air. That temperature, independently of the factor of moisture, cannot be called the principal "colds" producing agency, we may easily learn from the very even temperature of San Francisco, where colds are not less prevalent than anywhere else. The mean minimum temperature of January, the coldest month, is 7°C. (44.7°F.); of September, the warmest, it is 12.2°C. (54°F.); the mean maximum of January is 12.5°C. (54.6°F.); of September, 19.8°C. (67.2°F.). The difference during the year amounts to 5.2°C. for the mean minimum and 7.3°C. for the mean maximum.

The human body loses heat by radiation and conduction and in direct proportion to the amount of moisture in the air, provided the air temperature be not high. At such temperatures a rise of 25 per cent. relative humidity will give us a sensation of 2°C. (3.6°F.) loss of heat. The reverse takes place at 26° to 30°C. (79° to 86°F.) It seems that we are not materially affected even by an extreme export of moisture from our lungs, as long as the air is rather dry. It is a different matter when the incoming air contains such a surplus of aqueous vapor,

that evaporation by the lungs becomes impossible (Hann *l. c.*). For no matter what the temperature is and no matter what the amount of moisture is which the air we inhale brings into the upper passages, the exhaled air invariably returns saturated for a temperature between 30° and 37°C. (86° and 98.6°F.). To make this possible, the physical work inside our mucosa has as its aid the vasomotor nervous system as a reflex apparatus. The automatic work of this system, by dilating or contracting the vessels under its control, regulates the outflow of heat, of serum, of mucus into the nasal cavities. It supplies heat and moisture to the incoming air, to furnish the necessary amount for its journey to the lung vesicles. Every five seconds about 500 c.c. of incoming air pass the scrutiny of the watchful vasomotors situated in our nasal mucosa, and a few seconds later—during all our life—a similar amount of air returning from the lungs demands a fresh equalizing work of the mucosa in response to the changed conditions it brings to its surface. The air we inhale has to be heated to the amount of about 5/9 or the normal body temperature inside the cavum pharyngonasale (Landois, *l. c.*), and it has to be saturated there with aqueous vapor. By inhaling through the nose and exhaling through the mouth, by means of a glass tube containing a thermometer, the folowing temperatures were registered:

Air Temperature	Temperature of Exhaled Air
−6.3°C. (20.7°F.)	+29.8°C. (85.6°F.)
+17°−19°C. (62.6−66°F.)	+36.2°−37°C. (97.1−98.6°F.)
+44°C. (111.2°F.)	+38.5°C. (101.3°F.)

One would expect similar fluctuations in regard to the degree of saturation of the exhaled air, and it is clear that a deficiency of aqueous vapor in the inhaled air will call for considerable discharge of moisture by the nose and lungs. It is estimated that the lungs return about 450 gm. water in twenty-four hours—about an equivalent of the amount taken from the mucosa by the inhaled air. R. de C. Ward[9] found in Boston during a certain November a mean temperature of 2.2°C. (35.9°F.) outdoors, with 71 per cent. relative humidity, and had in his study a mean temperature of 20.6°C. (69.1°F.) and 30 per cent. relative humidity. The latter Dr. Barnes could increase by evaporation of water to 53 per cent. This percentage made 18°C. (64.4°F.) comfortable, whilst the air had to be raised to 22°C. (71.6°F.) without the evaporation to make it equally comfortable. The absolute humidity fails to explain these conditions. As Hann (*l. c.*) emphasizes, it is the relative humidity which, in addition to the temperature, creates and measures our demand for moisture and the need of evaporation.

"At San Francisco relative humidity throughout the year is high, but during the summer months, owing to low temperatures, the absolute weight of water vapor per unit of volume is much less than at coast stations of the Atlantic."[10]

Mean	Chicago		San Francisco	
	January	July	January	July
Rel. hum., per cent.	81	67	79	83
Vapor pres.	.099	.548	.282	.384
Temperature	23.7°F.	72.3°F.	49.8°F.	57.3°F.
	4.6°C.	22.4°C.	9.7°C.	14.1°C.

This explains the chilly feeling we experience in San Francisco during July, when a low temperature with a low relative humidity would have the opposite effect. Conditions in and on our mucosa are probably in a state of relative equilibrium, when the air temperature is between 18.3° and 20°C. (65° and 68°F.) and the relative humidity is as low as 30-40 per cent. This statement should include that dry air gives us greater comfort than moist air, provided there is absence of wind.

What is the effect of a draught, of a strong wind, on our mucosa? The air movement caused by each breath is comparable with the air movement by wind.

The moment that a movement of the air by wind enters as a factor we feel a cooling, as the wind will necessarily remove more heat from the surface by constantly changing the air above it. In consequence, as a first reaction, the smaller blood vessels of the surface contract, thereby preventing the additional escape of heat. In case of an increase of temperature above the average the reverse takes place the blood-vessels dilate and allow an escape of heat. The evaporation will be somewhat proportionate to these conditions. It proves[11] that the duration and intensity of the wind and the relative humidity are most important heat factors and that the thermometer fails to record it. Rubner (*l. c.*) found that wind velocity in itself, or a sharp draught of air, becomes harmful, not because of its quicker air motion, but because of the change it produces in regard to evaporation from our mucosa. On our hemisphere and in our latitude all winds from the southeast, south, southwest or west are generally warm, moist, and reduce air pressure; all winds from the northwest, north, northeast, and east are generally cold, dry, and increase air pressure. It is clear, then, that it is of the utmost importance for the mucosa work which set of winds is prevailing.

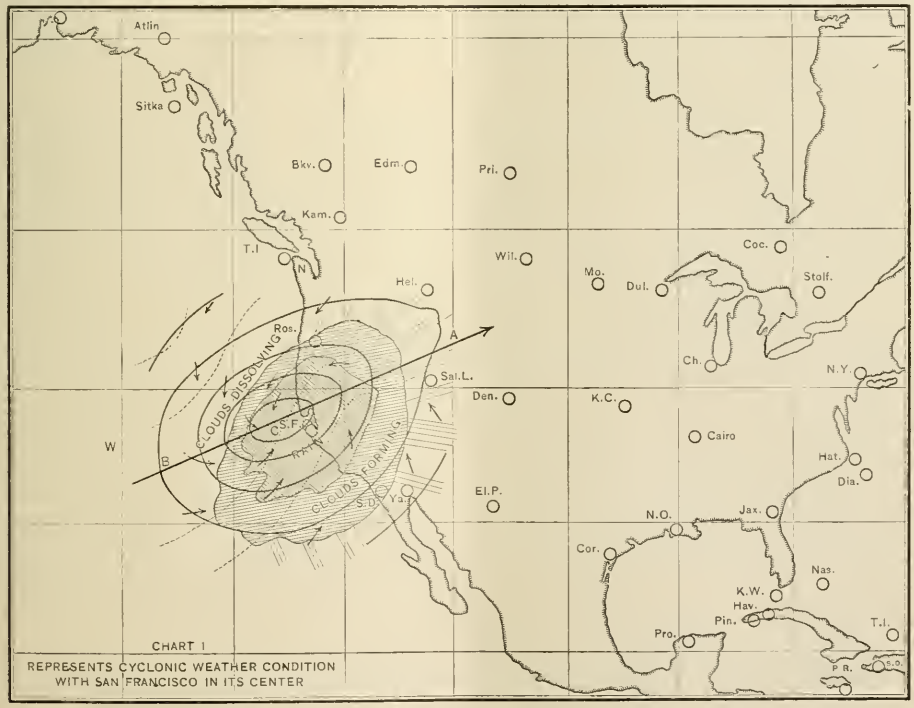
Acute Coryza.—Osler,[12] describing acute coryza, says: "At first the mucous membrane of the nose is swollen, 'stuffed up,' and the patient has to breathe through the mouth. A thin, clear, irritating secretion flows. The mucous membrane of the tear-ducts is swollen—the pharynx looks red and swollen, etc. Usually within thirty-six hours the swelling of the mucosa subsides and within four or five days the symptoms disappear." He adds: "Many attacks are so mild that the patients are able to be about and attend to their work."

This acute coryza represents a condition, which is brought about as a logical consequence whenever an excess of moisture, coming to the gate of our lungs, overtasks the vasomotor apparatus of the nasal mucosa in its effort to guard the lungs against this excess. The outer skin of our body has about 2,000,000 sweat glands, which act as regulators of humidity and temperature on its surface of about 16,000 cm.^{2} The mucous glands of the nose (there are about 100-150 per one cm.^{2}) have to act in a similar manner inside the cavum nasale. Its cubic contents amount to 15.7 cm.^{3} on the right and 18.5 cm.^{3} on the left side.[13] The secretory actions of these glands, together with the hygroscopic condition of the entire nasal mucosa furnish the reservoir of moisture, which is ever ready to adjust the temperature and moisture conditions of the air we breathe. Generally the moisture inside the nose appears to be insensible, similar to the perspiratio insensibilis of the epidermis—but any swinging of the hygrometer needle toward an unusual increase of moisture, will modify the amount of moisture on the mucosa correspondingly, it will increase the swelling of the swell bodies, and an overflow of the reservoir may result. In this event often a great quantity of serum is poured out, generally following

repeated sneezing, which seems to be especially helpful in opening these safety valves. By this discharge of moisture the swelling of the swell bodies is more or less slowly relieved and in the meantime the weather condition, that furnished the excess of moisture, is disappearing. It is inconceivable that with extreme dryness could be associated an increase of moisture in a hygroscopic substance. Wood, for instance, would get more and more dry, and so does the mucosa, except for a comparatively insignificant flow of moisture to relieve the vacuum caused by dryness. We have analogy to this apparently physiological action of the nasal mucosa to meet excessive incoming humidity in the action of the outer skin, whenever the air temperature goes beyond certain limits. For instance (Rubner—*l. c.*) the same degree of air humidity would cause a more liberal evaporation at a higher than at a lower temperature. At a temperature of 15-20°C. (59-68°F.) evaporation is comparatively minimal. Whenever air temperature goes higher, then, with increasing air humidity, evaporation—this truly seems paradoxical—is likewise increased. Profuse perspiration—similar to the running of the nose—covers the entire outer skin, thereby creating better conditions for evaporation. The limitation of this inverse action of moisture is not to be defined by certain figures, but must depend largely on certain physico-chemical conditions of the organism in question. Undoubtedly we find an acute coryza having a predilection for a child's mucosa ("the newly born animal, the human included, is not very subject to reflexes"[14]), or for a hyperesthetic one, rather than for a hardened nose. The conditions of civilization and certain habits predispose many noses to this affection. Among men and among women the effect of smoking tobacco should be considered, that of alcoholic drinks, of spice in food and drink, of perfumes, of city smoke, of dust; in general of more or less adulterated air, which any person is subjected to. Recently we have learned to consider certain idiopathic catarrhs, reminding of anaphylaxis. We have to consider the effect of ozone in the air and of different air pressure. Many of these factors favor functional disorders of the nasal vasomotor system and help to explain the great prevalence of an acute coryza, the great tendency to affections of that kind developing under certain weather conditions.

Assuming, then, that especially a southerly wind would give a foundation for the clinical syndrome of acute rhinitis, that it would call for a reflex action by the mucosa in question, represented by acute inflammation, it becomes necessary to consider the weather condition which is favored by the southerly wind.

Two wind systems represent in a general way the two weather conditions which dominate the weather in our latitude on our hemisphere. Every single day, when we look at the weather map, we find our city either inside a "low" or inside a "high". Seldom we will be found to be on a border-line between these two types. The continuous procession of such areas of low and high air pressure generally has an easterly direction. Inside the cyclonic system, or "low," we find unsettled, very windy, rainy, relatively warm weather; inside the anticyclonic system, or "high," there is generally less wind velocity, dryness of air, sunshine by day, cool nights in summer, intense frost in winter. Dense fogs sometimes are prevailing during the calm of an anticyclone. Suppose the tail end of a "high" is passing away from



us, we experience in advance of the approaching "low" generally an increase of absolute humidity. It indicates the first action of a southerly wind on our atmosphere. Presently the southerly wind, first from the southeast, then from the south and southwest, develops more velocity, temperature rises, cloudiness increases, rain is precipitated, and the air pressure decreases. This condition dominates our weather for a period of two to five or more days. It passes on with a wind velocity of about thirty miles an hour, whilst the now coming "high" moves with a lesser velocity. It is generally a southerly wind inside of "low" that causes a severe draught and which feels cold on account of its high relative humidity. It represents the specific weather which causes an increased hyperemia, increased resistance, increased leucocytosis[9] inside the nasal mucosa. An acute coryza develops principally at the beginning of or during the passage of a "low" and seems to be, therefore, primarily due to the effect of an excess of moisture in the air. Sneezing is often the first reflex action started by nature to do away with this excess and to relieve the abnormal condition. An anticyclonic condition with its extremely dry air may likewise cause sneezing, but for the very opposite reason of bringing moisture to the mucosa, that is losing its hygroscopic water. It occurs more rarely and seldom develops the acute coryza. No doubt the acute coryza, whenever the requisite flora is present inside the nasal cavity, may develop and generally does develop into an infectious condition, a catarrhal inflammation, due to the specific organism that finds a suitable field for growth inside the hotbed created by the abnormal physical condition of the nasal mucosa. As Abraham Jacobi[14] says: "As long as the mucous membranes are in their normal condition the germs cannot enter the tissues and the circulation. A catarrh removes this protection; the epithelia are swept away by the fluid. That is the chance for the living enemies."

I have refrained from considering in this paper the influence of atmospheric electricity and likewise that of air pressure on the mucosa in question, though it must be apparent that its physicochemical work depends to a considerable degree on these two factors. However, we have to wait for further research in regard to their influence.

I wish to close this paper with another quotation from Abraham Jacobi (*l. c.*) referring to the treatment of acute coryza, as it gives apparently another proof for the theory advanced by me. He writes: "Excessive nasal secretion—1000 c.c. a day—may be best stopped by absolute abstinence from drinking, together with enforced diaphoresis. Cocaine brushed or sprayed has been more often recommended than proved wholesome. Adrenalin spray acts a little better."

Conclusions.—1. Acute coryza, commonly called a "cold," depends for its development primarily on an excess of moisture in the air we inhale.

2. It develops, therefore, principally during the cyclonic weather condition called a "low," especially when a period of very dry weather has preceded a "low" and when, in consequence, the change from previous dry air to the incoming very moist air is most rapid.

3. The excessive and more or less continuous nasal secretion at the beginning of an acute coryza relieves the respiratory apparatus from the otherwise damaging effect of an overcharge of moisture.

4. A child's nasal mucosa and the hyperesthetic one are especially prone to suffer.

5. The "running of the nose" constitutes in part a physiological vasomotor action analogous to the profuse and more or less continuous perspiration of the outer skin, which sets in whenever air temperature and relative humidity transgresses certain limits and which forces thereby better conditions for evaporation.

6. Latent microbism becomes active on the mucosa only after these air conditions have favored its development for some time. Microbism is very rarely the primary cause of an acute coryza.

VENEREAL DISEASES AND PRACTICAL EUGENICS IN SMALL COMMUNITIES.

By EDWARD HUNTINGTON WILLIAMS, M.D.,

Montclair, N. J.,

formerly of the New York State Hospital Service

and

JAMES SPENCER BROWN, M.D.,

Montclair, N. J.

Surgeon-in-Chief, Mountainside Hospital.

There seems to be a very general impression, even among city physicians, that venereal diseases are confined largely to urban communities. In the absence of exact statistics it is impossible to determine to what extent this impression is justified in the case of the minor venereal infections, but the recorded cases of general paresis all over the country seem to indicate that syphilis is by no means confined to the large cities.

Thus we find that in the State hospitals for the insane in Iowa (a State singularly lacking in large urban communities) the proportion of cases of paresis to all other forms of insanity is about one to fifteen, while in the New York State hospitals the proportion is about one to eight. At first glance this would seem to indicate that the number of cases of syphilis in congested New York must be about twice as great as in rural Iowa. But when we consider the high mental tension under which the average New Yorker lives as contrasted with the relatively placid mental state of the average Iowan, and remember that this tension conduces indirectly, at least, to the production of paresis, it seems evident that the number of cases of syphilis per capita in these two States is not so widely different.

These statistics about paresis also give us indirectly a clue to the prevalence of the minor venereal diseases. For wherever we find syphilis we find also a proportionate number of cases of the other

venereal infections. So that there seems little doubt that Iowa, and nearly every community, rural as well as urban, has its quota of all classes of these diseases.

Undoubtedly the dangers from gonorrheal and syphilitic infections are the two greatest deterrents to illicit sexual intercourse in every community. But unfortunately the serious nature of gonorrhea is not appreciated by most laymen. With syphilis, however, the case is different. The horrible ravages of this disease—the fact that it is (or has been until recently) considered incurable; that it "eats off" noses, causes hair to fall out, makes offensive ulcers, and produces many other loathsome conditions—is pretty well understood by the majority of men. So that this disease has been the strongest single factor in keeping young men in the straight and difficult highway of chastity. Yet even its appalling dangers fail to keep many of them in that path.

Nor is the state of affairs of recent development. Apparently it has been about the same for centuries. And unfortunately it seems likely to continue, as our modern civilization prevents young men from marrying until several years after the compelling sexual desire is fully developed. Indeed, it is only reasonable to expect that this particular kind of immorality will increase rather than diminish, since the average age for marriage seems to be increasing, while the age at which the sexual instinct develops remains unchanged.

Moreover, the discovery of salvarsan, instead of acting as a deterrent to sexual immorality, seems likely to have the opposite effect by robbing syphilis of its greatest menace—incurability. So that salvarsan must be considered as a eugenic, rather than as a moral weapon, since its curative effect has been promulgated so thoroughly by the popular press that it is known to practically every intelligent layman in the country.

Naturally enough this new weapon has given fresh impetus to the activities of the various organizations interested in eugenics. These organizations may be considered as two great armies, the older one composed of medical men and scientists, the newer enlisted from the ranks of progressive ministers and laymen. Both armies are fighting in the same cause; but, as might be expected, their methods of attack are quite different. For the purpose of comparing these methods we may consider the recent action of certain divisions of this clerical army, and that of the surgeons in the United States Navy.

The most radical step in practical eugenics taken by the clerical army is that of demanding certificates of good health from both contracting parties before its members will perform the marriage ceremony. In this way the clergymen hope to prevent persons suffering from venereal and other transmissible diseases from infecting their consorts or their offspring. At the same time they propose to conduct campaigns of education in which they will teach sex hygiene, and portray the frightful dangers attending deviations from chastity. Thus they add to the course of instruction the menace of enforced celibacy to those who disregard their admonitions.

This is essentially a clerical method of attack, by promising reward and threatening punishment, although the promise seems somewhat overshadowed by the emphasis given the threat. But let us consider some of the practical difficulties that present themselves. As we have pointed out, most young men are sufficiently orientated into the dangers attending immorality without additional instruction from their pastors. So that the educational part of the campaign—at least the part concerned with the warnings against dangers—is likely to prove disappointing in practical results.

The important innovation is that of demanding medical certificates from those wishing to marry. But the practical application of this innovation is beset with serious obstacles. A pertinent question at once obtrudes itself: What will be the ultimate action of a young man who is refused a certificate of health because of an existing syphilitic infection? Will he seek a physician to be cured (if possible), or seek a dishonest physician, or a less scrupulous minister, or will he remain a legal celebate, while continuing to scatter his infected germ-plasm broadcast, thus doing far greater injury to future generations than by confining it to a single focus? These are questions that present practical problems for which there are as yet no practical and satisfactory answers. But until some satisfactory answers are found the mere denial of marriage will not carry far in practical eugenics.

The Navy's method of attacking the venereal disease problem presents a striking contrast to the one just outlined. It is essentially a medical rather than a clerical method. But it has two commendable features: It is simple, and it seems to be effective. The method is as follows:

Each sailor when he returns from shore leave is obliged to report to the "prophylactic room" if he has exposed himself to possible venereal disease infection. Here a hospital apprentice administers prophylactic treatment, which varies slightly in details on the different ships, but is essentially the same on all.

The treatment, as outlined by a naval officer, is as follows: "The penis is washed with soap and water, and then with bichloride 1-1000. A two per cent. protargol injection is given and held in for a short time. Then a 33 1-3 per cent. calomel ointment is rubbed around the glans and left under the foreskin. The man's name is recorded with the date.

"When a man reports with chancroid or gonorrhea he is required to state when and where he contracted the disease, and the venereal book is consulted to see if he received prophylaxis. If he did not, he is reported for punishment."

Thus the navy is fighting a prevailing evil by means of applied scientific knowledge, rather than with moral precepts. Yet such precepts are not wanting, for the navy has chaplains as well as surgeons, and the enlisted men are fully aware of the moral aspect of unchastity as well as its dangers. But since they, like many other robust young men in other walks of life, often disregard these moral precepts, their officers are now meeting the issue by supplementing moral teachings with what proves to be more effective, if less esthetic, measures. As a result, the navy, which has hitherto been considered a hot-bed of specific diseases, is becoming a model community as compared with many small towns. And it is probable that more U. S. sailors could show acceptable certificates to the clerical matrimonial censors of some communities than could a corresponding number of men picked at random from among the censors' own flocks.

Observing the good effects of his prophylactic treatment, a veteran surgeon of our navy who has

three boys of his own just reaching the "danger zone" age, was led recently to reflect to this effect: "Every day, as a matter of routine, I protect young men against the most dreadful diseases. Yet I have no particular interest in these men. Meanwhile I allow my own three boys to go their ways unprotected. I *hope* they will not 'take chances', but I should be blind to the teachings of my experience if I ignored the probability that they *will*. Therefore, it is not acting the part of a good father, or a good physician, to withhold from them the benefit of my knowledge—not to offer them the protection that I would give any stranger who sought my advice."

This point of view, we admit, is not that of the idealist. But ideal conditions do not exist. And the part of wisdom in any field of activity is to combat actual conditions, even while striving for the ideal. The navy is setting a good example in this struggle which could be followed, in its essentials, in other communities. For in some ways the community-life of the navy is similar to that of small towns, particularly in the relations existing between the enlisted men and their chaplains and physicians. The village pastor and the village doctor, like the naval chaplains and surgeons, are the mentors of their communities. Their relations with the young men of the town are much closer than those of the city ministers or physicians. Their advice is more freely sought, and because of their intimate acquaintance with their townsmen, this advice is more likely to be heeded.

But the great handicap to the clerical eugenist is his ignorance of the actual moral conditions in his community in most instances. Every one puts his best foot forward in the minister's presence; the doctor sees the other foot in all its deformity. Yet this deformity represents the actual condition which makes necessary our efforts in eugenics.

Before plunging too deeply into the eugenic movement, therefore, the members of the clerical army would do well to acquaint themselves with the facts about the moral status of their communities by consulting their medical confrères, particularly those most familiar with the venereal-disease situation. For in many towns there are certain physicians whose personalities do not invite the confidence of the erring, and who have scarcely more opportunities for keeping in touch with the community's immorality than do the ministers; while other physicians are constantly consulted. These latter could, without breach of professional confidences, indicating by numbers and not by names, impart valuable information—information that would amaze the clerical workers in many instances. And the physicians should supplement these revelations with information regarding certain phases of physiology and pathology that are not generally understood, or frequently overlooked, by clerical enthusiasts.

They should point out that, while the same code of morals for men and women may be ideal, such a standard is artificial and opposed to the physiological development of the two sexes. Thus in most normal men the impelling sexual instinct develops naturally without the stimulus of indulgence, while in most normal women it does not develop to anything approaching a compelling degree until after indulgence—a fact frequently ignored by the advocates of a uniform standard. Nature has made the path of chastity far more difficult for the average man than for the average woman.

Moreover, the eugenist must not close his eyes to the fact that there are dangers attending enforced celibacy, as well as those arising from unchastity. In certain neuropathic individuals attempts at complete repression of the sexual desire sometimes leads to grave pathological conditions even more incurable than most venereal diseases.

It should be further pointed out that there are some cases of syphilitic infection that are not detectable by the Wassermann, or any other test; and latent gonorrhea will sometimes escape the most conscientious scientific scrutiny. So that, at best, the doctor's health-certificate to a matrimonial censor can only state an opinion, and is not infallible.

It would seem logical, therefore, since the clerical eugenists have invoked the aid of medical science in passing upon the question of eligibility to marriage, for them to seek its aid in making such eligibility possible. It is quite as much a part of religion to offer forgiveness as it is to promise reward or to threaten punishment. If this forgiveness were supplemented with advice to use a prophylactic, administered by a physician, or under his instructions, it might aid practical eugenics in its present stage of development quite as much as moral advice, the purport of which is as familiar to the offender as to the adviser, in most instances.

In practical application the navy's method of enforced reports and prophylactic treatment cannot be pursued in outside communities; but with certain modifications it could be carried out, and with one important advantage—that it would be used very shortly after exposure in most instances. For the weak point in the application of prophylaxis in the navy is the fact that it is frequently delayed until many hours after exposure.

Of course no one supposes that any young man will rush to the doctor's office every time he falls from grace. But many young men would be glad to use a simple prophylactic if one were available. And, surely, at this time when prophylaxis is the watchword of progressive medicine, it is the height of prudish folly to withhold from them any effective prophylactic.

VIENNA, THE POSTGRADUATE MEDICAL AND SURGICAL MECCA.

INCLUDING PRACTICAL POINTS GLEANED FROM VIENNESE CLINICS AND FROM THE COURSES GIVEN BY THE UNIVERSITY OF VIENNA.

By A. M. FAUNTLEROY, SURGEON,

U. S. NAVY.

This paper is presented in response to a request from a number of my confrères with the idea of giving a brief outline of the postgraduate work to be had in Vienna and of the practical methods in diagnosis, technique, and treatment for which the Viennese school of medicine is justly famous. There is no place in the world where the postgraduate professional man will find a more appetizing medical and surgical "quick-lunch," so to speak, than in the Austrian capital.

The reason for this unique condition is twofold: First, there are the very large general and special hospitals with their inexhaustible clinical material under the control of the professors of the University of Vienna, whose courses along general and special lines are so arranged as to meet the demand for concentrated postgraduate work in a way which is as yet unparalleled by any other large medical center. Second, the American Medical Association of Vienna has control, as far as the postgraduate

work is concerned, of each and every course, so that when the newcomer arrives he finds the work so systematized that he is able to select the line of work he wants without having to be familiar beforehand with conditions which would otherwise be embarrassing to a stranger. The number of men in each course is necessarily limited, and the association decides how many men are to be in each course, so that the work will not be hampered by overcrowding and in order that the individual will get the greatest amount of good out of the particular line of work.

The American Medical Association of Vienna was organized November 28, 1903, and has so systematized and improved its organization from year to year that it is now firmly established as an important educational corporation working in perfect harmony with the faculty of the University of Vienna. The officers of the association are elected by ballot every six months and consist of a president, vice-president, secretary, treasurer, executive committee of five members, membership committee, and what is known as the orientation committee. This latter committee is composed of men in the different departments of medicine and surgery whose duty it is to organize the various courses and give information to all new arrivals. The association rooms are located at No. 28 Schlösselgasse, and here will be found an excellent reference library of modern medical works in German and English and also numerous medical journals, a reading and writing room having on file English and Continental dailies, a ladies' room and a room in which the register is kept and where all courses are posted.

The association has a permanent assistant secretary who has charge of the rooms and transacts all routine business. The fee for active life membership is five dollars, and in addition one dollar a month during the time the member is in Vienna. The association is governed along the lines of an ordinary club, and issues yearly a "Blue-book" which contains the constitution and by-laws, together with a full description of all the courses to be given for the ensuing year and a mass of general information. There are weekly meetings of the association proper, besides meetings of different medical and surgical branches, at which time papers are read and discussed.

When a physician arrives in Vienna he should enroll himself at once on the register of the association for the reason that priority in registration plays a prominent part in determining his eligibility to enter the courses at an early date. The different courses usually run from four to six weeks, and several days or a week before the new course begins it is posted so that those who wish to enter the course can sign their names. The number in each course being limited, precedence to enter a course is determined entirely by priority in registration. In addition to the regular or so-called "book-courses" there are to be had special individual courses in almost every line of work. The fees for the different courses vary according to the course taken, but are fixed for any particular course, and are very reasonable. The special individual courses are, of course, much more expensive than the regular courses and usually run from three to five dollars an hour. While a number of courses are given in English as well as in German, it is an undoubted fact that one will get a great deal more out of the work by having a good reading and a fairly good speaking knowledge of German. If one contemplates visiting Vienna for purposes of study he would do well to devote six months or a year to the study of the German language. In this way he will not be restricted to the courses which are given in English. The Vienna clinic is not a place where he who runs may read, but rather a place where he who lingers learns, and the man who is prepared for a reception of German medicine in the German language is the one who will profit mostly by his stay. It must not be understood that it is only necessary for a man to present himself at the association rooms to immediately get the line of work he desires. He must keep in close touch with the orientation man for his particular line of work and keep himself informed on all new and prospective courses. By not realizing this feature of the system some men allow several weeks or months to go by without gaining admission to a course.

Living expenses in Vienna may be classed as fairly reasonable, although this depends largely on the individual and what he is willing to forego in the way of American comforts and luxuries. Fairly good accommodations for a man or his family may be had in any of the numerous pensions at moderate rates, but the first-class hotels and restaurants or cafés are, if anything, a little more expensive than the first-class hostelries in America.

A description of each course would far transcend the limits of this article, and no effort will be made in this direction except to present some of the interesting details of the work I took personally with annotations here and there while visiting the various clinics. The courses I attended were as follows: Gross pathology, general and special urology, skin and syphilis, operative genitourinary, cystoscopy, and urethroscopy.

Gross Pathology.—The course in this work is to my mind the most valuable single course given in the university, and is presided over by Professor Stoerk, a man of rare genius in his line. Last year there were 2,503 autopsies performed in the Allegemeine Krankenhaus alone, which is an average of about eight autopsies a day. These are performed in the early morning and each body has attached to the right great toe a metal number tag which corresponds to the number of anamnesis, and this latter is reviewed before performing the autopsy. The manner of performing an autopsy is thorough to the last degree and no pathological point is overlooked. The incision begins just above the thyroid cartilage and extends in a straight line to the pubes. After the sternum and attached cartilages have been removed the upper part of the incision is deepened and the tongue, esophagus, and trachea are dissected downward, bringing out all the organs of the neck and chest together. Each organ in the abdominal cavity is removed and the alimentary tract laid open from end to end. If there is a history or suspicion of cancer a very careful search is made for metastases, the anamnesis being the general guide in performing all the autopsies. After this dissection the organs are assembled in large pans, with attached anamnesis, and placed in cold storage until the afternoon, when each pathological detail, with a careful review of the history of the case, is gone over before the class. Microscopical sections are made beforehand when necessary to bring out a point in diagnosis.

The class in this course is limited to ten members and this is not so large but that each man can see every detail that is brought out. The class meets every day for one month (except Saturdays), and

during that time the gross pathology of practically all human diseases is seen and discussed. A great many interesting specimens are sent to Professor Stoerk from various surgical clinics, and in addition to this the Pathological Institute has an enormous museum of well mounted exhibits which is referred to from time to time.

To mention in detail the large amount of pathology reviewed would be equivalent to reciting the pages of a complete text-book. Tuberculous and syphilitic changes in every organ and tissue are repeatedly seen, as well as every form of cancerous tissue and tumor growth. Professor Stoerk has recently cleared up the pathology of hypernephroma and demonstrated to the class the fallacy of regarding it as derived from adrenal tissue, making it absolutely clear as regards its purely renal origin. It was in demonstrating this to the class that the reason for regarding Hochenegg's sign as pathognomonic of hypernephroma of the left kidney, and sometimes the right, was clearly seen. This sign consists of a left-sided varicocele (sometimes also rightsided) which persists when the patient is lying down. The reason for this is that the pegs of hypernephromic tissue protrude into the renal veins, and sometimes all the way up the vena cava to the right auricle, thus blocking these veins and causing the blood to be permanently dammed back in the spermatic veins. We were shown numerous specimens of enlarged prostates which proved beyond a doubt that except in very rare instances the so-called middle lobe was the only part that became enlarged. Professor Doctor Zuckerkandl and Professor Stoerk recently published this fact and stated that what has been regarded as the capsult of the enlarged prostate was in reality the atrophied lateral lobes.

What makes the course so valuable to the surgeon is that he becomes familiar with a large number of pathological conditions in all parts of the body which knowledge, of course, is most valuable to him when he encounters these same conditions in the living body, and is thus able to identify what he is dealing with. To the internist the course would appeal with equal force in that he reviews many times the gross pathology of all the usual, and many of the unusual, causes of death. This is a course that it would be well to take several times and thus become more accurately familiar with what one has been over.

Urology.—This course, which runs daily for a month, is limited to ten members and is given at the Polyklinik Hospital by Docent Viktor Blum, chief in von Frisch's clinic, who is well known at home and abroad for his marked ability and scholarly attainments and a man who, before many years, will undoubtedly lead in his line of work. He is ably assisted in the large amount of work performed in this clinic by Doctors Prigl, Clingar, Zinner, Schwartz, and Bisdom. The "team-work" and efficiency of this clinic in its harmonious working was the best I saw in Vienna and speaks well for Dr. Blum's executive ability.

In this course a plentiful supply of clinical material admits of the presentation of practically every feature of urology. The surgical diagnosis of bladder, kidney, and urethral conditions is especially dwelt upon and a large assortment of other genito-urinary work is taken up systematically before the class. Functional kidney tests and minor operative work are conducted from time to time and the class is also present for interesting major operations. For the first two weeks of every month Dr. Blum gives, for two hours in the evening, a special genito-urinary operative course in which every urological operation is performed by each man taking the course. For the last two weeks of every month, and for two hours in the evening, Dr. Clingar conducts a very instructive special course in urethroscopy.

The treatment of uncomplicated urethritis (gonorrhea) consists of irrigating with either a one to four thousand solution of permanganate of potassium or a one to four thousand solution of gelatose of silver. The anterior urethra is first washed out with the solution, the bladder is then filled and the solution is voided. In chronic gonorrhea, besides the urethroscopic treatment to be discussed later on, the urethra is dilated three times a week by the passage of "Benique" sounds accompanied by massage along the sound to press out the contents of the glands. This usually sets up a mild exacerbation which is then treated by irrigations three times a week, the sounds not being used as long as the exacerbation continues. If after the first dilatation there is no exacerbation in two days the urethra is examined with the urethroscope and the mouths of the glands are touched with the actual cautery or the areas of so-called "soft infiltration" are touched with tincture of iodine or 5 per cent. nitrate of silver. When the posterior urethra is involved an instillation of 2 to 4 c.c. of a ¼ to ½ per cent. silver nitrate solution is made with a Guyon catheter or systematic urethroscopic treatment is instituted. A gonococcic vacine is also used in this clinic for various stubborn complications. Three injections are given in all, starting with 1 or 2 c.c. and increasing the dose by 1 c.c. on each third day.

Not only in this clinic but in several other Viennese clinics the quick routine tests for albumin are made with either one or the other of two stock solutions. The first and more delicate test is made by adding a few drops of a 20 per cent. solution of sulphosalicylic acid. The second solution is used in conjunction with a few drops of acetic acid and consists of several drops of a 10 per cent. solution of ferrocyanide of potassium. In either case a cloud forms in much the same way as by the heat test. The chemical test for pus in the urine is to add a small quantity of potassium hydroxide and a coagulum will form if pus is present. As regards the presence of albumin in the urine the Viennese clinic has directed attention to the condition to which they have given the name of lordotic albuminuria. This condition, which the older writers sometimes referred to as postural albuminuria, is characterized by the appearance of albumin in the urine in large or small quantity as the result of the patient assuming an exaggerated upright posture, such as in kneeling. It is especially common in young girls and is not infrequently met with in older people of both sexes. There are several theories as to the possible cause but none is satisfactory. Professor Stoerk tells me that as far as gross or microscopical changes are concerned there is absolutely nothing in these kidneys to give a clue to the albuminuria.

The routine examination of patients presenting themselves is as follows: the patient is made to urinate in two glasses (Thompson) and if the second glass shows cloudy urine attention is directed to the bladder. The prostate is next examined. This examination is conducted with the patient lying

on his back (French method) as it is claimed that not only prostatic enlargement but general conditions at the base of the bladder can be ascertained better by this method than by any other when combined with deep pressure over the bladder with the other hand. The next step is to examine the testicles and cord, followed by a microscopical examination of the discharge.

My notes on the differential diagnosis as regards prostatic enlargement, stone in the bladder, and vesical tumors are as follows: pain after urination indicates usually inflammatory prostatic trouble and sometimes stone in the bladder. With the finger in the rectum the extent and character of the prostatic enlargement can be made out. If of an inflammatory character it is felt as slightly enlarged and of boggy consistence. Upon massage the characteristic shreds and pus can be expressed through the urethra. A pedunculated, congested middle lobe can give the same symptoms as stone. As regards hematuria as a symptom there are three forms: (1) Initial hematuria is characteristic of a pedunculated tumor in the orifice of the urethra. (2) Total hematuria, when the urine is uniformly stained with blood, may be due to ulcer of the bladder, succulent mucous membrane, or hemorhage from the kidney. (3) Terminal hematuria is characteristic of nothing in particular but may be due to stone in the bladder or hyperemic membrane. Intitial and terminal hematuria is characteristic of trouble in the prostatic urethra, the first blood being washed out by the first flow of urine and the last blood being due to the squeezing of the prostate. Blood clots (in the absence of trauma) nearly always indicate tumor in the bladder or trouble in the kidney. One of the first symptoms of tuberculosis of the kidney is usually a hematuria due to an ulceration of the papillæ. Hypernephroma is also responsible for an intermittent type of hematuria. Interrupted bleeding is characteristic of stone and the urine in this condition nearly always contains some blood cells. Blood from the bladder may be caused by papillomata (benign), the only sign of which is blood in the urine; malignant tumors, which are always accompanied by pain and may closely simulate stone in the bladder; tuberculosis of the bladder (which is practically always secondary to kidney infection); succulent condition of the mucous membrane, as in stone of the bladder, and in a condition which has recently been noted and which is a form of cystitis hæmorrhagica. The pain in the case of stone in the bladder is terminal and at the head of the penis. Frequent micturition during the day, with occasional terminal hematuria, and quiet at night, indicate stone in the bladder. When the patient is lying down the stone is resting on the posterior bladder wall and does not cause irritation. On the other hand frequent micturition during the night points to prostatic enlargement. The "searcher" may be used to detect the presence of stone in the bladder but the cystoscope will clear up the diagnosis at once, revealing all loose and encapsulated stones, the condition of the internal orifice, enlarged or pedunculated prostate (middle lobe), and also the coexistence of any other bladder condition.

The form of cystitis hæmorrhagica alluded to above has been thoroughly worked up only very recently. It is characterized by small stellate or patchy hemorrhages in the bladder mucous membrane and sometimes by the appearance of small ulcers. There are usually symptoms of mild bladder irritation with the sudden appearance of a mud-colored hematuric urine, accompanied by fever, sore throat, and malaise. In Vienna it seems especially prone to follow influenza, and occurs mostly in the spring of the year. Dr. Blum thinks that the stomach is always affected and that in all probability the etiology has the same general constitutional background as when peptic ulcers are formed in the stomach. This assumption is borne out by the quick response which is made when the medication is directed towards making the urine less acid. He gives dram doses of bicarbonate of sodium thrice daily with urotropin and the entire condition disappears in three or four days. No local treatment is undertaken. This condition is interesting from a diagnostic standpoint in that unless one is familiar with the etiological pathology he may be led into taking a much more serious view of the case.

As regards prostatic enlargement it is divided into three stages. First stage: when there is no residual urine although the subjective symptoms and examination indicate an enlarged middle lobe. The symptoms are an increased desire to urinate, especially at night with possibly a little terminal hematuria. In this stage the middle lobe enlargement is due to a hyperemia of the gland which is the cause of the nocturnal pollutions and erections. Such a prostate is treated by massage and the "cold-sound." The latter is a hollow metal sound, about 18 French, which is divided along its lumen by a horizontal partition and thus admits of a return flow. A rubber tube connects the sound with a reservoir of ice-water and the latter flowing through the upper compartment around the end of the partition and back through the lower compartment. The same idea is sometimes carried out by applying cold water to the prostate through the rectum by means of a short bulbous metal tube which is partitioned and allows for a return flow. The second stage commences when ther is residual urine, the middle lobe of the prostate bulging up into the bladder. This condition is an aggravated first stage and in general is an indication for prostatectomy. In this stage the condition of the gland has passed beyond the stage of hyperemia and there is now hyperplasia. The third stage becomes apparent when the symptoms of retention appear. There is a large amount of residual urine, chronic cystitis, more or less aggravated, and, in the graver cases, "urolsepsis" is present. This latter term has been coined by the urologist to indicate general infection from the bladder upward and has a clinical picture of its own, consisting of marked emaciation, low grade fever, foul tongue, anorexia, debility, and other symptoms indicating an ascending infection. Here the indication is a permanent catheter. Care should be exercised in withdrawing the urine of old men—if there is a large quantity only a comparatively small amount should be withdrawn three times a day. On the first day about 300 c.c. is withdrawn three times. The next day about 400 c.c. at a time and so on until there is no danger of general collapse or from the danger of sudden withdrawal of urinary pressure on the atheromatous arteries of the bladder. Sometimes after complete withdrawal of the urine it is best to inject into the bladder about 200 c.c. of boric acid solution to take the place of the urine withdrawn. Depending on the condition of the bladder the urine may be only withdrawn once a day or twice a week. Prostatectomy is absolutely contraindicated in this stage as it is invariably followed by anuria and renal stasis.

There is a condition of prostatic atrophy which causes a permanent retention of the urine due to the fact that when the prostate atrophies the prostatic urethra is at first pulled into the vertical position and then backwards so that a valve forms at the internal orifice. The condition is relieved by removing the spur (suprapubic cystotomy) that makes the valve. It consists practically of removing the internal sphincter as there is little or no prostatic tissue left. No prostatectomy should be performed without careful functional tests being made beforehand. The indications for prostatectomy are as follows: in general, the second stage is the only stage when prostatectomy is indicated. The more or less specific indications are: (1) When the passage of the catheter causes bleeding or trouble in passing. (2) When the metal catheter has to be used. A patient is never allowed to pass a metal catheter on himself. (3) Social—when the patient has not the intelligence to use a catheter.

Urethroscopy.—This course takes cognizance of all chronic conditions in the anterior and posterior urethra, the latter embracing the prostatic urethra which contains the verum montanum, Cowper's glands and the prostatic follicles. There are two methods of examination: the so-called "dry" method in which simple nickel-plated tubes of different sizes are used, beveled at one end and flanged at the other; and the so-called "wet" or irrigating method which contemplates the use of a magnifying optical system closing the outer end of a tube with a prostatic curve through which water is allowed to flow by means of a small opening in the tube. In this latter method there is a small opening algonside the optical system for the introduction of a slender wire probe or cautery and it is by this means that operations are performed in the posterior urethra and around the margins of the internal orifice. The "dry" method is almost exclusively used for work in the anterior urethra while the "wet" method is rarely used except for posterior work. The illumination in the "dry" method is by means of reflected light at the outer end of the tube whereas in the "wet" method there is a small protected incandescent bulb at the distal opening in the tube. The picture seen in a dry urethroscope is a round field showing more of the upper wall of the urethra than the lower wall on account of the beveling of the tube. Where the walls of the urethra collapse there is a small dimple or depression which is called the central figure. The normal urethra shows a small central depression as the central figure, and leading out from it, like the spokes of a wheel, are small radiating lines (blood-vessels) on a pale background. Whenever the radiating lines cannot be seen the urethra is pathological and also the central figure may be eccentric or distorted into a slit. The glands of the urethra are Morgagni's and Littré's and it is only under pathological conditions that the openings of these glands can be seen. The glands of Morgagni are situated in the upper wall (roof) of the urethra and in inflammatory conditions the orifices are seen as more or less rounded or oval openings the margins of which become swollen and darker red than the surrounding membrane. The glands of Littré are much smaller and are scattered all over the urethra. In inflammatory conditions they are to be seen as fine red points, usually in clusters, the openings being obliterated by the swelling of the mucous membrane. Cowper's glands are two small glands situated just anterior to the prostate.

In chronic urethritis the pathological condition is either what is called soft infiltration or hard infiltration. In both of these pathological varieties the glands are more or less involved although during an acute exacerbation the membrane appears swollen and dark red in color and no glands are seen. Soft infiltration is a condition where there is a very slight increase of connective tissue of the urethra and a slightly swollen and hyperemic condition of the mucous membrane. Here the red lines are obliterated, the membrane is a deep red color and the central figure is eccentric or somewhat distorted. Hard infiltration is a condition in which there is a pronounced increase of connective tissue causing the mucous membrane to become pale, the red lines obliterated and the central figure distorted. This condition is the beginning of stricture, the latter being the extreme of hard infiltration. In soft infiltration, the urethroscopic tube is passed and then slowly withdrawn in a rotary manner and, as already indicated, the areas affected are touched with tincture of iodine or 5 per cent. nitrate of silver on an applicator. If any openings of Morgagni's glands appear they are touched with the point of the actual cautery and the glands of Littré are treated with iodine or silver nitrate. This is repeated about twice a week, the irrigations being prescribed and the sounds passed as previously noted. The appearance of the urine will be an indication as to the success of the treatment. In hard infiltration, besides local treatment to the glands, the urethra is slowly dilated by the passage of daily sounds accompanied by massage along the sound. The condition known as urethritis follicularis sometimes occurs in which there is hard infiltration, slight discharge, and the mouths of the glands are closed up so that small retention cysts or follicles occur. This condition is very chronic and should be treated by passing large sounds and massaging the urethra. The glands are cauterized as indicated and the areas of soft infiltration touched with iodine. When a soft chancre occurs in the urethra the endoscope is introduced (after cocainizing) and the ulcer touched with 50 per cent. nitrate of silver every other day. In the treatment of actual stricture a graduated series of sounds is used and when the desirable size is reached it is passed every day for a month. Then every other day for one month. Then twice a week for one month and once a week for each succeeding month up to usually the twelfth month. A special dilator is not used in this clinic as it is claimed to very often produce a break in the mucous membrane and cause ordinary infiltration. The indications and technique of internal urethrotomy will be discussed under operations.

In posterior urethritis the most usual site of inflammation is the groove between the verumontanum and the internal sphincter. Normally this area is of a flesh-like color with small blood-vessels running in a longitudinal direction. Edema bullosum (like the bladder condition) is not an uncommon form of chronic inflammation in this area (fossa prostaticus). In this and other forms of chronic inflammation of the mucous membrane the treatment is touching with half strength tincture of iodine or 5 per cent. nitrate of silver about once a week. After the inflammatory areas have been located in the posterior urethra by the irrigating method the urethroscope is held firmly in the position over the spot to be treated, the optical system withdrawn allowing the water to escape, the part to be treated is dried by pledgets of cotton passed down the tube on an

applicator and then touched with the half strength iodine or 5 per cent. nitrate of silver.

Very recently the pathology of the verumontanum has been engaging the attention of urologists and whereas the study of the disease of this structure (which is called colliculitis) is only in its infancy, enough has been learned to warrant the recognition of a definite classification of the pathology and certain encouraging lines of treatment. According to the pathological condition present the classification is as follows: (1) Hyperemia (usually without enlargement). (2) Hypertrophy (usually without hyperemia). (3) Papillomata (polyps). (4) Cysts. Any of these conditions may give rise to the symptom complex known as neurasthenia urethritis. The general symptoms of this form of neurasthenia are: pain in the perineum, over the pubes, down the front of the thighs, in the loins, and back of the head. Anorexia, insomnia, and mental depression complete the neurasthenic picture. The special symptoms are impotence, premature ejaculations, pollutions (with tendency to masturbate), and frequent micturition without distinct polyuria. The latter condition has been given the name of pollakiuria. The treatment of this condition depends of course on the findings with the urethroscope, although all local treatment of whatever pathological condition is present is accompanied by massage of the prostate and the daily passage of the "cold-sound." When simple hyperemia is present half strength tincture of iodine or 5 per cent. nitrate of silver is applied once a week. Hypertrophy of the structure calls for touching with the actual cautery once a week. Papillomata and cysts are also touched once a week with the actual cautery until they disappear. Small ulcers are treated in like manner. Should there be any adjacent areas of hard or soft infiltration appropriate treatment should be instituted. Both the "dry" (simple) or the "wet" (irrigating) urethroscope can be used in treating the verumontanum but only the irrigating instrument can be used in treating that part of the urethra posterior to the verumontanum and in the neighborhood of the internal sphincter. The irrigating instrument is the only one to use to form a correct idea of the pathology of the posterior urethra in that the constant flow of water balloons out the part under observation, the illumination is far better, and the optical system slightly magnifies the condition present. The instrument is to be rotated or turned so as to successively view the upper and lateral parts as well as the lower part or floor of the posterior urethra. It is not wise to use as strong solutions in the posterior as in the anterior urethra since strong solutions sometimes cause a violent inflammatory reaction. There is a condition of the internal sphincter which is especially common in women and consists of a more or less inflammatory proliferation of the mucous membrane, sometimes almost resembling polyps. This condition is due to the entention of an inflammation of the posterior urethra and usually gives rise to a distressing frequency of micturition. Cauterization gives good results but the condition is liable to recur. Actual polyps or cysts are to be treated in the same manner.

Genitourinary operations: Prostatectomy by the suprapubic route is universally followed in Vienna. In preparation for this the bladder is washed out and then filled with about 300 c.c. of a 3 per cent. boric acid solution and the catheter is clamped. The incision differs in different clinics. Professor Zuckerkandl uses the horizontal incision always and, if necessary, will partially divide the rectus sheath and muscle. This incision is certainly to be preferred when the tumor to be removed is large or when a good exposure of the interior of the bladder is indicated as in extirpation of large polyps, removal of a carcinoma or repair of a ruptured bladder. The incision in the median line is made in the usual way through the linea alba just above the symphysis and the posterior fascia is carefully incised, avoiding the peritoneum and opening up the prevesical space The upper and anterior surface of the bladder is now looked for, cleared and brought up into the wound with a vulsellum. Three double traction sutures are now introduced into the muscular wall, one on each side of the intended incision and one just above the proposed incision in the bladder. The assistant holds two of these traction sutures and the operator one, making a triangular area under traction and brought up into the wound. At this juncture the clamp is removed from the catheter and the bladder emptied so as not to contaminate the prevesical space with even the least amount of diluted urine when the bladder is opened. The knife is now plunged into the bladder and the opening widened longitudinally. The bladder is now explored and the condition of the prostate ascertained. The two lateral traction sutures may be temporarily attached to the skin to hold the bladder up in the wound. With a good view of the parts and guided by the finger, a pair of scissors incises the mucous membrane crosswise for about an inch on the most prominent part of the middle lobe. The index finger is now introduced into this opening and the prostate shelled out. Hemorrhage is controlled by temporary packing but on occasions, when the bleeding is very severe, I have seen a large pack of iodoform gauze left in the prostatic space, the end being brought out through the wound. In von Frisch's clinic the drainage is a very important feature of the operation and since the adoption of this special drainage there has been no death at the Polyklinik Hospital from this operation. It is accomplished as follows: a piece of rubber tubing about twenty-five inches in length is used and, about ten inches from one end, three fenestra are made one inch apart. The catheter, which is always in the bladder, is pushed further in and the end is secured to the long end of the rubber tube by passing the catheter into the lumen of the tube and then wrapping with silk. The catheter is now withdrawn through the urethra pulling the rubber tubing after it until one of the fenestra lies just inside of the bladder, one over the prostatic space and one in the posterior urethra. The remaining part of the tubing is brought up into the external opening and the bladder closed and anchored to the abdominal wall. Catgut is used and the ends of the first stitch are left long so that they may be passed through the rectus on each side and then tied again, bringing the bladder snugly up to the abdominal wall. The remainder of the bladder wound is now closed (except for the tube) by Lembert sutures into the muscular wall. The bladder is washed out twice a day through the long tube in the bladder and urethra, the fluid and clots escaping through the urethral portion. After five days the dressings are removed and the tube pulled up until the first opening is seen. At this point it is cut off and the tube is then withdrawn by pulling on the urethral end until it occupies its original position. This is left in place as a permanent catheter as long as necessary and the bladder wound allowed to heal.

In the operation of nephrotomy for the removal of stone the kidney is exposed and delivered through

the usual oblique incision. A shallow incision is now made about two inches in length and one centimeter behind the most prominent convexity of the outer border of the kidney. Into this incision a hemostat is introduced and pushed into the pelvis. The hemostat is now opened and slowly withdrawn through the kidney cortex, thus enlarging the opening into the pelvis to such an extent as to admit the index finger for purposes of exploration. In this manner the size and number of the stones is ascertained. The stones are now withdrawn and a small drainage tube introduced into the pelvis of the kidney. The wound in the kidney is now closed with deep matress sutures, one of these sutures passing through the drainage tube to hold it in place. The muscles and skin are brought together in the usual manner, except for the opening for the drainage tube. The latter is left until the catgut suture is absorbed and the tube comes away of itself. Drainage is absolutely necessary as considerable blood always collects in the pelvis after this operation. For the removal of stone lodged in the pelvis the incision in the pelvis is made as high up as possible and slightly behind the concave inferior border. It is closed by a layer of catgut Lembert sutures and no drainage is used. This is the operation of choice if the stone is low down in the pelvis and can be easily secured. Stone in the ureter is exposed on the line of continuation of the oblique incision for exposing the kidney. When located the ureter is incised longitudinally and the stone withdrawn, Lembert catgut sutures closing the wound. In this situation a cigarette drain is used.

In the operation for nephropexy two large single silk sutures are passed deeply through the kidney substance about one inch apart. The two ends on each side are now tied, the knot just reaching the kidney but not compressing it. One end of the inner suture is now threaded through a large needle and the latter passed around the twelfth rib and then tied to the other end of the inner suture. In the same manner one end of the outer suture is threaded and passed through all the muscles of the back and then tied to the other outer suture. The kidney is now secured above to the twelfth rib and posteriorly to the muscles.

The indications for internal urethrotomy are as follows: (1) Whenever gradual dilatation cannot be performed without bleeding. (2) Strictures (resilient) which resist dilatation beyond a certain point (3) Social, when patient cannot come for gradual dilation. In performing this operation a special filiform bougie is passed and is then screwed to a small metal sound having a groove in it through which can be inserted blunt pointed triangular knives of different sizes. The grooved sound is passed down the urethra, being guided through the stricture by the attached bougie. A number 20 knife is usually selected, and when the stricture is reached, it is made to pass through the top wall first and is withdrawn through the same incision. The instrument is now turned a little to the right and made to cut through the lateral wall. It is then turned so as to cut through the left lateral wall and is then withdrawn in the vertical position. The metal instrument is now withdrawn and unscrewed. A long metal guide is screwed on to the bougie and a large stiff catheter is passed over the guide into the bladder. This catheter remains as permanent drainage and dilatation for four days and then gradual dilatation is commenced. When the stricture is situated in the deep urethra an external incision is made and all the scar tissue is removed. The cut ends of the urethra are brought together over a catheter with fine silk sutures and the catheter allowed to remain as permanent bladder drainage until the integrity of the wound in the urethra is assured. Stones in the bladder are moved by crushing when possible and small polyps are snared with the aid of the operating cystoscope. When large polyps are present Zuckerkandl gets a large exposure of the interior of the bladder with the horizontal incision and extirpates the entire mass with attached mucous membrane. Packing with iodoform gauze and suprapubic drainage complete the operation. Carcinoma of the bladder, when operable, is removed by extirpation of the entire affected bladder wall and as much of the surrounding wall as can be spared. The wound in the blader is then brought together in the usual way.

Cystoscopy: The use of the cystoscope is taught in Dr. Blum's course, but there are those who make a specialty of giving private individual instruction along this line, and it is a decided advantage to secure their services in order to see a larger number of cases individually. Dr. Robert Bachrach, who has been Zuckerkandl's assistant for a number of years, gives an excellent course at the Rothschild Hospital. Dr. Hugo Schüller, chief of the orological department of the Franz Joseph Hospital, gives another such course. I found both of these courses very satisfactory indeed, and both of these gentlemen are peculiarly fitted for their line of work, having at their command a rich supply of clinical material. The cystoscopes in general use are the ones with which we are all familiar. The indirect Nitze scope is the one most used in general work and there are quite a number of direct scopes on the market which have their advocates. Lieter & Co., of Vienna, have recently perfected an interchangeable direct, indirect irrigating, catheterizing, and operating scope, all in one, which is proving very satisfactory. They have also just completed a very ingenious posterior urethroscope which will undoubtedly greatly improve the technique in this locality. As regards the diseases for which the cystoscope finds its special use the incidence of tuberculosis of the genitourinary tract is certainly more common in Austro-Hungary than in America. The tubercle is seen in the bladder as a small yellowish spot surrounded by a very narrow zone of red. It first makes its appearance as a distinctly one-sided affection, which in itself is of diagnostic value. It is, of course, secondary to kidney infection of that side and is accompanied by a hyperemic swollen condition of the ureter opening on the side of the affected kidney. To confirm the diagnosis, bacilli must be obtained from the urine sediment. Should the condition appear suspicious and yet no bacilli are recovered from the urine then guinea-pig inoculation is made, and after four to six weeks the characteristic changes are sought for. These consist of the appearance of small swollen lymph nodes in the greater omentum with enlargement of the spleen and possibly the occurrence of tubercles in the latter. If after the examination of two guinea-pigs the findings are negative then the diagnosis is not confirmed. Before removing the affected kidney, functional tests are made and the ureter of the apparently sound kidney is catheterized and tested for bacilli so as to make certain of the integrity of that kidney. From 70 to 80 per cent. of the tuberculous bladders clear up after removal of the infected kidney. For the chronic cystitis of a tuber-

culous bladder the following routine treatment has proved satisfactory: Iodoform, 1 to 2 grams; guaiacol, 1.5 to 3 grams; sweet almond oil, 30 grams. Four or 5 c.c. are injected into the empty bladder every second day. Four or 5 c.c. of a French preparation, oleum gomeral, injected into the empty bladder every other day have given very good results and this method has also been used with very beneficial effect on all other inclosed tuberculous lesions, such as in joints. Silver nitrate is absolutely contraindicated in a tuberculous bladder.

Colon infection of the kidney pelvis is diagnosed by catheterizing both ureters and examining the discharge for colon bacillus. When present the pelvis is irrigated with a 1-2000 silver nitrate solution once a week and in a chronic infection excellent results have been obtained with an autovaccine. In irrigating the pelvis it must be remembered that the normal capacity is only 4 or 5 c.c. The pelvis of the kidney may be filled through a catheter with a 5 per cent. collargol solution and in this way a radiographic picture obtained. In using this there is danger of infiltrating the kidney substance and collapses have been seen. The size of the pelvis may be estimated by injecting fluid slowly into the pelvis until the patient complains of pain. Any larger amount than 5 c.c. will indicate the extent of hydronephrosis. In this way, depending on the location of the pain, a floating kidney may be diagnosed and located.

Carcinoma of the bladder is rather frequently met with, especially among the Hebrews. An ulcerating indurated nodule, rapidly infiltrating, was the type most common and differing from the tuberculous ulcer by the raised character of the diseased area. In this connection the so-called "carcinoma reaction," which Dr. Schüller employed several times in his clinic is very interesting. It is especially applicable to bladder cases in which, on account of pain and hematuria, the cystoscope cannot at once be used.

It consists in treating carcinoma cells with the blood of the suspected patient. Normal human blood will dissolve 50 per cent. of the cells, whereas in a patient who has carcinoma the blood will dissolve but a comparatively small percentage (10 per cent. to 20 per cent.). Dr. Schüller frequently employs small capsules of radium in these bladder cancers with encouraging results. It is held over the ulcer by a specially arranged cystoscope for as long periods as the patient can stand.

As a miscellaneous note enuresis, when it does not respond to internal medication and faridization of the internal sphincter through the rectum is treated by epidural injection of salt solution. The needle is entered in the space between the coccyx and sacrum and when the bone is reached it is directed upward.

Dermatology: In this department the names of Finger, Zumbusch and Ehrmann are world known, while Pick, Kerl and Lier are the leaders among the younger skin men. The skin clinics of Vienna are famous, and justly so, since in no other medical center is there to be found such a vast variety and wealth of material. In would seem that skin diseases, as a whole, and a number of varieties in particular, are much more prevalent in Vienna than any place with which I am familiar. Tuberculous skin affections are frequently seen, and a week's attendance at one or other of the large skin clinics will run the entire gamut of dermatological pathology. The large museum of artificial specimens of Prof. Finger contains exhibits, each of which is indeed a work of art. Once the diagnosis is made the treatments in no wise differ from those found in our own modern skin books. The use of the so-called "glass pressure" method for the quick differentiation of obscure efflorescences from luetic manifestations is largely in vogue. This method is only applicable in the early stages of an eruption and depends for its demonstration upon the fact that all syphilitic skin disturbances are infiltrations, and do not disappear completely when a strip of glass (an ordinary glass slide) is pressed down on the affected part; whereas the other sudden eruptions are only hyperemic in character and disappear totally under glass pressure.

The therapy of syphilis is outlined under three heads: I. Prophylaxis: (a) Active immunization (theoretical) experimenting on monkeys with weakened virus. (b) Passive immunity along the same lines. (c) Virus destruction (calomel ointment, etc.). II. Abortive: Up to the fifth week (salvarsan and mercury). III. Curative: (a) Salvarsan, (b) Mercury, (c) Iodides. Under the head of prophylaxis, (a) active immunization and (b) passive immunization have been taken up along the lines demonstrated by Metchnikoff, but without other than theoretical value. Certain members of the monkey family have been inoculated with syphilis, but there are varying degrees of susceptibility among them. The nearer the approach to man the easier it is to effect an inoculation, as in the case of the chimpanzee. A good many of the lower animals have also been inoculated, such as the rabbit, dog, horse, etc., but only in some peculiar way, as injecting into the eyeball, and in most cases they were only affected locally, although the spirochetes multiplied and produced circumscribed local lesions. It was hoped that by the passage through the lower animals a serum would be developed which would be so modified as to be available for immunizing the human family; but this has not been found to be the case and many experiments have shown that no immunity can be hoped for in this direction. The spirochete, too, taken from the lesions in animals through many generations have been found to be just as potent as regards human infection as before. The prophylactic principle of (c) virus destruction gives much more hopeful results. Calomel ointment (33 per cent.) is regarded as having only a relative value and cannot be relied upon with any degree of certainty. Immediately after intercourse of a suspicious character any abrasions are cauterized with the actual cautery or carbolic acid, and if no abrasions are present, then the calomel ointment is used. As regards the abortive treatment the spirochete should always be demonstrated in every case before this line of treatment is undertaken. The very encouraging results as shown by the Viennese clinical reports may be classified under three general heads as follows: (1) Up to the fifth week, when the spirochete is positive, Wassermann negative and no palpable glandular enlargement, the abortive treatment is successful in 40 per cent. of cases. (2) Up to the fifth week, when the spirochete is positive, Wassermann negative, and only one-sided enlarged inguinal glands, the treatment is successful in 15 per cent. of cases. (3) Up to the sixth or seventh week, when the spirochete is positive, Wassermann negative, and bilateral inguinal involvement, no success has been recorded. At the outset of the abortive treatment the hard chancre is excised and the spot is then touched every day with tincture of iodine. In case the chancre is situated so that it cannot be ex-

cised, it is thoroughly cauterized with carbolic acid. Silver nitrate should not be used as it only cauterizes superficially. After treating the chancre in this manner the first intravenous salvarsan injection is given. Eight days later six weekly injections of salicylate of mercury is started, followed by a second salvarsan injection. A Wassermann is then taken and if negative the chronic intermittent mercury treatment is begun. If Wassermann is positive then a third or fourth salvarsan injection is made and followed by the mercury treatment. By this treatment it can be assured that no rash or glandular involvement will occur and that the Wassermann will remain negative for at least four years; this is as far back as the records with salvarsan go. As regards the curative treatment the Viennese clinician prefers, along with salvarsan, the intramusculr injections of insoluble salts of mercury (salicylate) or the inunctions. Other forms of mercurial medication are practically never used. Sometimes the thymolate of mercury and sometimes calomel is used when patients show an idiosyncrasy for the salicylate. The soluble sats (succinimide and bichloride) are only used when a quick effect is desired to be substituted later by the insoluble salts. The iodides are not regarded as a specific, but they have a quicker effect on tertiary lesions. They are given symptomatically, but do not take the place of mercury. The following prescription may be taken as the standard for intramuscular injections: Mercury salicylates, 3 grams; sterile liquid paraffin, 30 grams. M. Sig. 1 c.c. is injected weekly into the gluteal muscle. Six c.c. are spoken of as a "main cure" and are equal to thirty daily inunctions of about a dram each of blue ointment.

The routine for antisyphilitic treatment is as follows: The first year after infection three "main cures" are given four months apart. Eight days after each "cure" twenty grams of sodium iodide are given in divided doses in water. The second year two "main cures" six months apart are given. The third year two "main cures" are given six months apart, so that in three years there are seven "main cures" given. If during this time there are indications for salvarsan it is to be used. This is called the chronic intermittent mercury treatment. Salvarsan is not given in the beginning as routine treatment in most of the clinics, as it causes the sudden death of a large number of spirochetes and a toxic condition results. The following sums up the Viennese idea of salvarsan medication:

Indications: Abortive, to save life or rapid destruction of tissue, when mercury is refractive, mercurial idiosyncrasy, gumma. Contraindications: Arteriosclerosis, every organic heart affection, nephritis, fever, optic nerve affection, acoustic nerve affection, not given after fifty years of age.

A patient is allowed to marry as follows: Four years after infection, two years without symptoms, seven "main cures." Positive Wassermann does not necessarily forbid marriage. Unless a man has syphilitic lesions which are capable of communicating infection he will not be the father of a syphilitic child, unless the mother has previously been infected. Mucous patches are touched every other day with nitrate of silver stick, or a 50 per cent. solution of bichloride in alcohol. Sores on the skin are treated with "blue plaster," which is also used in congenital syphilis, being placed on the back of a new born child. When psoriasis patches occur on the palms and soles, a 1½ per cent. solution of bichloride in collodion is used and when the entire body is covered a bichloride bath (¼ per cent) is given. The routine treatment of soft chancres is to touch them every other day with concentrated carbolic acid, to powder them with iodoform three times a day and to cover them with iodoform gauze.

General Surgery: As regards general surgery the Viennese technique is in the main the same as ours. The site of operation is rubbed over with benzine, followed by tincture of iodine. The hands and arms, after scrubbing are rinsed off in 70 per cent. alcohol followed by sterile water. Over the rubber gloves the operator and assistant frequently wear ordinary cotton gloves, which are changed several times during an operation. The advantage derived from these cotton gloves would seem to be the prevention of the blood drying and sticking on the rubber gloves and they also admit of the easier handling of intestines and other abdominal organs. Silk is used a great deal more as ligature material than in our clinics. As regards anesthetics, ether and the ACE mixture are universally used. The nitrous-oxide gas-oxygen anesthetic is very seldom used. Local anesthesia is highly developed in a few of the clinics.

A great deal more might be written of the work to be had in every department of medicine and surgery in the University of Vienna, but it would take a considerable time to work up first hand observations and notes of all these clinics. Suffice it to say, that one can spend a very profitable two or three months in Vienna in any professional specialty. One can loaf in Vienna with the same amount of ease as in any other agreeable metropolitan city. In order to get anything out of the work, one must be willing to devote his whole time and energy to the undertaking. A certain few who come to Vienna, ostensibly for purposes of study, never seem to get much further in the work than to pose as a great specialist from their often obscure habitat in America and practically all they get out of their trip is the artificial glamour of having studied in Vienna.

GUMMA OF PROSTATE AND BLADDER.

SIX INTRAVENOUS AND ONE INTRAMUSCULAR INJECTIONS OF SALVARSAN AND TWENTY-SIX INTRAVENOUS INJECTIONS OF NEOSALVARSAN TO PATIENT SIXTY-SIX YEARS OLD.

By JOHN O. RUSH, B.S., M.D.,

MOBILE, ALA.

ASSOCIATE PROFESSOR, GENITOURINARY SURGERY AND VENEREAL DISEASES, SCHOOL OF MEDICINE, UNIVERSITY OF ALABAMA; ATTENDING GENITOURINARY SURGEON, CITY HOSPITAL; ATTENDING GENITOURINARY SURGEON, UNIVERSITY DISPENSARY.

This case is of unusual interest to me from several viewpoints, viz., the age of the patient, the disappearance of edema, the disappearance of albumin in the urine, the disappearance of all bladder and prostatic symptoms, and the continued improvement with the steady use of the drug. Medical periodicals have been flooded with papers on salvarsan and neosalvarsan, and it is useless to go into details on the technique of preparation and the administration of either drug. In that regard, all I will say is that I never dissect up the vein, all my injections are done by direct puncture, and in the case here cited, I have often punctured the patient's forearm several times in the attempt to get a vein, he having a very fat forearm and unusually small, obscure veins, but there isn't a scar anywhere to show he has ever had a puncture made.

The following diagnoses had been made on this case: Bright's disease, carcinoma of rectum involv-

ing prostate, senile hypertrophy of prostate, and vesical calculus. When I examined the patient and got his full history, I diagnosed the condition as gumma of the prostate. The following is the history of the case:

F. P.—October 22, 1911. Age 66 years; Scotland; single; steamship captain (retired). Family history: Father died, age 90, senility; mother dead, pneumonia; four sisters, good health; no brothers. Past history: Has never had any illness except syphilis, which he contracted in China, in 1869, while an apprentice aboard ship, since which time he has religiously taken treatment at intervals. He took mercury and potassium iodide three months each year. Donovan's solution, for three years steadily. Present illness: He has suffered more or less from indigestion for the past twenty years. One year ago feet began to swell, and pitted on pressure, his eyes were puffed, and dizziness was a frequent complaint. His headaches were unbearable at times. In 1910 he presented himself to a physician here, who examined him and when such large quantities of albumin were found in urine, all other symptoms were disregarded for a time. A large prostate, bloody urine containing pus, and a constant desire to get up and urinate were the conditions which most worried the patient. Treatment for chronic Bright's disease was at once begun by the attending physician. The patient left the city in April, 1910, and continued the treatment for one year. In April, 1911, he returned and reported to his physician that his condition was practically unchanged; his symptoms were about the same, and he had gotten so he had to use a catheter at night to draw off his urine. He insisted that the attending physician should administer salvarsan because of his syphilitic infection when a boy, believing that all his trouble was due to syphilis. Several surgeons were consulted, all of whom advised prostatectomy, but on account of the large amount of albumin present in the urine, they feared anesthesia. Finally his attending physician complied with his request and administered salvarsan intravenously April 25, 1911, although the urine at that time was loaded with albumin. In a few days the patient left the city. April 30: Patient improved, urinary symptoms improved, as to frequency, urine still loaded with albumin.

On October 22, 1911, the patient presented himself to me for treatment and upon finding such large amount of albumin present in urine I refused to administer salvarsan until his former physician assured me such was the case when the first dose was administered. When he presented himself to me for treatment, examination revealed a large prostate, apparently as large as a hen's egg, indurated and very sensitive on pressure on right lobe; his urine was dark and contained blood, mucus and pus. A small Nitze examining cystoscope was passed into the bladder with the idea of attempting an examination, but this produced such profuse hemorrhage, the examination was discontinued. The Wassermann reaction was faintly positive. An intravenous injection of salvarsan was given October 26, with marked reaction, and in a few days the patient left the city. March 26, 1912, the patient returned for another injection of salvarsan, claiming marked improvement in the symptoms since October. Examination of the prostate by the rectum revealed a mass apparently as large as when examined in October. Uranalysis showed albumin, but in less amount than in October, and no blood or pus; his general condition was somewhat improved. March 26: Another intravenous injection of salvarsan was administered with no reaction. March 27: Urine showed no blood, no pus, but albumin was still present in the same amount. April 2: Wassermann negative. April 12: Urine clearer, but containing mucus and shreds; no blood, no pus; albumin present but not in as large quantity. Urinary symptoms improved; gets up only once at night to pass urine. Digestive symptoms improving. Weight, 169. Intravenous injection of salvarsan, slight reaction. April 14: Patient says he feels better, urinary symptoms about the same, albumin the same. Patient left city. April 23: Patient returned; claims he feels markedly improved, insists on another intravenous injection of salvarsan. Uranalysis: Color, amber; reaction, faintly acid; albumin, present, about as on April 12; sugar, negative. The patient states he gained three pounds since April 12. An intravenous injection of salvarsan administered April 24; slight reaction. Patient left the city April 25. May 3: Patient returned for another intravenous injection of salvarsan. Looking better, appetite improving, sleeping better. Uranalysis shows about the same condition of urine as on April 23. Because of patient's claim of improvement, another intravenous was administered May 4. May 5: Patient left city. May 24: Patient returned, demanding another intravenous injection of salvarsan. Physical condition about the same as when last seen, May 5. Urine about the same but because of his claim of such marvelous improvement in feeling, I was inclined to give him another intravenous of salvarsan.

A consultation was held with Dr. R. H. Von Ezdorf, surgeon in command at the United States Marine Hospital, who was at that time my chief and co-worker with salvarsan. After deliberating we decided we had accomplished all possible from salvarsan intravenously, and we decided to give the patient a dose of salvarsan intramuscularly. This we did, using a neutral solution, diluted to 50 c.c. with physiological sodium chloride solution, 25 c.c. being injected deep into the gluteus on either side. The patient left the city. I did not see him again until June 20, when he returned, and used every unkind word in his vocabularly to me, because of the intense pain produced by the intramuscular injection. He insisted upon another intravenous administration of 606, but this I refused to give him, and instead administered hypodermically into gluteus a solution of mercuric iodide and potassium iodide in sterile cotton seed oil (*Journal of Military Surgeons*, 1910). Twenty drops of this solution were injected in the gluteus twice weekly. I left the city and was absent four months, during which time my assistant, Dr. Padgett, treated the case as outlined by me. In October, 1912, I returned and found the patient religiously following the treatment. During my absence I had seen several physicians of New York, and Dr. Uhle of Philadelphia administer neosalvarsan, and the question of kidney lesion seemed to play no part, so I began to investigate and found that neosalvarsan could be given in cases in which salvarsan was contraindicated. This particular case came to my mind at once, and as soon as I returned I began giving him neosalvarsan. On October 10 the first dose of neosalvarsan was given him intravenously in a dose of 0.9 gram; there was no reaction. October 12: Another intravenous injection of neosalvarsan given, no reaction, patient feeling marked improvement, albuminura markedly decreased in urine. October 18: Another intravenous injection of neosalvarsan was given with no reaction. October 20: Urine shows marked decrease in albumin. Patient gained five pounds since October 10. Urinary symptoms entirely absent. Patient claims he sleeps all night and does not have to get up to urinate. Prostate feels smaller, is not sensitive, and the former trouble at the neck of the bladder and in the rectum is entirely gone. October 23: Another intravenous injection was given, with no reaction. Urine shows less albumin. October 24: Patient claims marked benefit; says he feels better than in fifteen years. October 28: Patient returns for another intravenous. October 29: Patient left city. November 3: Patient returned, requesting another intravenous injection of neosalvarsan. Uranalysis showed a trace of albumin. Patient claims he sleeps from 8 P. M. to 6 A. M., without having to rise. Prostate shows marked decrease in size, appetite good, digestion good. November 4: Another intravenous injection of neosalvarsan was given. November 6: Patient left city. November 30: Patient returned, claiming a wonderful change for the better; says he feels as well as ever in his life. Has gained twelve pounds since taking the first dose of neosalvarsan. Insists on taking double dose. This was refused; but another intravenous injection of neosalvarsan was administered. Patient left city December 1. December 10: Patient returned feeling perfectly well, urine shows trace of albumin. He is enthusiastic over neosalvarsan, and wants to remain in the city one week, and take an intravenous injection every day. This request was refused, but another intravenous injection was administered December 10. December 11: The patient left the city. December 14: He returned and another intravenous injection of neosalvarsan was given. Urine shows just the faintest trace of albumin. The prostate is the same as when previously examined. No discomfort from urinary symptoms. Patient sleeps well all night without rising. Neosalvarsan administered December 19 intravenously. January 12: Patient returned for another dose. Urine shows a mere trace of albumin. Prostate shows a decrease in size. Appetite good, gained four pounds, sleeps all night, claims eyesight is improving with each dose. January 12: Another 0.9 gram dose was administered intravenously. January 13: Patient left the city again. January 17: He returned. His urine shows no albumin, and he sleeps well, his appetite is good, he urinates normally only three times daily, and not after going to sleep. January 17: Another 0.9 gram dose was given intravenously. The patient was not seen again until February 26. Feeling perfectly well, he says. March 10: Another in-

travenous injection was administered. Next seen June 25, when the Wassermann reaction was negative. July 6: Feeling fine, examination of prostate shows a gland about one-third larger than normal. No urinary disorder. Urine shows no trace of albumin; the urine is clear, amber color, and normal in quantity. Specific gravity 10.10. Acid reaction. The patient states he feels young again, and to use his expression: "I will live to be a hundred and still be young if you will keep shooting that into me." July 6: Another 0.9 gram dose was administered intravenously. July 7: Another 0.9 gram dose was administered intravenously. July 10: Patient declares he feels better than since he was sixteen years old. Prostate same as at last examination. Urine shows no albumin. Appetite good. July 13: Neosalvarsan 0.9 gram administered intravenously. July 16: Neosalvarsan 0.9 gram administered intravenously. July 16: Urine: color, amber; odor, urinous; reaction, acid; albumin, negative; sugar, negative. The patient sleeps from eight o'clock at night until six the next morning; his appetite is good, he feels as well as ever, and looks better than in fifteen years; his weight is 188. The prostate is not sensitive to pressure, and only one-third the size when first examined. July 30: Intravenous 0.9 gram neosalvarsan. Left city night of July 30. Returned August 10. Another 0.9 gram neosalvarsan intravenously. Left city night August 10. August 15 another 0.9 neosalvarsan was given intravenously. August 16 left city. August 30: Urine, clear amber, no trace albumin, no sugar; few hyaline casts. Specific gravity, 1016. Reaction acid. Weight of patient, 190 pounds; feeling like a young man; claims he has erections of penis, first time in six years; eyesight improved. Left city August 30; October 5 returned; another 0.9 gram neosalvarsan intravenously. Left city night of October 5. October 10, 0.9 gram neosalvarsan intravenously. Left city night of October 10. October 19, 0.9 gram neosalvarsan intravenously. October 20, patient feels better and insists on another dose. October 22, 0.9 gram neosalvarsan intravenously.

From every source I expect to receive the most severe criticism for the continuous use of an arsenical preparation, because so much has been written on the dangers of salvarsan and neosalvarsan that to-day there are those who are so skeptical they even refuse to administer the drugs. I have read numerous reports of deaths from the use of salvarsan and neosalvarsan, and I am of the opinion that the blame should not be charged to the drugs, but to the faulty technique in their administration or their use in cases in which they were contraindicated. This opinion is based upon my experience with six hundred (600) administrations of salvarsan, and eight hundred (800) administrations of neosalvarsan, with not a single death nor even any ill after-effects.

Knowing as I do, the wonderful benefits derived from the use of these drugs by the case here reported, who for a period of more than two years, has shown steady improvement and not one symptom of chronic arsenic poisoning, I am forced to the belief that I should have been derelict in my duty had I denied this old man the comfort, joy, and pleasure he now experiences in life as the result of the repeated use of these drugs. It must be remembered that for a period of fifteen years previous to the use of these drugs his life was a torture, from loss of sleep, indigestion, pain in bladder, etc., and now he sleeps like a child all night, digestion good, has no pain. This alone is justification enough.

The disappearance of albumin in this case, and the disappearance of edema, leads me to think that in addition to the involvement of the prostate there was considerable damage going on in the kidney due to syphilis. In the June number of the *American Journal of Urology* there is found the following abstract, "Damask (*Wiener med. Wchnschr.*, No. 39, 1912) reports the case of a man of 34, in whom evidences of a chronic parenchymatous nephritis set in 11 years after the acquisition of specific disease. As the Wassermann reaction gave a positive result both in the blood serum and in the globulin fraction of the urine, mixed treatment was instituted with very good results. The casts disappeared completely from the urine, the albumin, and red blood cells almost entirely, and the subjective condition of the patient was markedly improved."

Conclusions.—(1) Neosalvarsan should be given in larger doses and should be given at shorter intervals covering a period of at least one year in all cases of tertiary syphilis. (2) In cases of gummata neosalvarsan, alternated with mercury hypodermically, should be given for a period of not less than one year; the neosalvarsan should be given where it is possible to do so not later than seven days apart. (3) The negative Wassermann reaction should not prevent the continuation of treatment in cases in which benefit is noted by its continuation. (4) In cases of gummata, often the Wassermann reaction may be faintly positive or negative, when the lesion is of a serious nature and demands prolonged and consistent treatment.

PARTIAL FACIAL PARALYSIS DUE TO TRAUMATISM.

By B. ROSENBLUTH, M.D.,

NEW YORK.

It is patent that the facial nerve can be injured in any part of its course, either by disease or trauma. The cases to be described are conditions in which there is paralysis of the smaller branches of the facial nerve which ramify over the various parts of the face, as they branch out from the pes anserinus for final distribution to the superficial musculature of the face. No doubt similar cases have been observed, but as far as I have been able to ascertain, they have not been described; so from considerations of interest as well as for practical purposes, they are now placed on record. It is doubtful if these forms of palsy are at all common, for of one variety there was but one case, and of the other form there were four cases. As these five cases were taken from very active services, and are part of a very comprehensive collection of lesions of the seventh nerve, it can readily be seen that they belong to the rarer class of affections of that nerve.

Case I.—A female patient of Dr. D. Linetsky, aged 29 years, had tripped and fallen down a flight of stairs and struck against the projection of one of the steps near the bottom. She was able to rise without assistance and go home. At no time was there any loss of consciousness, and there was no bleeding from the mouth, nose, or ears. There was a contusion over the bridge of the nose, with discoloration that spread from here to both sides of the face extending as far over as the malar eminences, and upwards to the lower eyelids. The alarming feature to be seen was an apparent paralysis of a portion of the lower part of the left side of the face. At no time was there any nausea or vomiting, or any visual disturbance, or any trouble with the trunk or extremities. The patient was alarmed, and apprehensive, fearing that she was seriously injured. Examination showed that the paralysis was limited to the face; this, on further analysis, revealed that the palsy was limited to the left ala of the nose, and part of the left side of the upper lip. This demonstrated itself as follows: the outlines of the left ala of the nose were less distinct than those of its fellow, its depressions being shallower than on the opposite side; it also hung at a slightly lower level than the other ala. The upper lip was slightly deviated to the right, so that the infranasal folds pointed from above, downwards, and to the right. On attempting to expose her teeth by everting the lips, it was demonstrated that the upper row of teeth on the left side remained covered by the drooping of the upper lip of that

side with the exception of the central incisor, which was exposed by the upward pull of the lip of the other side. The lower row of teeth was equally exposed on both sides. The musculature of the forehead and eyes showed the same amount of functional ability on both sides, and the lower lip was drawn down and to either side with the same facility. The tongue and uvula remained in the median line both actively and passively.

The question which presented itself in the study of this case was—were we dealing with a central or a peripheral condition, as the whole management of the case depended on whether it was one or the other. Since there were none of the constitutional symptoms above noted, and no disturbance of the extrinsic or intrinsic muscles of the eyes, as well as no aural or vestibular symptoms, it was evident that the cranium and its contents had escaped injury. As only a portion of the facial musculature showed loss of function, one could rule out dehiscence of the facial nerve before its subdivision into its smaller branches. Evidently, the individual twig that supplied the muscles of the ala of the nose, and of the upper lip was damaged. The lip muscles involved were the levator labii superioris et alæque nasi, and the levator labii superioris. I am inclined to place the levator anguli oris among those that were palsied, as the nasolabial ridge was perceptibly flatter than that of the other side. That the angle of the mouth was properly placed, is due to the zygomatic muscles which perform this function. The nasal muscles involved were the intrinsic muscles of the left ala of the nose. In searching for the site of injury of the nerve, I was able to feel that the inferior border of the zygomatic arch was indented below the malar eminence, at which point it was also tender to touch and pressure. There was no other point of bone injury. Apparently, the patient had struck the malar arch as well as the nose in her descent down the stairs, and on this side had crushed the branch of the facial in this situation between the hard stairs, and the bone against which it lay, with resulting palsy of the muscles which it supplied. Considering the nature of the accident and the fact that the patient showed a partial facial palsy which would lead one to think of a possible cerebral origin of such a condition, it was natural enough to fear that the ecchymosis about the eyes was an anomolous form of, or equivalent to, a subjunctival ecchymosis, which would point to a basilar fracture. And it was only by the strict delimitation of the muscles involved, showing them to be a nerve grouping of muscles, and not a cortical action group, and by the identification of the location of trauma, that enabled the differentiation of the nerve palsy to be made with assurance.

As this was a case of accidental trauma, it was important to diagnosticate the condition from a prognostic viewpoint for medicolegal purposes. Necessarily, the case assumed a much milder aspect when considered as a local condition. This being the first case of the kind that had come to my notice, and being able to find only one case described that was somewhat similar to it, it is interesting to note that the examining physician of the liability company asserted that these particular cases were not at all uncommon, and also that they were easily cured. It is common knowledge that neuritis secondary to trauma in time becomes an interstitial neuritis, which will always interfere with the regeneration of a certain number of axons. This in a limb with its large muscles is hardly noticed, and quite negligible, but on the face, where the muscles are very small, any weakness from whatever cause will show itself through a facial asymmetry.

The case spoken of above as similar to this, reported by L. Minor* of Moscow, was in a severely injured man, who among other injuries, had a compound fracture of the right zygomatic process, with paralysis of the frontalis, orbicularis palpebrarum, and the zygomatici besides the muscles involved in my case, a much more extensive neural injury which was escaped by the injury occurring a fraction of an inch in front of the location in Minor's case. Dr. Linetsky reported two months later that the case was in a condition of complete palsy, and that the muscles had not yet regained their faradic irritability.

One of the reasons why I did not lay much stress on the electrical reactions was the fear that I entertained at the time that the woman would develop a neurosis, which would be helped in its development by too much apparent attention, the patient being of a neurotic type, and appearing anemic and generally below par physically, besides being in a receptive state of mind from a psychiatric standpoint on account of her claiming damages for alleged negligence. Hence the case, though not serious in the final analysis, was likely to be troublesome and in all probability would never be completely cured.

Of the other variety of cases to be described in this communication there are four. They are all taken from my Beth Israel Hospital Dispensary service. They all showed a paralysis of the muscles of the lower lip, which are supplied by the supramaxillary or mandibular nerve, a branch of the cervicofacial division of the facial nerve. They all followed the opening of a submaxillary abscess. There had been no palsy or defect before the surgical procedure. In passing it might as well be noted that none of the cases had been operated upon in the institution from which these cases are collated.

The affection showed itself by a slight drooping of the median portion of the lower lip on the injured side. The angle of the mouth on the side of the palsy does not droop but is usually drawn up to a higher level than the sound side by the unopposed pull of the zygomatici whose antagonists are paralyzed. Any action of the oral musculature gives asymmetry to the mouth on account of the loss of action of the muscles of one side of the lower lip with the mental muscles of the same side. The lip on the palsied side cannot be everted, in consequence of which the lower row of teeth on that side cannot all be voluntarily exposed, except the central incisor which is brought to view by the downward pull of the opposite lip. There is no interference with the management of food in the mouth, as also there is no dribbling of saliva, as the rest of the buccal musculature seems to be well able to overcome the defect of the muscles in abeyance for this purpose. The cases show a reaction of degeneration with the galvanic current, and do not react to faradism.

The course of the trouble is chronic, with no tendency to regeneration in spite of most painstaking measures at the command of the neurologist. It seems that the nerve is cut when the abcess is opened, and the ends become lost in the connective tissue formed in the healing of the abscess, and are thus kept from uniting. The nerves involved being very small, I feel that it would be very difficult to dissect them out, and possibly more damage might be done in such a small operative field. That being the case, the ends cannot be searched for and sutured, or freed from their connective tissue entanglements so that they might grow towards each other and unite, or regenerate, as would have to be the case after so long a severance. The surgeons with whom I have discussed the cases are dubious of any one being able to find the situation of the hiatus in the nerve twig in such a complicated pathological environment.

*Minor, L.: Über Unfallslähmungen des N. Facialis. *Mon. für Unfallheilkunde und Invalidenwesen.* Vol. XII, 1905, page 267. The case is No. 2 on page 269.

The instructive feature of the four cases of mandibular nerve palsy is that they occurred after surgical measures were instituted for the relief of submaxillary abscess, which is situated in front of the angle of the jaw, and that the affection seems to have been due to some part of the surgical procedure. To me it seems that the cases are comparatively few considering the frequency of submaxillary abscess, and also the proximity of the nerve under consideration to the superficial lymphatics in front of the angle of the jaw, and beneath it. When one considers how the anatomical relations must be distorted by the swelling of the abscess, it speaks well for the care that is undoubtedly exercised in opening these cases. But in showing these cases to my colleagues, I have repeatedly shown how easy it is to pull the scar from the lower border of the jaw upward on to the face. So I would recommend that when such an abscess is to be opened, the surgeon should retract the skin of the face from over the lower jaw upwards, so as to pull the skin from the abscess upwards over the lower part of the face. With the skin still being held in this position, the abscess is to be opened. As the nerve is situated very superficially, it is readily seen that the mandibular nerve will thus be out of harm's way and escape the knife or curette. Besides, this will give a less conspicuous scar, as it will be well tucked up under the margin of the jaw.

Though, as already mentioned, this palsy is not of serious import, still it shows a defect on the most prominent part of the body—the face. This is particularly unfortunate in girls. The cases that came under observation were all girls. No doubt, cases occur in boys, but a small defect which causes no worry if it occurs in a boy, seems a serious matter in the case of a girl, who the parents believe depends so much on her looks and appearance. There is also the possibility that a defect of this nature may interfere with the means of earning a livelihood. For example, in my series of refrigeratory facial palsy, there was a musician who was a wind instrument player. Though he was apparently cured of his facial condition, he was unable to play the high notes for a very long time on account of the slight weakness of the lower lip muscles which allowed the wind to escape through the corners of the mouth. Also, I have no doubt that the condition might be a cause for action if the patient falls into the hands of a certain class of lawyers.

In the discussion of these cases one cannot but reflect that though the discussion of the great problems of medicine may be most interesting, still the greatest worries of the practitioner are the small details which present themselves in the management of every individual patient. Most physicians are pestered and worried by what are seemingly the most inconsequential of things, but being uncommon, are quite confounding. Thus the last four cases are regarded as bad results of very mild conditions, and I have no doubt but that the gentlemen who treated them had considerable annoyance from them on account of the persistence of the deformity. The first case had many possibilities of error, which were happily avoided, though the patient looked to be in a very serious state with her disfigurement. To me, personally, all of the cases were very instructive for they gave the opportunity of pointing a guiding finger for the benefit of the practitioner and surgeon.

TUBERCULOSIS, AND THE VON PIRQUET TEST IN CHILDREN.

By LOUIS SHALET, M.D.,

NEW YORK.

ATTENDING PHYSICIAN, TUBERCULOSIS CLINICS, DEPARTMENT OF HEALTH, NEW YORK CITY.

Early in 1907 von Pirquet published his now famous method of diagnosing the presence of tuberculous infections. This has since been so abundantly proven to be specific for that disease, that that phase of it might well be dismissed with bare mention.*

This being an established fact the question is only of the scientific interpretation of results, which for clearness of presentation may be subdivided under three headings: (1) Those in which the test is negative because of the total absence of tuberculosis infection. (2) Those in which the test is negative even in the presence of tuberculosis. (3) Those in which it is positive, which may further be subdivided into (*a*) when the same is of clinical importance and (*b*) when it is not.

Now to take up these subdivisions a little in detail:

1. Those in which the test is negative because of the total absence of tuberculosis infection. These speak for themselves. It remains only to point out under what class of cases one is apt to come across these fortunate ones. Briefly stated it may be said without any fear of contradiction that all children except medical curiosities are born free from tuberculosis, at which time they are therefore negative to the von Pirquet test. From their birthday and on the number of those reacting positively rises, so that by the time they reach puberty, the vast majority of them (in cities anyway) have received enough tuberculosis infection to react positively to the test. And by the time adult life is reached practically everybody reacts positively.

It will thus be seen that the younger the child the less likely is it to be tuberculous and equally less likely is the von Pirquet test to be positive.

2. Those in which the test is negative even in the presence of tuberculosis. First in line are those who are too ill with tuberculosis to react; such as the various forms of acute miliary tuberculosis, meningeal or general, very acute cases of pulmonary tuberculosis, cachectic children with extensive tuberculosis of the bones and joints, such as Pott's disease with psoas abcess, or severe forms of tuberculous hip and knee disease. Included are also those with moderate tuberculous infections, who would otherwise react but who are suffering from various intercurrent acute infections, such as lobar pneumonia, typhoid fever, rheumatic, malarial, and like fevers, also epidemic cerebrospinal meningitis, etc.; the various acute intestinal diseases, common to children, that are accompanied by fever; certain extensive skin diseases, and particularly the exanthematous fevers, during the occurence of all of which the von Pirquet test may be negative in the tuberculous, until full convalescence of the intercurrent disease has been established, and provided the underlying tuberculous infection has not flared up in the meantime. Lastly, the von Pirquet test will be negative in all those tuberculous children who are undergoing or have recently completed successful treatment with tuberculin, in the course of which there has necessarily been established an active immunity to tuberculin.

* Shalet, L.: A Simple Method of Applying the Von Pirquet test. *Journal A. M. A.*, July 5, 1913, pp 27.

3. Those in whom the test does react positively may be subdivided into (*a*) when the same is of clinical importance, and (*b*) when it is not. One who has ever had the least tuberculosis in him, has been for all time sensitized to tuberculin, so that he will ever after react positively to the von Pirquet test. This practically applies to all adults. In children the test is of utmost clinical importance in those who do not react to it, which proves that the case so far harbors no tuberculous infection. When the test is positive it merely means that the case has joined the great majority, as one might style all who react positively to this test. While a positive reaction is always present in those with active tuberculosis requiring treatment, it is found just as often in those who have only enough tuberculosis to react positively with this most sensitive of biological tests but not enough to be of any clinical importance.

Again I would call attention to the vast amount of incontestable data, proving the certainty with which tuberculosis may be excluded in those children who do not react to the von Pirquet test. A persistent negative von Pirquet in a child (excepting those in class No. 2) just as surely excludes the diagnosis of tuberculosis as a positive sputum confirms it; all else being equal one is just as specific as the other.

Summary.—The writer has come across not a few cases in children who have been definitely diagnosed tuberculous on the presence of a few physical signs in the lungs accompanied by some temporary fever so common in children. On the strength of which diagnosis these children have been sent away to some of the public sanatoria (to the exclusion of the really tuberculous who need them the most and for whom alone these should be reserved) where they remained for a variable length of time, usually about six months. On their return the von Pirquet test done as a routine measure is found to be negative, thus proving that so far they had as yet no tuberculosis infection in them, and that whatever the pulmonary physical signs were when they were first diagnosed these could not have been tuberculous in nature, else the test when applied later would have been positive. Some of the children so diagnosed who have not been sent away to sanatoria for lack of room or for other reasons and who have therefore been compelled to remain in the city sometimes for as much as two years or more, and who have since had the von Pirquet test applied have also been found negative, thus proving the total absence of tuberculous infection. It is interesting to note that the clinical history of these little patients during these two years and more belies the diagnosis of tuberculosis, as they showed a normal progress in weight increase, absence of fever and of the other common symptoms of tuberculosis in children.

Conclusions.—In view of the above statements of fact and of the great importance of properly diagnosing tuberculosis in children, and the scientific advisability of removing the same as much as possible from the domain of personal opinion to that of biological fact it is herewith suggested that a rule be laid down that no ambulant case of possible tuberculosis occurring in children under sixteen years of age, be diagnosed as such unless the same reacts positively to the von Pirquet test.

A CASE OF PNEUMOCOCCUS SEPTICEMIA.

By G. A. RUECK, M.D.,

NEW YORK.

This case is reported on account of the similarity in its symptomatology in the first stage to other diseases and on account of the much-ignored necessity of taking blood cultures early in diseases characterized by "fever." The history is as follows:

Florence H., Canadian, four years old, was in St. Francis Hospital from February 7 to April 4, 1912. Family history: Father and mother are living and well, the patient being their only child. Previous history: She had whooping cough at one and measles at two years of age. Otherwise she was never sick. Status præsens: February 7, 1912, she was taken with severe cramps in the right hypogastric region. The temperature was 103° F., the pulse 112, and the respiration about 40. The family physician advised an operation for appendicitis. The leucocyte count made in the hospital, February 8, 1912, was 16,200. There were no malaria parasites present. The urine was muddy, acid, of a specific gravity of 1020, contained no albumin, no sugar, no microorganisms, many urates, and a few mucous threads. The patient appeared to be very sick. A laparotomy was performed. The appendix was found to be normal and was not removed. A blood-culture taken by the house surgeon the day of the operation and examined by me the next day was negative. February 9, 1912.—The chest seemed normal as to shape and size. The supraclavicular fossæ were rather prominent. The expansion was good. The heart appeared normal as to size and impulse. No murmurs

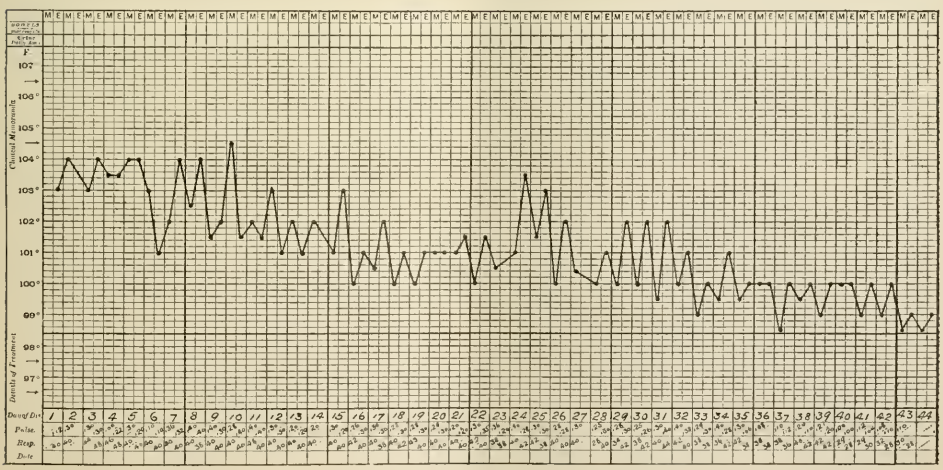

Chart in a case of pneumococcus septicemia

were present. The pulse was rapid and weak. There were a few moist rales anteriorly and posteriorly over both lungs, which were attributed to the ether used during the operation. On percussion a small area of slight dullness was found in the region of the lower lobe of the left lung, just above the spleen. At this place a paracentesis of the thorax for empyema was performed with a negative result. The abdomen was too tender for an examination. The limbs were normal as to shape, size, and reflexes. The feces were yellowish, hard, and of an offensive odor. Typhoid fever was now suspected and the patient was transferred to the medical division. The Widal reaction for *B. typhosus* was negative. Physical examination by the medical staff: The patient is nervous and very irritable. Eyes and ears are normal, mouth and lips dry and pale. The tongue is markedly coated and the breath offensive. The teeth are in a poor condition, the mucous membrane of mouth and throat is markedly inflamed. The tonsils are enlarged and inflamed, but there is no false membrane present. The patient complains of pain on swallowing. Diphtheria was suspected, but a throat-culture was negative for *B. diphtheriæ*. February 10, 1912.—The moist râles heard at the last examination have now disappeared. A faint, dull area about the size of a dollar is made out at the base of the left lung posteriorly over an area where the aspirating needle was inserted. No râles are heard at all over both lungs. The child is still very sick, the temperature high, the pulse rapid and weak. A diagnosis has not yet been made. February 13, 1912.—A blood-culture was made by the author, 5 c.c. of blood drawn from the median basilic vein being squirted into 100 c.c. of Bolduan's medium (1 per cent. glucose, 1 per cent. calcium carbonate, meat infusion broth). February 14, 1912.—Next day a micrococcus in a pure and luxuriant growth was found in the culture. It was lance shaped, single, in pairs, and in short chains; it stained Gram positive and had a capsule (Hiss' capsule stain). In later tests it was dissolved by rabbit's bile (1 c.c. of a 24-hour growth of the micrococcus in bouillon plus 1 drop of rabbit's bile gave a clear solution) and suspensions of it from 24-hour glucose-agar cultures in normal saline solution were agglutinated by the serum of pneumonia patients and by the serum of a rabbit immunized against the pneumococcus. The reaction took place in dilutions of the serum of 1:80, 100, and 320. From the morphology of the organism alone a diagnosis of pneumococcus septicemia was ventured and the later tests described abve confirmed it. A physical examination by the author revealed lobar pneumonia at the left side in the state of resolution. February 25, 1912.—Improving. Temperature and pulse better. Left lower lobe still shows a few crepitant râles. The patient eventually recovered.

What was the reason that the first blood culture was negative?

The condition in man is probably the same as in laboratory animals and may be explained as follows: The pneumococci which had invaded the body of the child were much reduced in number by the protective action of the body tissues and were absent in the peripheral circulation when the first blood culture was taken. After the initial decrease in their number the pneumococci multiplied and appeared again in the peripheral circulation.* The proper thing would have been to make a second blood culture at an earlier date, say about two days later.

The case teaches: (1) The necessity of making daily examinations of the lungs in a child complaining of pain in the abdomen. (2) The necessity of studying the ratio of respiration and pulse. (3) That lobar pneumonia is to be regarded as a generalized infection, a septicemia, with a localized process of acute inflammation in the lung. (4) That early and, if necessary, several blood cultures be made in diseases characterized by fever when their diagnosis is difficult and without blood cultures impossible.

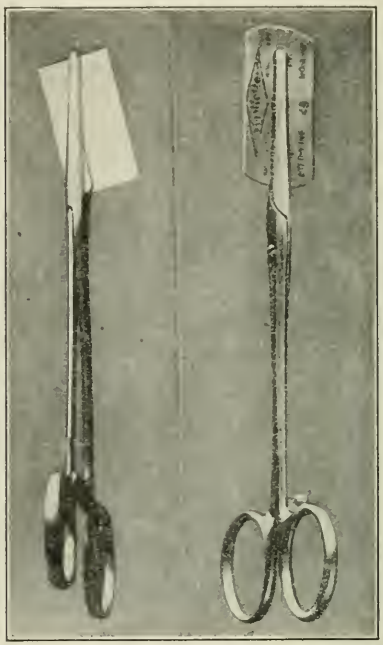
A HEMOSTAT AS A SAFETY BLADE HOLDER.

By A. MERRILL MILLER, M.D.,

DANVILLE, ILL.

Since the introduction, two or three years ago, of the safety razor blade into surgical use many appliances have been produced to serve as holders. These are open to the primary objection of cost, besides most of them have three or more parts.

Recently I was confronted with the necessity of a holder and found it missing. No scalpels were included with instruments since the safety blade had taken their place. The solution of the immediate problem was the use of an ordinary Kocher



6-inch mouse-toothed artery forceps. The 6-inch forceps seems best adapted because of a slight degree of spring action in the blades. The teeth occlude in the distal opening of a Gillette blade. Others—Gem, Jr., Ever Ready, United States, etc.—may be held with equal facility.

A straight or angle edge (see cut) may be secured by the handle adjustment. The forceps is easily held as a scalpel, the ring giving support for the little finger.

The following points may be presented in its favor: (1) Simplicity, (2) no additional expense, (3) the double use of a common instrument, (4) two cutting edges when a Gillette is used, (5) any safety blade serves as a cutting instrument.

508 The Temple.

The Salomon-Saxl Reaction in Cancer.—Luigi Marenduzzo investigated the diagnostic value of this reaction which consists in the excess of neutral sulphates in the urine of cancer patients. He found that this reaction is present in many cases of cancer, but that it is not specific, and is found even in healthy individuals.—*La Riforma Medica.*

A NEW KIDNEY CUSHION.

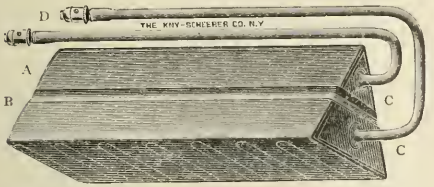
A TWO COMPARTMENT AIR CUSHION DESIGNED PARTICULARLY FOR USE IN KIDNEY, UPPER ABDOMINAL, AND NECK OPERATIONS.

By WESLEY GROVE VINCENT, M.D.,

NEW YORK.

INSTRUCTOR IN SURGERY, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The Edebohls cylindrical kidney cushion always had two great faults: (1) a tendency to slip out sidewise, and (2) the fact that it could not be used fully inflated except with patients of approximately normal abdominal contour, hence the pressure on the abdomen was diffuse instead of being directed at the definite point desired. The patient was always insecurely balanced over this type of kidney cushion, and often it had to be readjusted one or more times during the progress of an operation. This, besides being time consuming and unpleasant for the operator, was a distinct menace to the sterility of the operative field. To obviate the tendency to lateral slipping someone devised a triangular cushion. This worked admirably when the cushion could be nearly or quite fully inflated, otherwise the objections made above to the cylindrical applied to the triangular cushion. As assistant to Dr. Edebohls and in his own kidney operations the writer experienced these inconveniences times innumerable and finally conceived the idea of utilizing the tri-



Vincent's Kidney Cushion. A, upper compartment; B, lower compartment; C. C, rubber tubes for inflation of each compartment separately; D, bicycle-type valves

angular shape but dividing the cushion horizontally into two compartments, an upper and a lower, each independent of the other as regards inflation. Also it seemed best to make the inflation tubes about 30 inches long and equipped with a bicycle-type valve so that whenever desired the degree of inflation could be increased or decreased in either or both compartments by a nurse at a safe distance from the operative field.

Theoretically the making of such a cushion was simple but practically much difficulty was experienced in forcing the upper horizontal dividing sheet to remain level when one compartment only was distended and there was also difficulty in preventing the bottom from rounding when the lower compartment was strongly inflated. The writer's thanks are due to the Kny-Scheerer Company for working out the necessary details of construction; proper stiffening materials in the bottom piece and a complicated series of ties leading from the horizontal dividing sheet upward and downward finally giving a cushion equally stable whether the upper, lower, or both compartments are inflated. The base of the cushion is 20 x 8½ inches and when both compartments are fully inflated the cushion measures 7½ inches vertically (base to apex of triangle). The horizontal division into two chambers is at a point somewhat above the center of this vertical line.

We thus get (1) a very high, sharp-angled cushion for use in kidney work when the patient is in the lateral position (for Kelly or Mayo incisions); (2) with nearly or quite complete inflation of the lower compartment we have a sufficiently high cushion with narrow, nearly flat top suitable for nephropexies or other kidney operations with patient in prone position. In these cases if the upper compartment also be *slightly* inflated the corners pout up at each side and the patient is held absolutely securely. If the peritoneum be opened intentionally or otherwise, its closure is difficult while the patient rests upon a cushion. With this cushion the air can be let out by a nurse at a safe distance from the field and a bicycle pump may be used to reinflate after peritoneal closure, the patient and sterile operative field not having to be disturbed. (3) Occasionally the small upper compartment may give all the elevation necessary, while combinations of the two sections will give any desired degree of elevation up to 7½ inches. The writer has found his cushion a great improvement over sand bags in upper abdominal cases (particularly in gall bladder surgery) and in neck cases (thyroid, tonsils, cervical adenitis, etc.); while in general work, with the patient in dorsal position and under general anesthesia, if the large compartment be partially inflated and placed under the lumbar curve of the spine patients do not suffer from the annoying post-operative pain in the back due to stretching of ligaments and other tissues incident to prolonged dorsal decubitus on a hard, level table.

The writer's cushion was perfected in 1908 and has been in use continuously by him and many others since then. It has stood the test of time and its advantages over sand bags and all other types of air inflated cushions have been completely demonstrated.

The cushion has been more than satisfactory to all who have used it during the past five years and the writer feels that the time is ripe to present it to the profession at large.

498 West End Avenue.

The Sleeping Sickness in Uganda.—Since the disastrous results of the use of atoxyl in this affection, the question of substitute procedures, old or new, becomes of much interest. Schilling gives the results of his recent study on this subject. At Entrebbe there had been no deaths for 18 months. The inhabitants, intelligent people, have carried out all the prophylactic measures submitted to them. In other localities, however, much sleeping sickness still prevails despite the haste with which the populace is being removed from infected regions. All houses, boats, etc., in the latter are at once burned. Deforestation is practised to a certain degree, although large trees are not molested. The river banks are sown with citronella grass, yet this is proving an obstruction to agriculture and is besides of questionable value. The papyrus plant which grows in damp, marshy soil is doubtless superior. The glossinæ are not found where it grows. All "carriers" of sleeping sickness residues are sterilized when they are known by the ordinary medical treatment, but this is a resource of minor extent. A lady named Robertson has done excellent research work on the native apes and has found trypanosomes in the circulating blood. Much work remains to be done in this field. What trypanosomes are parasites and what flies are hosts, is still undecided. Attempts are naturally being made in the direction of a specific serotherapy of the disease in man, but as yet without success.—*Deutsche medizinische Wochenschrift.*

MEDICAL RECORD.

New York, December 6, 1913.

EUGENIC LEGISLATION.

As illustrating what he considers the dangerous tendencies of laws authorizing the sterilization of the unfit, Charles A. Boston, of the New York Bar, has parodied the existing laws in the form of an imaginary statute as follows: *"Whereas,* inordinate individual wealth is damaging to society, and undesirable civic tendencies are transmissible by heredity, it is hereby enacted that each association for the improvement of the poor shall call in two philosophic anarchists and one socialist, who shall determine whether any person who shall have acquired inordinate wealth is, by reason of overdevelopment of his acquisitive greed, a menace to the peace and welfare of the community, and if they so determine, they may cause to be performed upon him an operation for sterilization to prevent procreation, provided, in no event shall anarchists and socialists receive more than $3 for their consultation fee." It is not surprising that much of the so-called eugenic legislation has called forth such drastic criticism as that implied in the foregoing legal burlesque. It has often been said that legislation is a cheap panacea for evils. But like most cure-alls, the laws designed for the remedy of social disease are often such unscientific mixtures of different brands of reform that no specifically good results can be expected from them.

Eleven States have so far enacted some sort of "sterilization of the unfit" legislation. In many of these the provisions of the law have far outrun the results of scientific investigation. It is in fact still an open question whether confirmed criminals and feeble-minded persons are especially apt to propagate their own kind unless they mate with persons, who, like themselves, carry a neuropathic strain. With few exceptions, the impediments to marriage, imposed by the new legislation, appear to disregard the unsettled state of eugenic science, and assume that the theories advanced by this or that particular school have correctly solved the principles underlying the inheritance of good or bad germ plasm.

But it is not only in the effort to prevent the propagation of neuropathic strains that the various eugenic laws have run riot. Amateur legislation strives to deal with venereal disease in a wholly impractical manner. Michigan, Utah, Washington, North Dakota, Indiana, Pennsylvania, and Wisconsin have all legislated with the design to prevent the spread of venereal disease through marriage. In Michigan and Utah the marriage of a person who has an uncured case of syphilis or gonorrhea is illegal and punishable as a felony. But there is no provision for a physician's certificate that the candidate for marriage is free from venereal taint. In Washington the applicants for a marriage license must make an affidavit that they are free from disease. In this case the whole question appears to be left to the honor of the contracting parties. In many States the means provided for obtaining a physician's certificate are either so ridiculously easy or so obviously impracticable, as to give the statute the semblance of burlesque. Thus, in North Dakota, the law provides that the applicant for license shall have the affidavit of a duly licensed physician showing that the *male* contracting party is not afflicted with any contagious venereal disease. It further provides that for this examination and affidavit the physician must not charge over $2. Consequently if the physician's examination results in negative findings he may collect $2 for the affidavit to that effect, but if he finds venereal disease the matter of charge is entirely unprovided for. In Wisconsin, the framers of the law appear to have taken counsel with genito-urinary specialists, for here the physician giving the certificate must certify that the applicant is free from syphilis and gonorrhea and must also state under oath that he has arrived at this conclusion after having used the recognized clinical and laboratory methods of diagnosis. But this wise provision seems to be largely offset by another clause in the same law which states that the fee for the required examination shall not exceed $3. So the Wisconsin physician has three possible courses open to him: (1) He may do a Wassermann for syphilis and a complement-fixation test for gonorrhea for a sum which will scarcely pay him for the actual cost of the materials used. (2) He may issue the certificate and perjure himself as to the methods used in making the diagnosis. (3) He may refuse to have anything to do with the case at all. In the last event the State Laboratory will see that the test is properly conducted. But here is the weak point. Instead of making the State responsible in all cases and thus removing the personal element altogether, the matter is left entirely to the honesty and ability of the local practitioner to deal with as he sees fit.

These examples of social reform legislation, hastily enacted and totally inadequate for their avowed purpose, might be greatly multiplied, but they are sufficient to show that legislation which so intimately affects both personal liberty and the protection of society at large should not be undertaken without careful investigation of the evils which are intended to be remedied. In this connection the conservative policy of Massachusetts is worthy of emulation. At the recent session of her legislature it was "Resolved that the State Board of Health and the State Board of Insanity are hereby empowered and directed jointly to investigate and to report to the general court, on or before the second

Saturday in January next, what further impediments to marriage, if any, should be recognized by law in the Commonwealth. If they make any recommendations they shall include in their report drafts of bills suitable for carrying them into effect."

THE SIGNIFICANCE OF CHYLIFORM EFFUSION.

Relatively very little attention has been paid to the pathology of the thoracic duct and of its tributaries. One reason for this is that the thoracic duct, owing to its out-of-the-way location, is rarely examined at autopsy. Moreover, symptoms pointing to disease of the chylous lymphatics and of the main lymphatic trunks of the body are exceedingly rare. Suppuration in the thoracic duct was described several years ago, apparently for the first time, by De Forest of New York. The most common manifestation of disturbance in the chylous lymphatic system is chylous ascites of which sixty-eight cases have been collected by Batty Shaw. This condition is one that may be produced by any of a large number of causes, which usually brings about an obstruction or occlusion of the receptaculum chyli or of the thoracic duct at any part of its course in the abdomen or thorax. The obstruction may be of inflammatory or neoplastic nature. The two most important causes are tuberculosis and cancer. These are illustrated in the two cases reported by H. A. Lediard in the *British Journal of Children's Diseases,* October, 1913.

One of these cases was that of an 18-year-old boy who came under treatment for what was apparently tuberculous peritonitis. The abdomen was greatly distended, and diarrhea was a prominent symptom. Six pints of a chylous fluid were removed on tapping the abdomen. Death occurred three weeks later. A careful autopsy was performed. Evidences of tuberculosis were found in many parts of the body. The receptaculum chyli was obliterated in a mass of glands and fibrous tissue, and the different lymphatics were markedly distended. These were the main features in the pathology of the case, in which transudation provided the mechanism by which the chyliform ascites was produced. One peculiarity was that the shape of the abdomen seemed to show that the fluid was collected more in the upper half, and it is suggested that this peculiarity may be of diagnostic service in a similar case.

The second example of chyliform ascites was presented in a girl aged 18 years, suffering from Hodgkin's disease. She had undergone two operations for the removal of masses of glands on the left side of the neck and in the left axilla. There were symptoms pointing to peritonitis and to the presence of fluid in the abdomen. Tapping demonstrated a chylous ascites. Although no autopsy was obtained in this case, it is suggested that pressure by an enlarged gland on the thoracic duct at its termination caused a transudation of chyle within the abdomen. Of the 68 cases of chyliform ascites collected by Batty Shaw, 18 were due to compression of the thoracic duct.

The question of the relative frequency of tuberculosis or of malignant disease in the production of chylous effusions is answered by Lediard in a discussion of the above interesting cases. Rotman collected 20 cases, of which only two were attributed to tuberculosis. Of 9 cases of milky effusions in the thorax only 1 was associated with tuberculosis. It is pointed out that the relative frequency of cancer and tuberculosis as causes of chylous effusions is as three is to one. Chemical and microscopical examination of the milky fluid may furnish some clue as to its origin. If pure chyle, it probably comes from a leak. But such an occurrence is exceedingly rare. A transuded fluid shows chyle mixed with lymph. The presence in the fluid of different kinds of cells, as blood corpuscles, lymphoid cells full of fat granules, or epithelial cells with fat granules may indicate the presence of cancer within the abdomen. Rupture of the receptaculum chyli rarely occurs. The treatment of chyliform ascites is a surgical problem, but one which at present offers little of promise.

PHAGOCYTOSIS IN ACUTE INFECTIOUS DISEASES.

A subject which at first sight seems to be closely allied to that of the determination of the opsonic index, but which is a distinct and separate phenomenon, is the degree of phagocytic power of the leucocytes in the acute infectious diseases. The variations in phagocytosis were studied particularly with reference to their practical prognostic indications by H. Schaefer-Hieber who reports a number of important and interesting results in the *Deutsches Archiv für klinische Medizin,* October 2, 1913. In determining the degree of phagocytosis he employed with certain modifications the method recommended by Achard and Foix. Suspensions of the fungus *Oidium albicans* were used in testing the leucocytes of a given specimen of blood. Normal leucocytes, a diluting medium consisting of ascitic fluid, capillary pipettes, a centrifuge, an incubator, the Grünwald or Leishmann stain, and the oil-immersion objective are all necessary accessories in the determination of the phagocytic index. Without describing the details of the method employed it will suffice to allude to the results obtained by the author in the investigation of this subject in a series of twelve cases of various acute infectious diseases.

At the beginning and at the height of an acute infectious disease the phagocytic power of the leucocytes is more or less below the normal. According to the progress of the disease the phagocytic process may either rise or fall. One may recognize in the phagocytic curve three different phases: the phase of phagocytic weakening, the phase of phagocytic crisis, and the phase of the return to normal. The first of these corresponds to the height of the disease process. The character of the curve gives an idea of the extent of the protective forces of the body. In cases that run a favorable course in spite of the high fever the phagocytic curve shows a greater height than the curve in fatal cases.

One important point is emphasized by the author, namely, that there is no relation between the leucocytic count and the power of phagocytosis. At the beginning of the disease the phagocytic curve sinks whether there is a leucopenia or a leucocytosis. The conclusion is drawn that it is not so much the number of leucocytes as their phagocytic capacity which exercises a potent influence in combating an infection.

The "critical" phase of the phagocytic curve is distinct only in cases that run a favorable course. The curve rises at first slowly, then rapidly, in many instances markedly so, crossing the fever curve. The phagocytic critical rise often precedes the critical fall in the temperature, or may coincide with it. The abrupt rise in the phagocytic curve usually announces an approaching critical fall in the temperature. The former phenomenon is one therefore of prognostic value, indicating a favorable outcome. The development of complications is accompanied by a fall in the phagocytic curve. In three of the author's fatal cases, respectively of pneumonia, tuberculous meningitis, and sepsis, the phagocytic rise did not occur; the curve showed rather a tendency to fall below the base line. Hence in all cases in which this tendency of the curve is present an unfavorable prognosis may be taken for granted. During convalescence the phagocytic curve returns gradually to the norm, but it is occasionally interrupted by slight elevations.

Splenectomy for Pernicious Anemia.

The claim that splenectomy has cured cases of true pernicious anemia will naturally be regarded as quite ill-founded and based on an error of diagnosis. Only when the anemia is due directly to a diseased spleen, as in Banti's disease, would it appear rational to remove the latter, and the clinical results entirely bear out the theory. Nevertheless it appears that about last June Unger removed a spleen from a patient who presented an increased hemolysis *in vitro*. Mosse also removed a diseased spleen from a woman whom he believed to have pernicious anemia. Hardly any one would agree at first with his diagnosis on account of the robust appearance of the patient after her operation. Before the latter her red cell count was but 1,100,000; now it is more than 4,000,000. At the October meeting of the Berlin Medical Society (*Berliner klin. Wochenschrift,* November 3) Huber read a paper on the influence of splenectomy on pernicious anemia which will appear soon in full in the same journal. He also presented the patient. In discussion it was shown that an Italian, Antonelli, had anticipated the Berlin surgeons by a splenectomy for pernicious anemia done at Baccelli's clinic. Huber denied that there is any contraindication to the operation in the presence of the pernicious blood state. Leucemia is the sole contraindication.

Mendel as Student.

So little is known of this man, who, judged by what he produced, was great, and whose greatness was thrust upon him many years after his death, that any data whatever, especially those which pertain to his formative years, should possess great interest for all who pursue the exact sciences. As the Historical Section of the Society of German Physicians and Naturalists, which met last September (*Münchener medizinische Wochenschrift,* October 28), Iltis, who considered Mendel's student years, dwelt upon two leading factors, viz., his extreme poverty and his inability to pass examinations (not uncommon among the really great). Lack of food seems to have forced him to enter the Brünn theological foundation as novice. That his true bent was toward science is inferred from his subsequent career. In the seminary he formed friendships with a number of bright young men. His theological studies completed, being little suited for parochial duties, he sought to qualify as an instructor in the local gymnasium. When, however, he came to pass his examinations he failed in every branch. He was lucky at the same time in meeting a prelate of his old seminary, who caused him to attend the University of Vienna. He was registered for 4 semesters (1851-3) as a lecture attendant extraordinary. In 1854 he returned to Brünn and joined the faculty of the new State Middle Class School. He worked here two years, returned to Vienna for examination and failed. He seems to have at once returned to his old seminary where in the gardener's hut he began his now famous experiments.

News of the Week.

Department of Health Reorganized.—Because of its growth and the extension of its work, a reorganization of the Department of Health of the City of New York has been found necessary, and Commissioner Lederle announced recently that this had been accomplished by raising to the rank of bureaus several branches of the work which had formerly been classed as divisions, apportioning the work definitely among these bureaus, and making the chief executive of each answerable directly to the Commissioner of Health. The activities of the department will henceforth be carried on through the following: the Bureau of General Administration, under Eugene W. Scheffer; the Sanitary Bureau, under the Sanitary Superintendent; the Bureau of Infectious Diseases, under Dr. John S. Billings; the Bureau of Child Hygiene, under Dr. S. Josephine Baker; the Bureau of Hospitals, under Dr. Robert J. Wilson, Superintendent of Hospitals; the Bureau of Laboratories, under Dr. William H. Park; the Bureau of Food Inspection, under Dr. Marion B. McMillan, and the Bureau of Records, under Dr. William Guilfoy, Registrar of Records. The Bureau of Administration, which was originally created in January, 1912, and has been under the supervision of the secretary of the Board, will in the future include two divisions: the Division of Supplies and the Division of Audits and Accounts. The Bureau of Infectious Diseases will include the divisions of contagious diseases, tuberculosis, venereal diseases, veterinary diseases, institution inspection, typhoid fever, and nurses, and the diagnosis laboratory. The Bureau of Child Hygiene will comprise the divisions of midwife and foundling inspection, institutions and day nurseries, school medical inspection, employment certificates, infants' milk stations, and children's clinics. Control of the milk, meat, fish, vegetable, and drug supply will be by the Bureau of Food Inspection.

City Health Commissioner.—It is rumored that Mayor-elect Mitchel of New York has selected Dr. Harvey W. Wiley to succeed Commissioner Lederle on the expiration of his term. No official comment on the rumor has been made, but it is said that if such an offer were made to Dr. Wiley it would find him in at least a receptive mood. Dr. Lederle was appointed commissioner of health by Mayor Gaynor in 1910, and had previously served in the same capacity from 1902 to 1904.

Sir Arbuthnot Lane at the Polyclinic.—On Friday of last week an all-day surgical clinic was held at the New York Polyclinic Medical School and Hospital. Sir Arbuthnot Lane operated upon a child, ten days old, for cleft palate. He also operated upon several patients who had chronic intestinal stasis, doing a colectomy. Mr. Herbert J. Paterson of London and Dr. William Seaman Brainbridge also operated for similar conditions. The short circuiting for chronic intestinal stasis had proven to be of great value as attested by many who were present. Sir Arbuthnot Lane also demonstrated his method of bone plating upon a man who had a fracture of the thigh. His results in these cases had been carefully watched by *x*-ray pictures, and were found to be excellent. The dressings used were contained in a small box; they had been sterilized in London and only opened at this time. The box contained everything necessary for the operation. The clinic lasted from 9 A.M. to 5 P.M., and was most interesting and instructive.

Gift to Diet Kitchen.—The New York Diet Kitchen Association has recently received a gift of $63,000 from Mr. and Mrs. Edward Tuck of this city, as a donation to the endowment fund. The income will be used in maintaining the Tuck Diet Kitchen at 35 West 139th street, one of the eight stations supported by the association.

Bequests to Charity.—By the will of the late Emily Scheetz of Philadelphia, the sum of $5,000 is bequeathed to the West Philadelphia Hospital for Women.

The Home for Incurables, New York, receives a bequest of $50,000 under the will of the late Mrs. Kate Warner of this city.

Ask Hospital Investigation.—Three physicians on the medical staff of the North Hudson County Hospital, Weehawken, N. J., have requested the Board of Governors of the Hospital to authorize an investigation of charges which have been made against the management of the institution, offering to pay the cost of such an investigation. There has for some time been friction between the superintendent of the hospital and the members of the attending staff.

Anesthesia Number of the Annals of Surgery.—The December issue of the *Annals of Surgery* is a special Anesthesia number and is almost double the size of an ordinary issue. It contains some of the most important papers on this subject ever presented, and has a long list of eminent contributors.

Labor Legislation.—The seventh annual meeting of the American Association for Labor Legislation will be held in Washington on December 30 and 31. The programme, which includes a joint session with the American Political Science Association, will bring out the plans of the Federal Industrial Relations Commission, recently appointed. Of interest to medical men will be the discussion on: "Is Compulsory Sickness Insurance Practicable in America?"

Examination for Admission to the Public Health Service.—An examination of candidates for admission to the grade of assistant surgeon in the Public Health Service will be held in various places on the morning of January 12, 1914. Candidates must be between twenty-three and thirty-two years of age, graduates of a reputable medical college, and of good professional and moral character. The examinations are: 1, physical; 2, oral; 3, written, and 4, clinical, and usually cover a period of ten days. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order. They will receive early appointments. Assistant surgeons receive a salary of $2,000 a year, and after four years' service are entitled to examination for promotion to the grade of passed assistant surgeon. For invitation to appear before the board of examiners, application should be made to the "Surgeon-General, Public Health Service, Washington, D. C."

Civil Service Examination.—The United States Civil Service Commission announces an open competitive examination for men only, for the purpose of filling a vacancy in the position of anatomist at a salary of $1,600 a year, in the Army Medical Museum, Office of the Surgeon-General. It is desired that the person appointed to this position shall be young, in good health, and a graduate in medicine, and shall have a thorough knowledge of pathological histology, pathology, and bacteriology, be capable of making photomicrographs, understand microscopes, surgical instruments, and appliances, and be able to prepare, card, and keep in order museum specimens. Persons who meet the requirements and desire to take the examination should apply at once to the United States Civil Service Commission, Washington, D. C., for application form 1312.

A Complimentary Dinner to Sir Arbuthnot Lane was given by Dr. William Seaman Bainbridge on Friday of last week in the Louis XV room of the St. Regis Hotel. The guests numbered about 120. Addresses were made by Drs. Bainbridge, John A. Wyeth, and William Hanna Thomson, Sir Arbuthnot Lane, Mr. Herbert J. Paterson of London, and Mr. Augustus Thomas. After the dinner, at the conclusion of these addresses, Sir Arbuthnot Lane gave a most interesting exposition of his theory of intestinal autointoxication as a cause of many serious ills, including rheumatoid arthritis, cardiovascular disease, cancer, and tuberculosis, dwelling on the mechanical factors in the production of intestinal stasis, and demonstrating their action in a series of lantern slides. At the close of the lectures an informal discussion took place, among the speakers being Dr. William Louis Rodman of Philadelphia, Dr. Stevens of Ohio, Dr. Ernest Laplace of Philadelphia, Surgeon Williams of the U. S. N., Dr. J. W. Draper, Dr. Jerome Morley Lynch, Dr. Foster Kennedy, Dr. George Reese Satterlee, Dr. Robert H. M. Dawbarn, Dr. Lewis Gregory Cole, Dr. Adoniram Judson Quimby, Dr. Willy Meyer, Dr. Reynold Webb Wilcox, Dr. Lots of Australia, and others.

Bay Ridge Hospital.—The Board of Directors of the Bay Ridge Hospital, Dispensary, and Training School for Nurses has acquired title to the large parcel of land situated at Ninety-second street and Seventh avenue, Brooklyn, on which they intend to build a modern hospital with accommodations for one hundred patients, at an estimated cost of $150,000. The movement for the establishment of a hospital in the extreme southern section of Brooklyn

was started fifteen years ago, and since 1905 active clinical work, including a tuberculosis clinic has been carried on at the old Kent Mansion at Sixtieth street and Second avenue.

Petition to Install Nursing Sisters.—A petition containing over 150,000 names of residents of Paris has been presented to the Municipal Council praying that the nuns be restored to their former places as nurses in the Parisian hospitals. Complaint is made that many patients prefer the sisters to lay nurses and the petition asks that those who ask to be attended by the sisters may have their wish.

Low Death Rate.—For the first forty-seven weeks of 1913, that is, up to November 22, the death rate in New York City was 13.71 per thousand of population, making this so far the healthiest year on record. For the same period of 1912 the rate was 14.07 per thousand. The autumn season of the present year has been particularly free from sickness as judged by the number of cases of infectious diseases reported. During the seven weeks ending November 22, there were reported 2,602 cases of tuberculosis, a decrease of 7 per cent. as compared with same period of last year; and the number of cases of diphtheria was 14 per cent., and of scarlet fever 17 per cent. less in the same comparison. The number of cases of measles, on the other hand, was increased about 5 per cent.

Wholesale Meat Poisoning.—Over one hundred persons in Puente Ovejuna, near Cordova, in Spain, have been seriously poisoned by eating contaminated meat. Thirteen of these have died and many others are seriously ill.

Diphtheria in Chicago.—The prevalence of cases of diphtheria in Chicago has caused some alarm, 412 cases having been reported from November 6 to November 20. The disease thus far has been of a comparatively mild type and the efforts being made to check its spread will probably prevent it from reaching the proportions of an epidemic.

Nurses Graduate.—The twenty-fifth anniversary and the graduating exercises of the German Hospital Training School for Nurses were celebrated on November 27 at the hospital. Twenty-three women received diplomas on the completion of the three years' course. Dr. Abraham Jacobi addressed the graduates, the oath was administered by Dr. Gustav Seeligman, a member of the Medical Board, and the diplomas were distributed by the President of the Hospital.

St. John's Guild.—At the annual meeting of St. John's Guild, New York, held on November 18, the following report of the work was made: The New Seaside Hospital, established by the Guild at New Dorp, Staten Island, which opened on June 9, 1913, cared for 2,134 sick mothers and their babies during the summer, of whom 2,088 were discharged as cured or improved in September. Two hundred patients were admitted for the winter service, of whom 108 have already been discharged. The floating hospital on its sea trips last summer carried 15,252 women, 28,254 children of six years or under, and 14,381 babies. During July there were 3,600 applicants in excess of the accommodations.

Obituary Notes.—Dr. Charles Mayrant Rees of Charleston, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1887, and professor of surgery in the same, and a member of the American Medical Association, the South Carolina Medical Association, the Charleston County Medical Society, the American Association of Obstetricians and Gynecologists, and the Southern Surgical and Gynecological Association, died at his home on November 15, aged 52 years.

Dr. A. J. Hatzfield of Pueblo, Col., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1881, died at his home after a long illness, on November 14, aged 67 years.

Dr. James A. Koehler of Shelby, Ohio, a graduate of the Ohio Medical University, Columbus, in 1898, and a member of the Ohio State and Richland County Medical Societies, died at his home, from pernicious anemia, on November 13, aged 40 years.

Dr. William Shippen of Petersburg, Va., a graduate of the Medical College of Virginia, Richmond, in 1887, a member of the Medical Society of Virginia and the Petersburg Medical Faculty, and for twenty years a surgeon in the United States Army, died at his home on November 17, aged 52 years.

Dr. Robert Lee Edwards of Richmond, Va., a graduate of the New York University Medical College in 1894, died at his home on November 13, aged 42 years.

Dr. William B. Jones died at Philadelphia on November 18 at the age of 77 years. He was graduated from the Eclectic Medical College of Philadelphia in the class of 1861. He served in the Bucktail Regiment throughout the Civil War.

Dr. Albert W. Hendricks died at Philadelphia on November 19 at the age of 73 years. He was graduated from the Eclectic Medical College of Philadelphia in the class of 1871. He was a veteran of the Civil War, for thirteen years a member of the Thirty-fourth Ward Sectional School Board and at one time Surgeon to the Old Soldiers' Home.

Dr. Joseph D. Rush of Orlando, Fla., a graduate of the University of Alabama, Medical Department, Mobile, in 1873, and a member of the American Medical Association, the Florida Medical Association, and the Orange County Medical Society, died at his home on November 18, aged 66 years.

Dr. L. E. Bratton of Atkins, Ark., a graduate of the Memphis Hospital Medical College, Memphis, Tenn., in 1896, died at his home after a long illness, on November 18, aged 49 years.

Dr. John McI. Morrison of Point Richmond, Cal., a graduate of the Cooper Medical College, San Francisco, in 1893, died at the Roosevelt Hospital, Berkeley, Cal., on November 15, aged 42 years.

Dr. Frederic Matthew Helbig of New York, a graduate of the Bellevue Hospital Medical College in 1890, a member of the New York State Board of Pharmacy, and of the American Medical Association, the New York State and County Medical Societies, the Greater New York Medical Association, the Medico-Legal Society, and the American Dermatological Association, died at his home on November 26, aged 47 years.

Obituary.

DR. EDWIN KLEBS.

BERNE.

Dr. Edwin Klebs, pathologist and bacteriologist, and first to describe the *Bacillus diphtheriæ*, died recently at Berne, Switzerland, in the eightieth year of his age. He was born in Königsberg, Germany, and studied medicine in the university there, and during his long life had held professorships in the universities of Berne, Würzburg, Prague, and Zurich, and in the Rush Medical College, Chicago.

His identification of the *Bacillus diphtheriæ* in 1883 preceded by one year the growth in pure culture by Loeffler of the organism which thus became known as the Klebs-Loeffler bacillus. He was also the first apparently to make use of cold-blooded animals in the preparation of bactericidal fluids and had prepared serums which under the name of tuberculocidin and antiphthisin have received much consideration.

DR. LOUIS WICKHAM.

PARIS.

Louis Wickham, M.V.O., M.D., founder of the Laboratoire biologique du Radium and physician to the Hôpital Saint-Lazare, Paris, died recently, after a long illness, at the age of fifty-three years. Dr. Wickham was most widely known for his researches on the value of radium in the treatment of cancers and other diseases of the skin, researches which had twice obtained recognition from the French Academy in the granting of the Barbier and Benjamin Godard Prizes, and shortly before his death secured for him the decoration of the Legion of Honor. He began his work on radium in 1905, and in 1906 established the Laboratoire biologique du Radium, where he instituted a school center and with his colleagues developed this branch of physiotherapy. Here he received and instructed numbers of workers from England, Germany, and America, as well as from France, and from it he published, in conjunction with his coworker, Dr. Paul Degrais, the results of his researches. Translated into both English and German, these books have been accepted with much interest as containing the conclusions of one of the pioneer workers in the field of radium therapy.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SCHOOL OF TROPICAL MEDICINE—COMMITTEE ON ANTHRAX—UNIVERSITY EDUCATION IN LONDON, CAMBRIDGE—CONCLUDING FITZPATRICK LECTURE—INSURANCE TROUBLES—MEDICO-PSYCHOLOGY—OBITUARY.

London, Nov. 14, 1913.

Mr. Austin Chamberlain presided yesterday at the General Committee of the School of Tropical Medicine when Mr. C. N. Rothschild brought up the report of the city committee. The appeal for £100,000 has so far been successful—the fund having reached £71,444. In the original appeal, approved by Sir P. Manson, the pioneer and father of all this work, it was proposed, if money enough were obtained, to devote some of it to persons from the tropics of a class just above those for hospital charity but unable to pay for special treatment. This intention is now to be carried out and a Chamberlain ward endowed in recognition of the great work of Mr. Joseph Chamberlain and its continuance by his son. The government of India and several of the Dominions have contributed substantial sums and others are likely to arrive. The city committee has been dissolved and the fund practically closed.

The Home Secretary has appointed a committee to inquire into the prevalence of anthrax, the dangers arising from infection in the processes concerned with wool and hair, and report whether amendments are required in the regulations in force.

The recent report of the Royal Commission on University Education in London has given rise to consternation among the graduates of the University of London and especially among those in medicine. The members appointed to examine the matter had not their confidence at the beginning and the report amply confirms their distrust. The proposal is made to apply the multi-college system of London to the constitution of a single college university—proposes, in fact, to set up a new local body and give it the name of the university which has done good work for 55 years. It will destroy the whole of the so-called external work of the university and create one which will debar the unattached from degrees—thus abolishing the chief object for which the existing university was founded. The commission has utterly failed to understand the system of medical schools at our hospitals and would destroy them in its desire to Germanize them.

Cambridge University does not display much enthusiasm about the proposed government grant on behalf of its medical school. In fact it looks as if the professors were divided as to its advantage, judging from the discussion in the Senate House. Sir Clifford Allbutt, Regius Professor of Physic, spoke of the poverty of the medical department and urged that the grant would enable them to do more and better work and he did not think the conditions would endanger freedom of teaching and procedure. Provided the department was highly efficient it would be safe; at present he was of the opinion that its efficiency was imperilled through lack of funds. The Disney professor of archæology (Prof. W. Ridgeway) opposed this view, arguing that no financial assistance could compensate for government inspection and partial control, and these were conditions to be submitted to. This opinion was further held by the Cavendish professor of Experimental Physics (Sir J. J. Thomson), who held that some educational authority ought to be free from interference or control by the Board of Education and able to work out its own schemes independently.

In continuance of his subject of astrology in relation to medicine, Dr. Mercier describes in his other Fitzpatrick lecture some of the beliefs that had been held as to the influence of the planets on the functions of the human body, its diseases, death, etc. For example, Saturn presided over the bones, teeth, right ear, and bladder, besides being responsible for deaths from falls, shipwreck, and hanging. Jupiter over deaths in wars, duels, and those by command of princes; Mars over those from weapons, fire, bites of animals, and blood-letting by ignorant surgeons; Sol over those due to plague, syncope or the battlefield; Mercury over poisons or punishments for perjury, forgery, or passing false money, and Juno deaths from drowning. The masters of astrology of cast horoscopes by the movements of the celestial bodies and allowed their humbler followers to work on a less elaborate scheme which cast the burden of medical astrology on the moon, its position and its waxing or waning. Leaving what appears to us nonsense Dr. Mercier remarked that such men as Bacon and Albertus Magnus certainly believed in it and to understand it we must try to realize the overwhelming power of authority and the belief that the earth was the center of the universe. Within the memory of living men a philosopher had said there was nothing great in the world except man—no doubt he meant Scotsmen. Need we then wonder what men had

thought was the use of the heavenly bodies? The sun caused day and night and brought change of season, but it was one of 7 planets and it was a natural deduction that the others had influence over man. When all seemed chance the mind would grasp at any explanation. The moon was comparable to the sun and in its changes of position was one in opposition to him and therefore considered antagonistic. So the sun being benevolent the moon became malevolent. It was not strange then that to the planets were attributed pestilence, etc. The whole came of man's passionate desire for explanation. Astrology is outgrown, but absurdities are taught still by logicians. How about medicine? Explanation of aphasia is attempted by describing it as loss of memory and of ataxia by calling it loss of the power of co-ordination. Delusions are ascribed to lesion in the brain. The hypothetical increase in appendicitis to the hypothetical increase in meat food, acute diseases are said to be due to intestinal stasis, chronic to that blessed combination of words alimentary toxemia.

The working of the Insurance Act is still giving rise to unexpected questions and annoyances. In London there is a sum of money accumulated owing to insured persons not having selected their panel doctor. To this sum a claim has been made by those on the panel. It is, however, difficult to see the right of this claim for which no service has been done. It looks as if the money belonged rather to the insured persons and should be returned to them or used to reduce rates or taxes. But the committee has resolved to divide it among the panel doctors. At Worcester the committee has, by 15 votes to 9, allowed insured persons to choose a herbalist as their panel doctor. Surely this must be illegal and must be contested. Perhaps the general medical council will take up the question.

In Kensington the Health Committee has agreed to supply the panel men in the borough with outfits for collecting material and to pay for bacteriological examinations at the Lister Institute. The *Times* and other papers approve and would utilize the laboratories of all hospitals for this purpose. This looks like a long step in the direction of a state medical service—very acceptable to socialists.

The death of Dr. Dimock is the most regrettable incident so far due to the act. He was induced to go to Wisbeach to work the panel. Some friction seems to have occurred with the resident doctors who would all have worked it, but the committee resolved to engage an outsider. Some of the resident doctors were assailed with scurrilous, anonymous letters, some said to be unfit to print. Detectives were consulted with the result that the chairman of the local medical committee summoned Dr. Dimock for slander. The case was adjourned and before the next hearing Dr. Dimock, who was said to be greatly worried, was found dead in his bed. Veronal tablets were under the pillow and he seemed to have taken an overdose. A mob then attacked the houses of some other doctors, apparently fancying they had driven the deceased to suicide, though there was no foundation for their impression. But mobs do not reason and the riot act had to be read. The inquest is adjourned for an analysis, the Home Office expert stating it will take him a month to complete. The coroner said on Wednesday that he had been inundated with letters, but would not allow his court to be turned into a controversial arena and the only question for the jury would be the cause of death. The Statutory Local Medical Committee has recorded its entire confidence in the honor of the resident doctors and its sympathy with their wives and families. Moreover, in view of the allegations and inferences of a section of the press this body has made the strongest representations to the Home Office for a judicial investigation into the circumstances.

University College is not exactly the place where you would expect to meet mesmerists, spiritualists *et hoc genus omne*. But this week the Earl of Sandwich presided there at the opening of a "medico-psychological clinic." He told the audience that during his life he had had experience as a governor of several hospitals and there were few serious maladies he had not successfully treated. Further, he never failed in painful cases. He possessed "powers of healing" and had been examined by a committee presided over by the Dean of Westminster. Many thought him, he said, a lunatic, impostor, or liar, but it was enough for him to heal the sick and relieve the suffering. The medical surgical profession were opposed but he did not interfere with any doctor and was only happy to assist them. He thought probably many might possess the power he had though in less degree and had not the chance of using it. The knowledge of it would spread vastly. A professor and two or three others supported the movement, one of them frankly saying their main object was to get financial help. They had £650 and wanted a further £1,000.

Dr. R. D. Sweeting, senior medical inspector of the Local Government Board, died on the 10th inst. Dr. Sweeting was a barrister as well as a medical man. He was a temporary inspector during the cholera survey of 1885-6 and joined the medical department in 1890. He was the son of a doctor and born in 1856, educated at Oxford and the London Hospital, where he became in due course house physician, having gained the Buxton scholarship. He was medical superintendent of the Western Fever Hospital for about ten years.

Dr. H. F. Parsons, who died on October 29, was also in the same service and during a long time a most earnest and able sanitary reformer. He seemed, too, to be full of knowledge in every other branch of his profession and the sciences connected with it. He retired a year or two ago in ill health, but hoping to record some of his experiences. One volume is said to be completed and ready for publication.

Dr. Surg.-Gen. J. S. Comyn has died at the age of 76. He graduated at the University of Dublin, taking also the F.R.C.S. there. He joined the army medical service in 1858. He was in the Egyptian expedition in 1882 for which he received the medal with clasp and was also awarded the bronze star. He retired in 1883.

Dr. W. R. Shortt, who died at Ealing, was surgeon in the National Field Force, 1899-1901. He had been assistant medical officer in Durham Asylum, was a Durham medical doctor, and held the qualifications of the two royal colleges.

The Tuberculous Nature of Acute Nephritis in Childhood.—Debié and Paraf, at the recent French Congress of Pediatrists alluded to the relative frequency of tuberculosis as a possible cause of acute nephritis in childhood. They reported four cases in three of which recovery was complete. The tuberculous nature was indicated by the antigen reaction and by the positive result following inoculation of the guinea-pig.—*La Presse Médicale.*

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

THE LEYDEN LECTURE—ABDERHALDEN ON THE SEROLOGICAL DIAGNOSIS OF ORGANIC CHANGES—THE BIOLOGICAL SIGNIFICANCE OF DIGESTION—THE DEFENSIVE FERMENTS OF THE BLOOD—THE DIAGNOSIS OF PREGNANCY—THE SPECIFICITY OF THE DEFENSIVE FERMENTS—THE DIAGNOSIS OF ORGANIC DISEASES—A NEW ASPECT OF INFECTIOUS DISEASES.

BERLIN, November 1, 1913.

FOR the past three years the winter's sessions of the Berlin medical societies have begun with the Leyden lecture at the Society of Internal Medicine. This lecture, which commemorates the great clinician, is attended with considerable festivity and seems more and more to awaken the interest of Berlin physicians. On the present occasion the auditorium was filled to its capacity. Both the lecturer and his theme occupied the center of medical interest. Abderhalden was the speaker and his subject was the "Serological Diagnosis of Organic Changes."

The speaker began with the question: What is the real aim of digestion? Hitherto it has been thought that the disintegration of complicated nutrients results in the production of simple diffusible bodies. This is not the case. For diffusible cane sugar is not absorbed, but undergoes further splitting in the intestine. The object is to deprive the nutrients of their individuality in order that the body cells may receive the same structural elements for their activity. This conception might presuppose a far-reaching agreement in the building-up process in the different cells. This is, however, not the actual state of affairs. Each cell has a structure peculiar to itself. If it be borne in mind that the cellular substance is composed chemically of twenty structural elements, one can readily understand how by the different combinations of the single components it is possible to obtain the extraordinary number of 2,000,000,000,000,000,000 separate compounds.

The labor of transforming the nutrients for the needs of the body belong to the ferments in the intestine. These ferments are not normally present in the blood. But they arise in this medium as soon as substances foreign to the body gain access to the blood. They thus constitute defensive ferments whose function is to make the foreign substances assimilable, in this manner imitating the work of the digestive ferments. If the blood-serum of an animal that has not previously been operated upon be brought into apposition with albumin by means of a dialysis apparatus no dialysis will occur. If, however, albumin is injected into an animal beforehand, and if the latter's blood-serum is used in the above experiment, there will then pass into the dialysate decomposition products of albumin. From this it may be concluded that there is present in the blood-serum a ferment that causes the disintegration of albumin. This ferment may also be detected by means of the polariscope.

The first practical application of these researches was in the diagnosis of pregnancy. It had already been discovered that during pregnancy a large number of chorionic cells gain access to the circulation. According to the above experiments this occurrence would evoke a ferment which would become manifest if placental tissue were brought into contiguity with the blood-serum of the pregnant woman in the dialysis apparatus. This has actually been demonstrated. Abderhalden has investigated serologically 550 cases of pregnancy and has amply proved the diagnostic value of this procedure.

In the course of further investigations it was shown that the defensive ferments are specific. For instance, the blood-serum of a carcinomatous patient does not disintegrate placental tissue. A patient was under observation in whom the clinical diagnosis of esophageal carcinoma was made. Serological examination did not confirm this diagnosis. Exploratory excision then revealed the presence of a sarcoma. The question now arose whether it would not be possible to detect pathological changes in the organs by revealing the defensive ferments arising from the passage into the blood of the products of disintegration resulting from the above pathological changes. Let one suppose that an obscure ailment is under observation. The patient's blood-serum is now brought into contact with a large number of organ tissues, such as liver, spleen, etc. The organ which undergoes disintegration is the one that is concerned in the disease process. In a case of otitis media there was detected a disintegration of brain substance. At operation a cerebral abscess was revealed.

Likewise infectious diseases may with the aid of this method be looked upon in a different manner than has been the custom. The healthy body represents a completely closed-in organism. Into this there wander bacteria whose metabolism is fully foreign to that of their host. The bacteria die, their cellular detritus gets into the circulation and evokes the defensive ferments. These may be sought for. In fact they have frequently been detected in cases of tuberculosis. The defensive ferments are probably the substances that free the body of the various infections. It is also possible that the defensive ferments, produced in an excess, actually provide the noxious factor. These theories may not be of permanent value. The speaker particularly realized this. But he hoped that the facts revealed by his method would lead to serviceable results.

8. Relation of the Hospital to the Hygiene of Pregnancy. J. L. Huntington.

1. **Infantile Summer Diarrhea.**—A. I. Kendall, A. A. Day, and E. P. Bagg, Jr., present the following conclusions drawn from a study of the cases of diarrhea occurring in the Boston Floating Hospital in 1911: In every case of infantile diarrhea studied (with the exception of the few fermentative diarrheas) there was a general conformity in bacterial type of the intestinal flora, which was uniformly proteolytic in character. This proteolytic flora forms a striking contrast to that of normal children of similar age, in which the putrefactive activities are minimal. Superimposed upon this proteolytic background various of the well-known intestinal pathogens may stand out conspicuously. In the past the isolation of such organisms has sufficed to establish the diagnosis; it now appears that such is not necessarily the case, inasmuch as one or more of them may be present without the production of noteworthy symptoms. On the other hand, cases are met with in which these organisms cannot be found,

yet show blood, pus, and mucus in the stools, and severe toxemia. In these latter cases the flora has been found to be proteolytic in character.

7. **The Wetnurse Problem.**—F. B. Talbot believes that the wetnurse problem can be solved by establishing a wetnurse directory such as has been established by the author in Boston. It is probable that such an institution can become self-supporting. The secret of success lies in widely advertising the fact that wetnurses can be obtained quickly, and in giving the prospective wetnurse a place where she can live without expense until she obtains a position. Infant mortality can be lowered to a minimum by insisting that the mother and baby are not separated. The directory for wetnurses gives these babies an opportunity in life which they can not get otherwise, and makes it possible to save the lives of many babies that would otherwise die.

8. **The Pregnancy Clinic.**—J. L. Huntington points out that in the ideal pregnancy clinic all patients should apply without reference to the subsequent confinement, being guided as far as they are willing by the physician in charge. The nurse who receives the patient and assists the physician in making the examination should make the follow-up visits. She should be trained to take the blood-pressure and make the nitric acid test for albumin and carry with her on her visits to the patient's home the necessary apparatus for taking these observations. From the date of application the patient should be visited by the nurse or report to the clinic at least every two weeks. Patients failing to report at the clinic should be traced by the nurse. All patients when applying to the pregnancy clinic should be given a complete physical examination. In the clinic the urine examination should include an examination of the sediment in every specimen showing albumin by the heat test. Such an ideal pregnancy clinic must be associated with a hospital providing beds and adequate obstetrical care for the graver complications of pregnancy and for operative obstetrics. It should also be associated with an out-patient service providing care for patients in their own homes.

9. A New Apparatus for Proctoclysis. W. D. Miningham.

1. **Recent Progress in Orthopedic Surgery.**—C. Ogilvy first discusses the progress made in the treatment of the deformities of anterior poliomyelitis. Arthrodesis has been successfully employed for a number of years. Tendon transplantation has been effective in selected cases. Artificial silk ligaments were first employed by Lange in 1903. Nerve transplantation and nerve anastomosis are still in the experimental stage. In congenital dislocation of the hip the author has found Calôt's modification of the Lorenz method to be even better than the Lorenz method itself. In the operative treatment of Pott's disease he prefers Albee's procedure to that devised by Hibbs. The mobilization of ankylosed joints has been attained by Baer with the use of chromicized pig's bladder. In appraising the value of Abbott's method of treating rotary lateral curvature of the spine, the author concludes as follows: Rotary lateral curvature of the fixed type, developed in childhood and persisting in adolescence, cannot be perfectly cured. The general condition of the patient can be much improved. The anteroposterior postural deformity, the lumbar lordosis, and the lateral deviation of the body can be corrected. The lateral deviation of the spine is corrected in earlier cases. The rotation of the vertebræ may be improved but not corrected. The results obtained by the use of the plaster jacket applied by the Abbott method in flexion, with corrective felt pads, are very satisfactory in that one is enabled to obtain the results in a shorter time (within six months) than by any other method of treatment.

2. **Vaccine Therapy.**—M. J. Synnott states that the vaccine therapist should have a well-equipped general and special laboratory, a vast store of clinical experience, the ability to estimate accurately the opsonic index in doubtful or difficult cases, and the skill necessary to prepare quickly an autogenous vaccine when one is required. He should also understand how to test therapeutically the various strains of bacteria as to their immunizing power, so as to determine the doses of the vaccines made up from them. In long standing chronic infections vaccine therapy can be expected to give definite results only after a long succession of inoculations and there is no security against a relapse until the infections have been completely extinguished. Hence the inoculations should be continued even after an apparent cure for a long period, at intervals of several weeks or longer, in order to prevent a recurrence.

5. **The Aurometer.**—M. Lubman describes an instrument which he has devised for the exact determination of the hearing distance and of progress in the treatment of various conditions of deafness. It consists of a circular headband adjustable by a thumbscrew to fit any size of head. At the sides of this headband, opposite the ears, are extended two angular bars graduated in ½ inches. On each bar is a sliding upright piece controlled by a thumbscrew and with a small hook at the top to suspend a watch; the watch will be in the exact line of the external canal. The headband has two eye shields to obstruct the patient's vision. The watch should hang on a string from the hook, as this will prevent the transmission of vibrations from the watch.

1. **Diagnosis and Treatment of Vesical Tumors.**—H. H. Young notes in a review of 117 cases of vesical tumor, 83 per cent. of which were malignant, that excision, as usually carried out, is utterly inadequate and is followed by a prompt recurrence in both benign and malignant cases. The cautery is an extremely valuable agent in conjunction with suprapubic or intraperitoneal operations, and when it has been thoroughly applied even in apparently hopeless cases some brilliant cures have been obtained. Carcinoma of the bladder, except in very ex-

tensive cases, is best treated by suprapubic resection of the bladder, leaving a wide area of healthy wall around the tumor, the ureter being transplanted if necessary, and the peritoneum excised when the tumor involves that portion of the bladder. Intraperitoneal operations are rarely necessary (except in tumors of the vertex and posterior wall), as an excellent view of the bladder can be obtained by an extensive median incision, wide separation of the recti muscles, upward displacement of the peritoneum, a long incision into the bladder and good retraction. The use of 50 per cent. resorcin, or alcohol, to kill any tumor particles which may have dropped into the bladder also seems desirable, but a better plan is to cauterize the tumor thoroughly before beginning the resection of the bladder. For benign tumors the treatment with the high-frequency spark seems thoroughly satisfactory, but should be vigorously applied, and for this purpose in extensive cases the fulgurating sound or the application of a strong spark through an open endoscope or cystoscope, the bladder being filled with air, may be very helpful. In apparently hopeless cases, destruction of the tumors and their bases and adjacent portions of the bladder wall by means of a Paquelin, hot-air, or electric cautery may occasionally give unexpected cures and brilliant results. Before applying treatment an adequate specimen should usually be obtained by means of the cystoscopic rongeur for microscopic diagnosis. When one depends on examination of a few villi washed from the bladder or removed by small forceps a satisfactory diagnosis is often impossible.

4. **Transplantation of the Testicle.**—V. D. Lespinasse states that transplantation of the testicle is a successful procedure in frogs and chickens; spermatogenesis and sexual characteristics are preserved. In guinea-pigs, rabbits, and dogs the results are variable. Some experimenters report that there is no success at all; others assert that the interstitial cells remain and functionate. In the two human cases that have been tried to date, the one with the blood-vessel anastomosis was a failue as far as spermatogenesis is concerned; but the interstitial cells may be and probably are present. In the author's case the result clinically has been perfect. The man has regained his sexual powers completely, both as to desire and as to ability to perform. These powers have continued for two years.

7. **Treatment of Inguinal Hernia in Children.**—By A. E. Hertzler. (See MEDICAL RECORD, June 28, 1913, page 1189.)

8. **Hospital Management of Contagious Diseases.**—By D. L. Richardson. (See MEDICAL RECORD, June 28, 1913, page 1191.)

9. **Hollow Foot.**—C. A. Parker concludes that hollow foot, or cavus, is usually accompanied by some malposition of the foot as varus or valgus, equinus or calcaneous. So-called true or essential cavus is rare. Cavus is practically always of neurogenic origin. Leaving out of account the paralytic calcaneus and possibly the congenital types, it is safe to assume that a perversion of the normal reciprocal action between the flexors and extensors of the toes can account for most if not all of the remaining types of cavus. Simple measures commonly suffice to restore the normal balance in the initial stages, while in the fixed deformity severe force, frequently accompanied by resection of bones and section of soft tissues, is often necessary to restore in a measure the normal condition of the foot.

12. **Typhoid Fever in the Canal Zone.**—W. G. Baetz and L. B. Bates state that typhoid fever in the Canal Zone tropical native pursues the same variable course as in patients of the temperate zones. The absolute diagnosis of typhoid fever may be obtained only by a positive blood culture. The earlier in the disease the blood is cultured, the greater the chance of making a positive diagnosis. The Widal test has been positive in 89 per cent. during the second and third weeks. At the same time the test has also been positive in 22 per cent. of the authors' advanced tuberculosis cases and in 15 per cent. of non-tuberculous cases of various diseases. The value of the test seems to depend entirely on its repeated application in selected cases. The white blood count is of great value in the diagnosis of typhoid fever. During the fever a change from leucopenia or normal to leucocytosis invariably points to a complication. Splenic enlargement in the tropics is of practically no value in the diagnosis of typhoid fever, unless previous or coexisting malarial infection can be definitely excluded. In the differential diagnosis of typhoid fever, disseminated or acute miliary tuberculosis and "acute infections of undetermined origin" present the greatest difficulty and should always be kept in mind in the presence of leucopenia and repeatedly negative blood cultures. The most frequent complication of typhoid fever in the Canal Zone is malaria. To prevent the discharge of typhoid carriers, routine stool and urine examinations of convalescents are necessary.

9. A Note on Five Cases of Porocephaliasis in Man from Southern Nigeria. J. W. S. Macfie and J. E. L. Johnston.

1. **Degeneration of the Neuron.**—F. W. Mott points out that degeneration of the neuron may occur from an inherent lack of durability of certain correlated functional systems, as occurs in certain diseases which affect members of families at the same age in life and often generation after generation—*e.g.* Huntington's chorea, hereditary ataxia. Degeneration of the neuron may result from direct injury or local extension of inflammation or by ischemic softening due to obstruction of the blood supply by vascular occlusion; the degeneration that results therefrom is secondary. But when for whatever cause nervous tissue disappears the neuroglia always reacts by a nuclear and fibrillar proliferation—a law formulated by Weigert in 1890. The replacement of the nervous tissue by the neuroglia tissue causes a "sclerosis." But the term "sclerosis" in the sense of a neuroglia proliferation being the primary cause is incorrect; the sclerosis is the effect, not the cause. A pure primary decay of the neuron has been termed by Sir William Gowers "abiotrophy." Many of these conditions of abiotrophy are associated with chronic inflammatory changes, and it is very difficult to say how far these cause the decay of the neuron or are the result of it; certainly a proliferation of neuroglia tissue may result from simple atrophy and decay of the neuron, but a perivascular lymphatic infiltration with lymphocytes and plasma cells is evidence of a reaction to the poison. There are two diseases in which this perivascular cell infiltration, together with neurolgia proliferation, is particularly marked and more or less universal in the central nervous system. They are the diseases caused by two specific protozoal organisms—the *Trypanosoma gambiense* and the *Treponema pallidum*.

8. **Abderhalden's Method in the Diagnosis of Carcinoma.**—R. St. L. Brockman believes that there is sufficient evidence to show that the blood of persons suffering from carcinoma contains a substance absent in the blood of all others, and that this substance has a proteolytic action on carcinoma tissue only. There are also several factors which point to its being of the nature of a ferment. If the serum from a patient is left to get stale it becomes inactive, but the addition of a trace of fresh human serum will activate it again. The reaction takes place best at 37° C. At room temperature the reaction does not occur, while heating the serum to 55° C. for 5 minutes inactivates it beyond recall. If, then, as is maintained by the author, this substance is of a protective nature it would be natural to expect to find it present in larger quantities in patients who are in good general health. The results of these tests point strongly to such being the case. The author has noticed throughout his whole series of cases that a patient with a growth of the tongue or of the breast, who is in good general condition, will give an intensity of coloration in 12 hours which a patient in a low state of health would fail to give in 24. A case of carcinoma of the larynx which gave a negative result only brings this test into line with others. No pathological test is infallible. It is obvious that for practical use such a test must give a reaction in the early stages of the disease. Two of the tongue cases were early localized ulcers, one intestinal growth was small and easily removable, while one breast case was an early scirrhus. All these gave a markedly positive reaction in 24 hours. The facts set forth point to the test being of some practical advantage as an aid in the diagnosis of carcinoma, especially in such sites as the stomach and intestines, thereby allowing early surgical interference.

1. **Degeneration of the Neuron.**—By F. W. Mott. (See page 1045.)

2. **The Internal Secretions and the Female Characterestics.**—W. Blair Bell asks: What is it that makes a woman a woman? In answering this question he states that although the potentiality to produce femininity exists in the earliest stages of segmentation of the ovum, this potentiality is directed towards the future development and correlations of the endocrinous glands which are to control the sexual evolution of the individual. The ovaries alone are not responsible for the female characteristics. It has been shown that the suprarenal cortex is largely responsible for the secondary sexual characteristics. Although the genitalia may be normal morphologically at birth (primary development), they become functionally active only at puberty (secondary development) if the whole endocrinous system is in perfect harmony and acting efficiently. Thus, thyroid or pituitary insufficiency may cause the genital organs to remain infantile; and disease of these structures may cause retrogression in the genitalia even after they have functionated normally. Removal of the thyroid alone produces an intense degree of atrophy in the uterus. The ovaries, however, do not retrogress; on the contrary, there appears to be increased activity, especially in the follicles. While suprarenal hypernephromata in male children are practically always associated with precocity of the sexual organs and secondary characteristics, in female children with suprarenal hypernephromata the sexual organs are not precociously developed, for the tendency is rather to produce in them the characteristics of the male—a deep voice, enlargement of the clitoris, hirsuties, and so on. An excessive ovarian secretion leads to an increase in sexual activity both locally and generally. The local effects may be seen in an increased and prolonged menstruation. An excessive ovarian secretion affects the metabolism in the opposite way to oöphorectomy, and one of the most important metabolic disturbances is the abnormally large excretion of calcium salts. A few years ago Bossi of Genoa suggested the injection of suprarenal extract as an alternative to oöphorectomy. Apparently many cures have been effected by this treatment, and also by the injection of pituitary extract. Thyroid insufficiency always causes a decrease in or the complete cessation of the function of menstruation, according to the degree of insufficiency. Insufficiency of pituitary secretion is associated with amenorrhea or scanty menstruation. Various investigators claim for different portions of the pituitary body different functions, but the author believes in the unity of the whole gland. Patients with pituitary insufficiency are always obese and dull. An excess of pituitary secretion, such as occurs in acromegaly, produces masculinity, and while in the male this may give rise to excessive sexuality, in the female it causes amenorrhea and loss of desire, as is only natural if masculinity be produced.

Berliner klinische Wochenschrift.

October 27 and November 3 and 10.

Treatment of Cancer with Benzol.—Kiralfi states that his work was really experimentally carried out on cancer patients. The benzol was injected directly into the cancerous tissues of two subjects, the disease being inoperable. The drug exerts an intensive action on the cancer cells, destroying them in part. This may be due in a measure to the setting free of cholin by the benzol from the lecithin of the cells. The benzol does not come in direct contact with many of the destroyed cells. Those cancer cells which are uninfluenced by the benzol continue to proliferate, so that the drug can only have a limited use.

Treatment of Pneumonia with Ethylhydrocuprein and Pneumococcus Serum.—Lenne has employed these two alleged specifics for croupous pneumonia together, using the remedies for a separate series of cases. In one series of 17 cases treated with ethylhydrocuprein alone the mortality was 11.8 per cent. and in another of 18 both drugs were employed together with a mortality of 16.5 per cent. In a small series (six cases) treated with the serum alone the mortality was 33 per cent., while in a series of 40 cases treated without the aid of either specific the mortality was 30. This small material appears to show, as has long been conceded, that the serum treatment of pneumonia is a rank failure and that nothing is gained by combining it with ethylhydrocuprein. The value of the latter is still problematical. Two children and a man of 60 were not saved by its use.

Present Status of Treatment of Malignant Tumors.—Blumenthal of the Berlin Cancer Research Institute, writing especially of chemotherapy, discusses the tumor-affin substances, otherwise tumoratrophic. He states that the halogens increase the tissue affinity of arsenic. Iodine alone has considerable tumoratrophic power. The affinity possessed by selenium is enhanced by eosin. All substances of this class are naturally toxic, especially in combination. Some which are very effective are but little toxic—for example the iodides. The problem seems to be to form synthetics which shall get the greatest possible use out of the less toxic and more highly specific factors. The metalloids appear to attack the cancer cells only by damaging the capillaries. The once praised combination of novocain and adrenalin as a starvation procedure is now forgotten. The good results obtained with mesothorium show most plainly that cancer is not incurable, and

should point the way to further advance if we succeed in finding out whereby the cure is effected.

Surgery of the Nervous System.—Loewy notes the most recent advances in this field. Among these are the cure of hydrocephalus by ventricular puncture. In tumors of the brain we see daring interventions along with a tendency toward conservatism, the former being indicated of course when life is menaced. When delay is obtainable von Eiselsberg, a leading cranial surgeon, pushes Hg and I for months. A few intraspinal tumors are amenable to operation. Hypophysis operations are of course on the increase and the author speaks of von Eiselsberg's 18 cases as if it were a record. Cushing is ignored. Förster's operation for spastic palsy continues to be a subject for endless discussion.

Cylinders and Cylindroids.—Posner refers to the original cylindroids of Thomas, described in 1870. The nature of these cast-like substances was variously interpreted in subsequent years. They were found to differ much from true cylinders when subjected to intensive study. Most of them seemed to consist of mucin and were not casts, as shown by their contours, which were not parallel, and by their ramification. With the introduction of dark field illumination it became possible for the first time to understand the relationship between cylinders proper or true casts and cylindroids. They could not be separated by such criteria as branching or want of parallelism of their edges, for even true cylinders exceptionally show these peculiarities. In fact there is no doubt that the cylindroids of Thomas and others were in many or most cases true cylinders, the nature of which is still far from being understood. Dark field illumination has revolutionized our knowledge of hyaline casts. We know that in certain cases of nephritis the albumin is visible to the naked eye as a "nubecula." It represents a coagulation of albumin and if studied under dark field illumination is seen to be made up largely of very coarse filaments of the relative thickness of casts. These are extremely wavy, doubling at times upon themselves, or drawn out into long, tapering streaks and branching in a rude fashion. Instead of terming individual fragments cylindroids it would be much better to regard the whole mother substance as cylindroid material. Hence there can be no absolute distinction between true cylinders and some at least of the cylindroids, in that both represent coagulated albumin, whether in the renal tubules or elsewhere. There are cylindroids of mucoid substance which simulate these bodies and proceed from the ducts of the urinary tract, and it may be necessary to exclude them in diagnosis, but this should not be difficult, and their presence has no practical bearing.

Magnesium Sulphate in Tetanus.—Berger gives a collective review of this subject, concluding with a summary by Kocher who is termed a "second father" to the latter, Meltzer being of course the first one. It holds off the danger until the antitoxin can penetrate to the hiding places of the germs. Kocher thinks the 15 per cent. concentration better than Meltzer's 25 per cent., but he gives larger amounts, sometimes five times the maximum child's dose of some physicians. If the spinal canal puncture is followed by escape of blood the injection is not made. Posture is of absolute importance, varying with the case. If there be tetanus of the head and thorax muscles, the solution must be able to anesthetize the cerebrum at once. We must however be prepared to treat a sudden arrest of respiration (artificial respiration, physostigmine injection, deep insufflation of oxygen). Arnd had advised washing out of the entire meningial sac after lumbal puncture, and speaks of the astonishingly good results. Kocher states that magnesium has given brilliant results in the severest cases. Serotherapy should always accompany its use.

Vaccination Against Chickenpox.—Kling makes a provisional communication on this subject which concerns work done under Medin, the well-known Swedish pediatrist. In the midst of an epidemic of the most typical forms of chickenpox the idea occurred to him to seek to prevent the transmission of the disease to certain young children. He took the clear lymph from a pock and inoculated it into the arm of an infant. After eight days appeared a papule, small and red, which within 24 hours passed into a typical varicella vesicle, about which appeared an areola the size of a penny. On the third or fourth day the vesicle dried up and the efflorescence slowly vanished. At the site of the vesicle a small scab formed and was not cast off for about two and a half weeks. There were no tendencies of generalization of vesicles nor was there any systemic reaction. The author obtained positive results in 58 cases, in only 6 of which was autoinoculation successful. In regard to the amount of protection, no one can say. Out of 31 nurslings exposed, but 1 took the disease in a very mild form.

Münchener medizinische Wochenschrift.

November 4, 1913.

Treatment of Granulating Wounds.—Heisler reports a severe case in which skin grafting appeared to be the sole outcome but which he succeeded in healing by physical therapy (he is director of an air cure sanatorium). None of the new cell proliferants were tested, although the opportunity presented was excellent. The patient's hand had been badly shot, leaving a large granulation surface. A surgeon advised immediate transplantation to prevent serious ciratricial contraction. The author had just been reading Bergeat's work on the power of the hot-air douche, but as he was unable to obtain one, simply allowed a current of air to be blown upon the surface. The effect was surprising. Shreds of the injured tissues began to come away, and a glistening pellicle was seen in the act of formation. The air treatment was continued for half an hour daily. No epithelial bridges formed. Only a zinc dressing was used after healing was nearly complete. An objection to the method was the coldness of the air as it impinged on the limb. Hence the douche should often be interrupted. The author thinks that the rationale agrees with that of the hot-air douche, *i.e.* in both cases it is a matter of active drying of the surface.

Apex Catarrh.—Litzner writes at length on the subject of nontuberculous apex catarrh. An enthusiast in a Western city, now deceased, who used to defend against all comers this view of a simple apex catarrh and who was ridiculed good-humoredly by all his colleagues, would have rejoiced to see this day. Litzner states that as a result of the increased thoroughness of physical examinations in sanatoria we have learned that the supposed anatomical and physiological differences between the percussion sounds of the two apices may have caused us to dwell too slightingly on these differences. He states that we can now allow for such dissimilarities and still detect the presence of a catarrhal condition of one apex, which is certainly not tuberculous. The author is inclined to impute the catarrh to inhalations, especially in connection with trades. However, in such cases both apices are affected. Certain microorganisms, as the influenza bacillus, can also attack the apices. The American specialist referred to claimed the existence of a, for the most part, unilateral right apex catarrh, recognized by flatness on percussion and diminished heart sounds heard from behind. He preferred to treat these cases as tuberculous to give them the benefit of a mistaken diagnosis and insisted that they regularly cleared up under treatment. Some of the author's cases are counterparts of the preceding. A very severe type was not infrequently seen in which hemoptysis, involvement of the left apex, night

sweats, etc., occurred; but strange to state these were not of tuberculous origin, the actual cause being the irritation of sensible bodies inhaled in connection with occupation, pneumomycoses or perhaps, as already suggested, some bacterium like the *B. influenzæ*. While essentially bilateral, such cases begin in the right apex, for reasons well known to the pulmonary specialist.

Deutsche medizinische Wochenschrift.

October 30 and November 6, 1913.

Changes of Doctrine in Gastric Lavage.—Boas refers back to the indications for lavage as taught by Kussmaul nearly fifty years ago which he states to be fundamentally sound to-day. The progress which has been made in the meanwhile is documented in the fact that we no longer use lavage throughout the treatment but only at the onset of the latter. For the rest it has been supplanted by dry expression. No longer is lavage the dominant factor in treatment, but an accessory doomed to be supplanted in part by improved dietetics. Other uses are empirical and unscientific such as washing a stomach which should expel its contents into the intestine.

Cause of Variola and Vaccinia.—Very recently several authorities have claimed the relative isolation of the smallpox exciter. Paschen, the well known Hamburg expert, now comes to the fore with a long article. He describes an organism which agrees in part with those isolated by Prowazek and Casagrandi. They are not only extremely small but take stains very poorly. Evidently they live within the body cells in which they produce vacuolation. The cytoryctes of Guarnieri while specific for smallpox is not an organism but a reaction product of the cell, and can be demonstrated at will in infant lymph. The cytoryctes may sometimes be found to contain a minute, coccoid, blue stained (Giemsa) corpuscle in groups. These may or may not be a form of the actual microbic exciter, but at any rate is commonly associated with the supposed cause of the disease, which does not stain with Giemsa, and which passes through a Berkfeld filter. The author does not allude to the work of Fornet (abstract in Medical Record) and his apparently successful cultivation of a parasite, until the very close of his paper. He expects to be able to cultivate his own discovery.

Attempts to Prepare Vaccine Which Shall Be a Pure Culture of the Exciting Cause.—Paul of the Vienna Vaccination Institute has already made wholesale efforts to prepare a vaccine which shall derive its efficacy from Paschen's bodies as described above. The antivaccinationists in Austria urge that no attempts are being made to isolate the active cause of smallpox and employ it in pure culture. This contention is a just one and the best neurobiologists in the world are now at work upon the problem. Prowazek went to Brazil in 1905 where the disease always flourishes, while lymph cannot endure the heat and rapidly deteriorates. The dark field illumination is a discovery which makes for increased knowledge of this subject and a general advance along the line has been made in filtrable viruses. Paul has installed a large filter for separating alien matter from the true exciter. He believes that filtration will confer the necessary separation. Glycerin may be added to the filtrate as preservative and the author makes but a mere suggestion as to keeping the virus fresh by cultivation, as emphasized by Fornet. The source of the crude lymph for him will still be the calf. Much else remains to be done. Glycerine preservation is a makeshift and something more must be done to prevent secondary contamination of pure lymph during vaccination.

Pseudopélade Brocq.—Dreuw discusses an affection of the scalp which must be differentiated carefully from alopecia aerata. Under the name alopecia atrophicans it is barely known in medical literature. Brocq described it in its matured state in 1885, but little has been known as to its initial stage, and this manifestation is what the author means to clear up. The affection has now become quite common in the Berlin schools and something must be done to detect it in its early stages, as is possible with ringworm diseases. In 1910 the author had occasion to study 200 incipient cases of this affection in school children, the incidence being practically epidemic. However, the diagnosis was extremely difficult, since so many affections had to be excluded. So great was the confusion that an attempt was made to settle everything upon a strictly bacteriological and cultural basis. Before undertaking this research, it was found that over a dozen kinds of alopecia had to be reckoned with clinically. The usual parasitic diseases were represented, but many accidental and transitory forms were present. The author found two types of alopecia which did not fit into any system. These are *A. atrophicans* of Brocq and *A. parvimaculata*, which from their independent status in regard to other affections, may be assumed for the once to be identical. The parvimaculate form may or may not be atrophic in character. Clinically many photographs are given to illustrate it—its beginning as a mere point, with loss of a few hairs. A few of these minute areas may coalesce to form a bald spot the size of a dime. In other cases the minutest spots are diffused over the scalp, with no attempt at enlargement. These minute areas the author regards as the initial stage of Brocq's pseudopelade. Since no parasite could be discovered in the author's epidemic, he is thrown back upon the hypothesis of a neurotrophic origin, dependent upon the unusual conditions inseparable from beginning school life.

Pneumonia and Cardiac Lesions.—Keller states that in pneumonia, even so slight a lesion as a lateral arteriosclerosis may be sufficient to render the heart the *locus minoræ resistentiæ*. During the pneumonia the arteriosclerosis may become apparent, perhaps as a stenosis and insufficiency of the aortic valves. The author no doubt refers to this complication as it occurs in young and middle-aged people, since in the old the association must be extremely common. A subject who has never experienced any illness is stricken at an advanced age with pneumonia. If some evidence of arteriosclerosis did not crop out during repeated examinations, one would be surprised. The author's patient was a man of 36, in apparently perfect health. He passed through a typical pneumonia, the heart behaving throughout in a normal manner, until about four weeks after the onset of the disease, when he complained of dyspnea. Heart boundaries were normal but a systolic murmur was everywhere present. Later the noises became loudest about the aortic valves. Recovery occurred to some extent, the patient being able to go about as usual, but the state of the valves showed no change. The author had made a diagnosis of endocarditis following pneumonia but the picture and history showed that the heart lesion must have been atypical. An *x*-ray showed a heart of normal size and site. There was no evidence of arteriosclerosis, and as a high degree of anemia was present it was believed that this formed a link between the pneumonia and cardiac lesion. Some months later a second examination showed that the anemia had disappeared, while the symptoms pointed entirely to arteriosclerosis. There could be no doubt that an early arteriosclerosis or presclerosis had been intensified by the pneumonia.

Privileged Communications.—The testimony of a physician as to the state of his patient's general health and mental condition is admissible if it does not appear that what he stated on the stand was information which "was necessary to enable him to prescribe for her," which is essential, in order to bring it within the Michigan statute as to privileged communications.—Steketee v. Newkirk, Michigan Supreme Court, 138 N.W. 1034.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE TECHNIQUE IN HELLER'S TEST FOR ALBUMIN.

Heller's test maintains a well-earned reputation for reliability and simplicity. Other excellent tests have been devised, but it is doubtful if any of them possess greater, if as great, merit. It would seem that the presence of a very small quantity of albumin is indicated occasionally by the reaction of some other test when the result by Heller's method is negative with the same specimen. This is especially true of the test in which a saturated salt solution and acetic acid are employed. After working with this test for some time a good many observers have come to suspect that it is oversensitive or reacts with other substances as well as with serum albumin. In any event, long experience teaches that Heller's method, properly and carefully conducted, is sufficiently reliable and sensitive for all clinical purposes; furthermore, that albumin present in quantity small enough to escape detection by this procedure is negligible.

A trace of albumin is often overlooked in urinalysis when one or more of the few following simple directions are not observed. The directions apply to all tests as well as Heller's:

1. Cleanliness of test tubes and apparatus. A small amount of albumin is liable to escape detection when the tube is dirty or covered with smears and stains. The glass should be cleansed to the state of crystalline transparency, so as not to obstruct vision to the smallest degree. Nitric acid followed by rinsing with clear water will remove stains from the inside. The outside surface of the tube becomes sooty from the flame, or cloudy from the salts remaining after evaporation of moisture from the outer surface of the tube; in either case the tube should be gently cleansed with a damp cloth before inspection of the contents.

2. Clear urine. The urine should be filtered until clear, so that the contrast between the portion containing the coagulated albumin and that in which no change has occurred will be marked. A specimen containing bacteria will not be clarified by ordinary filtering. If, however, the earthy phosphates are precipitated by the use of ammonium hydroxide and the urine then filtered, it will usually be found that the precipitate has carried the bacteria with it.

3. Light. Tests cannot be properly made or read by dim or artificial light. A trace of albumin may easily be passed by unless looked for in a good natural light.

4. A background of black at a window will assist in the discovery of albumin. A good practice is to hang a board with a blackened surface on the window sash for this purpose.

Further details applicable to Heller's test appears in the following description of the two methods for conducting it.

1. Pour half an inch of pure, colorless nitric acid into the test tube. The tube is then held at an angle of at least 45 degrees while clear urine is allowed to trickle from a pipette slowly down the side of the tube until one inch of it overlies the acid. If this is carefully done there will be no mixture of the urine and acid.

2. A more sensitive method and one requiring more skill to prevent mixture of the acid and the urine, is the following: Place about one inch of the suspected urine in a perfectly clean tube; allow pure nitric acid to trickle slowly from a pipette down the side of the tube, which is inclined to at least 45 degrees. The acid should collect in the bottom of the tube without mixing with the urine.

In both methods the presence of albumin is denoted by the presence of a white layer or cloud immediately above the acid. The white zone will occasionally form slowly for some unknown reason. Consequently, the tube should invariably be set aside for at least fifteen minutes. The band of albumin may form and become diffused during this time, however, so it is necessary to inspect the contents of the tube about every three minutes until the procedure is completed. These two precautions are often neglected, and this accounts for many of the apparent shortcomings of Heller's test.

A diffused cloud with a layer of clear urine between it and the acid indicates urates or nucleoproteid, not serum albumin. If the person has been taking any oleoresin, such as cubebs, copaiba, etc., a white ring may form at the junction of the two liquids, but the presence of these substances may be easily differentiated from that of albumin by means of the heat test.

Failure of the Colleges to Teach Insurance Medicine.—Gaillard considers that the reason why medical colleges have not included instruction in life insurance work in their curriculum lies in the fact that the teaching faculties of these colleges have failed to realize the vast importance of modern life insurance institutions, and the vital part the medical profession must necessarily exert in such great activities. The professional prominence usually enjoyed by those who attain the privilege and distinction of teaching our undergraduates is such as to bar them more or less from active participation in insurance examining work, and they are inclined, by unfamiliarity with its requirements, to minimize the qualifications absolutely essential to an examiner who hopes to be successful.—*Lancet-Clinic*, September 6, 1913.

Life Insurance as an Aid to Longevity.—J. M. French, in a paper on this subject, says that some wives object to life insurance for their husbands, because of a superstitious fear that it would hasten their death, but these wives can hardly be twentieth century wives. Life insurance is, in fact, an aid to a longer life, and the insured live to a greater age than the uninsured. The reason given is that the minds of the men who are insured are freed from worry as to the preparation for the future, hence the reaction of the mind on the body is much lessened, resulting in a happier and better old age, through less impaired physical condition. Especially is this true in those past middle age. Then, too, if the man who carries life insurance outlives his family—providing he has one—he has more assurance that he will be taken care of in his old age, if only for the hope of his insurance. A sad thought, but a true one. Life insurance is a potent factor in the physical and mental improvement of the race, and this is of even greater importance than the promotion of long life in the individual, as it tends to make the next generation longer lived and more enduring than the present. Life insurance promotes eugenics because it stands as a guarantee that the men and women who are insured and who marry are of sound mind and body.—*American Medicine*, October, 1913.

Book Reviews.

The Medical Record Visiting List or Physicians' Diary for 1914. Newly revised. Price $1.25. New York: William Wood & Company.

This old and favorite visiting list contains the usual ruled pages for daily use, and also space for consultations, obstetric engagements and practice, vaccinations, addresses of patients and nurses, and for cash account. There is also the usual introductory matter, and a number of necessary changes have been made in the table of drugs and doses, in order to bring it up to date, and some of the unimportant and obsolete preparations have been omitted. The visiting list has long enjoyed a well deserved popularity, not only on account of its excellent arrangement but also because it is of convenient size and is handsomely bound.

Studies in Cancer and Allied Subjects. Contributions to the Anatomy and Development of the Salivary Glands in the Mammalia. Conducted under the George Crocker Special Research Fund at Columbia University. Vol. IV. Price $5.00 net. New York: Columbia University Press, 1913.

This volume of studies, the second to appear though the fourth in the series, is devoted to the anatomy and development of the salivary glands. It includes contributions by Churchill Carmalt, George S. Huntington, and H. von W. Schulte and presents what is probably the most complete study of these glands yet published. It is far too extensive to review here in detail. The work is based upon the extensive research of the late Dr. Carmalt on the comparative morphology of the salivary structures. At his death the work was scattered and to a certain extent unfinished. Huntington and Schulte went over the mass of material which was left, completed some of the lines which he had begun and present this volume as the result. The book is profusely illustrated with excellent drawings and is published in the same style as the previous work done under this fund. The publication of this work under the Crocker fund is justified on the basis that one of Dr. Carmalt's purposes was to furnish a sound morphological foundation for the study of neoplasms of this region.

Gould and Pyle's Pocket Cyclopedia of Medicine and Surgery. Based upon the Second Edition of Gould and Pyle's Cyclopedia of Practical Medicine and Surgery. Second Edition, revised, enlarged and edited by R. J. E. Scott, M.A., B.C.L., M.D., New York; formerly Attending Physician to the Demilt Dispensary; formerly Attending Physician to the Bellevue Dispensary; Author of "The State Board Examination Series"; Editor of "Witthaus' Essentials of Chemistry and Toxicology" and "Hughes' Practice of Medicine," etc., etc. Price $1.00 net. Philadelphia: P. Blackiston's Son & Co., 1913.

This is a wonderfully compact little volume, full of information arranged for quick reference. The flexible leather binding, the thin paper, the gilt edges adapt this book admirably for the coat pocket. The paper is however, too thin, the print showing through. It may also be noted that the name of the author of this revision has strangely been omitted from the cover.

The Physicians' Visiting List (Lindsay & Blakiston's) for 1914. Sixty-third year of its publication. Price $1.25. Philadelphia: P. Blakiston's Son & Co.

This popular visiting list appears promptly for the sixty-third time but with the same familiar face. It contains the reading matter usual in these annuals, such as a dose table, list of incompatibles, rules for the treatment of asphyxia, and direction for first-aid in cases of poisoning. Some of this reading matter might be brought up more nearly to date, for example the section on the treatment of asphyxia; but as few people ever make use of such matter the lack of revision will do no harm.

Practical Bacteriology, Blood Work and Animal Parasitology, Including Bacteriological Keys, Zoological Tables and Explanatory Clinical Notes. By E. R. Stitt, A.B., Ph.G., M.D., Medical Inspector, U. S. Navy; Head of Department of Tropical Medicine, U. S. Naval Medical School; Professor of Tropical Medicine, Georgetown University, etc. Third Edition, Revised and Enlarged. Price $1.50 net. Philadelphia: P. Blakiston's Son & Co., 1913.

In its third edition this book shows evidence of a distinct enlargement, which, however, is not commensurate with the large amount of new material which has been introduced into it. It has been quite thoroughly revised and many new methods have been added. The work is divided into four parts, bacteriology, study of the blood, animal parasitology and clinical bacteriology, and parasitology together with an appendix containing sections on chemical examinations and the preparation of histological specimens. Everything is condensed to the last possible degree. The section on animal parasitology is particularly complete and satisfactory. It is to be regretted that the author has seen fit to vary somewhat one of the standard terms in immunity. He divides immunity into inherent and acquired and the acquired into natural and artificial. In the minds of most of his readers the term natural immunity connotes what he means when he says inherent immunity, while his natural immunity is generally known as active immunity. There is hardly a good reason for the change and the subject is difficult enough without introducing a confusion of terms. It is rather surprising that he retains a description of the Cammidge reaction which has been pretty thoroughly discredited since the appearance of the second edition. The volume is an attractive one and contains an immense amount of information.

Operationen Am Ohr (Operations on the Ear). By Dr. B. Heine, Professor and Director of the University Ear Clinic, and Poliklinic for Diseases of the Ear, in Munich. Third Enlarged Edition. Price 8.80 marks. Berlin: S. Karger, 1913.

The first edition of this work appeared in 1903; the second in 1906. With the rapid development of operations on the middle ear, labyrinth, semicircular canals, and the new and fearless surgical work in connection with dural and pial brain abscesses, as also in conjunction with sinus thrombosis and inflammations of the jugular bulb and vein, a work of this class under the auspices of a University cannot but meet with approval. The third edition enlarges more particularly upon the use of the Roentgen ray in mastoid disease; describes plastic operations for the cosmetic as well as physiological healing of bad curettage of mastoid and tympanum. As to opening of the mastoid, the author does not wait a given time—four to six weeks. Each case must rest on its own merits, although the position of the surgeon in a symptomless case is most disagreeable. The Roentgen ray is of use to define the limitations of large and small cells in the mastoid rather than the inflammatory processes of the mastoid itself. There is apparently little new in the method of the author as to Lanfols' and Schwartze's radical operations, here given in detail. Some fresh facts are brought out, as, for example, the harmlessness of injury to the horizontal semicircular canal, provided the preceding steps of the operation are thoroughly aseptic. A clear and succinct description of the course of pus from middle-ear through the oval and round windows through the horizontal rather than the posterior or superior canals, until the labyrinth is reached, is well written. The author points out the danger to life of the complication of pus in the labyrinth. Wonderful advance has been made within the last few years in this localized surgery. Not only can labyrinth disease be diagnosed, but its purulent processes can be checked and life saved. The author has prepared a useful guide for the otologist and aural surgeon. He is evidently not familiar with the English and American surgical work of the last ten to fifteen years—and in so far fails of a broad, comprehensive view which this work commands. The illustrations by Frln. Lisbeth Krause from the author's preparations are highly artistic.

Das Gehörorgan und die oberen Luftwege. By Dr. William Hasslauer, General Staff Physician. Price 6.50 marks. Berlin: Oscar Coblentz, 1913.

This little monograph has special regard to the muster in and military necessities of the soldier in service during peace or war, and is written from a German army surgeon's standpoint. It is a most readable and instructive guide to both candidate for army service and examiner of recruits. It illustrates the extreme care given to examinations of the aural passages, the anterior and posterior nasal fossæ, the pharynx, fauces, tongue, teeth, and gums—not only of the probationed recruit but of the soldier in military maneuver. Relations and behavior of the muscles of head and neck, development of glands and auricles, epiphyses of bones, neuroses of neck and ear, are written of in minutest detail. Aural and nasal reasons for refusing otherwise healthy recruits, the physical care and protection of these organs in foreign climates, monaural deafness, malingering, etc., are depicted with most instructive pen, so that even an anatomical artist might tread on the ground covered by this little work with fear and trembling. The aural examination for the German, Bulgarian, Danish, French, Italian, Austrian, and other European armies, also for the Japanese army, are reported in fullest detail, as given by the war ministry of the various nations.

Society Reports.

NEW ENGLAND PEDIATRIC SOCIETY.

Special Meeting, Held in Boston, November 8, 1913.

THE PRESIDENT, DR. JAMES F. STONE, IN THE CHAIR.

THE Pediatric Section of the New York Academy of Medicine, the Pediatric Section of the Medical Society of the State of New York, the New Jersey Pediatric Society, and the Philadelphia Pediatric Society were the guests of the New England Pediatric Society on this occasion. Clinics were given at the various hospitals of Boston during the day, dinner was served to the visiting physicians at the University Club, after which a scientific session was held in John Ware Hall, Boston Medical Library.

On the Bacteriological Diagnosis and Treatment of Alimentary Disease in the Infant and Child.—Dr. RALPH VINCENT of London, Eng., presented this paper in which he first pointed out the importance of appreciating the nature of the biochemical processes occurring under normal conditions before it was possible to appreciate the significance of the abnormal. He grouped the organisms concerned in the alimentary conditions of infancy under four heads: 1. Bacteria producing lactic acid, but not producing gas. This group was represented by the *Streptococcus lacticus* and the *Bacillus lacticus*. The *Streptococcus lacticus* was the typical organism growing in pure milk at a temperature of 38° C. At a later stage, when the acidity had become too great for the streptococci, the *B. lacticus* appeared, this organism being exceptionally tolerant of acid. 2. Bacteria producing lactic acid, carbon dioxide, and alcohol. This group embraced the whole of the colon group and included the *B. acidi lactici* of Hueppe, *the Bacterium acidi lactici aërogenes* of Escherich, and the *B. coli communis*. When raw milk was incubated the growth of the organisms belonging to this group was inhibited by the growth of the organisms belonging to the first group. When milk was grossly contaminated the colon organisms might gain dominance, and in such cases the curdled milk showed evidences of gas production. 3. Bacteria growing in pasteurized milk. The *B. putrificus* and the *B. enteritidis sporogenes* were examples of this group and their products were of highly irritant and dangerous character. 4. Bacteria growing in the milk after it had been raised to 100° C., owing to the fact that their spores had not been destroyed. These organisms were found in milk that had been boiled or sterilized, or in condensed milk. This group embraced a large number of organisms, the chief representatives being *B. subtilis, B. mesentericus,* and *B. mesentericus vulgatus*. When they developed in the intestines extremely powerful poisons of an alkaloidal nature were created and their absorption produced profound coma and death. These organisms were quite unable to grow in raw milk, for their growth was entirely prevented by the acid-forming bacteria. A series of experiments showed that pasteurization of milk at low temperatures did not destroy the lactic organisms as they finally appeared after long incubation in all instances. In the majority of cases they were so badly injured that they failed to appear at all within twenty-four hours, while the effect of their being unable to develop was that other organisms did develop, such as the *B. megatherium, B. subtilis, B. mesentericus,* and *B. enteritidis sporogenes*. It was impossible to find a method of pasteurization which would destroy pathogenic organisms without destroying the lactic organisms. The grave alteration of the milk was shown in the development of the acidity and the time of curdling. Fresh milk curdled at 38° C. within twenty-four hours, the acidity being from sixty to seventy degrees, while in pasteurized milk the average time of curdling was fifty-five hours and the average acidity at the end of twenty-four hours 20 degrees, which was the acidity at the time of milking. In raw milk *B. enteritidis sporogenes* never developed. If a milk was heated at 10° F. it was nearly certain that *B. putrificus* would appear on incubation despite the fact that there were other organisms in the milk capable of developing if only the conditions were favorable. If the temperature was too high for the *B. putrificus* to escape destruction, then the *B. enteritidis sporogenes* developed and held back all other organisms. In pure milk the *Streptococcus lacticus* grew rapidly for twenty-four hours, when the acid produced inhibited its growth; in about forty-eight hours no further growth was seen. The production of acid did not proceed regularly, the largest amounts being produced in the hours from the sixteenth to the twenty-fourth. The contents of the small intestine were normally acid owing to the formation of lactic acid from lactose by lactic acid bacteria. The lactic content gradually diminished as the food products passed through the alimentary canal, till, in the lower part of the colon there was no acid at all. This explained the difference between the flora of the large and small intestine. Were it not for the acid condition putrefactive processes would occur. This statement of the effect of acidity was absolute as regarded the obligate proteolytic organisms, but it was relative as regarded the colon organisms. The colon bacilli could act in an alkaline as well as in an acid medium, but the acid must be moderate in amount. One of the dangers of pasteurized milk was that while some of the organisms of putrefaction produced most unpleasant odors, others, notably the *B. mesentericus vulgatus,* grew in profusion without creating any change that could be detected by the senses. Dr. Vincent then described the technique for the examination of the intestinal dejecta. He stated that he preferred the Zeiss microscope. He had used two routine staining methods, the Loeffler's blue and a special method which he had devised, in which the Gram method was used with the Loeffler's blue as a differential stain. The great advantage of this method was that it differentiated all the lactic group from the colon group. The normal dejection contained numerous lactic acid bacilli, some colon bacilli, and possibly a few diplococci. In some instances lactic acid bacilli were found in almost pure culture, in others masses of diplococci or streptococci were seen, and these might be combined with lactic bacilli; in still other cases one might find a mixed specimen, lactic organisms and colon bacilli, together with the *Oidium lactis*. All of these acid conditions quite excluded a colon toxemia. This was a valuable indication as to treatment. Fresh milk would completely rid the intestines of *Oidium lactis* and similar fungi in about twenty-four hours. A cooked milk containing an excessive amount of sugar favored the development of these organisms. The colon organisms were facultative fermentative organisms and could deal with the remnants of lactose that might pass the ileum producing not only lactic acid but a small amount of gas. The administration of starches markedly encouraged the growth of the colon organisms. Some considerable practical experience was necessary to enable the observer readily to pick up the leading indications presented by the specimens, but it would be found that the majority of cases were straightforward, while in others there were special factors which had to be taken into account. Among the workers at the Infants' Hospital there was no doubt that by the means of bacteriological examination they had arrived at a means of diagnosis which in respect of accuracy and precision was far superior to any other means at their disposal. Their diagnosis and treatment were fundamentally dependent upon the reports from the research laboratory as a number of instances cited demonstrated. Upon the question of the relationship of proteolytic streptococcus to alimentary disease Dr. Vincent said he had not been able to arrive at a definite conclusion. In the large majority of cases he had not been able to attribute any serious conditions to the presence of proteolytic streptococci. As a rule the children in which they were present were suffering from a mild toxemia. The speaker stated that his investigations in regard to the biochemical changes occurring in raw milk had taught him that the usual periods of bacteriological incubation were too long; they systematically investigated the conditions found at the end of four and eight hours' incubation at 38° C. Dr. Vincent reported a number of cases demonstrating their method of making a diagnosis on the basis of their bacteriological findings. In England involvement of the intestinal mucosus membrane was distinctly rare in diarrheal diseases. This statement was based on the examination of many thousands of consecutive cases. Cases of acute colitis caused by the *B. enteritidis sporogenes* were not uncommon, but he had never seen a case in a child under twelve months of age. In dealing with an intestinal condition due to the dominance of the acid forming organisms, the first line of treatment was the exclusion of all diet calculated to assist the lactic organism. Raw milk must be forbidden. Cooked milk with the lactose reduced to a minimum was indicated. In such cases a reasonable amount of fat might be given and a considerable amount of protein in the form of caseinogen. They employed precipitated casein. In these cases chalk might be useful together with minute doses of opium; thus some very old fashioned remedies were found to have their justification in the bacteriological condition of the intestine. Another preliminary treatment was albumen water made with normal saline to which a few teaspoonfuls of meat extract were added, while small doses of brandy were given at intervals. Very gradually a milk

diet was introduced. The treatment was constantly checked by the examination of the dejections. In these cases the value of purgation had been overestimated; active stopping of the diarrhea was not unsound treatment, as it gave the irritated intestine rest by stopping the excessive production of acid. The treatment of the condition arising from the predominance of the colon bacilli depended upon the age of the child. In infants under six months of age, particularly under four months, it was a mistake to undertake too active treatment. It was better to adopt dietetic measures favoring the development of the lactic organisms. If the cases did not respond to these measures cultures might be administered. Cases of intestinal toxemia never occurred in their experience unless the infant had been fed on cooked food, or there had been some other marked departure from a rational diet. In cases of bronchopneumonia the dejections should be examined and on the appearance of colon dominance, cultures of *Streptococcus lacticus* should be immediately administered. Children fed on boiled milk were more likely to contract tuberculosis by reason of the toxemia resulting from the proteolytic action of the colon bacilli. Treatment by cultures of antagonistic organisms was, as a rule, not indicated in young infants, but in older infants and children most gratifying results had been obtained by the bacteriological treatment. The bacteriological examination should be made by the physician; he should know everything at first hand about his patient. The cultures must be prepared under his direction and control. The patient must be kept under observation and control and the dejecta subjected to systematic examination. Bacterial treatment had better be altogether neglected than carried out in a perfunctory or superficial manner.

Dr. E. S. Dow of Boston, Mass., said that Dr. Vincent had touched on the main point at issue. There were two groups of men at work on the problems presented by the diarrheal diseases of infancy. The one was working along chemical lines, studying fat, carbohydrate, and protein intolerance, and this group was inclined to omit the importance of bacteriological conditions. On the other hand, the bacteriologists were inclined to neglect the chemical aspects of the problem. These two lines of study should be brought into harmony. It had always seemed that bacteriology would furnish a sound basis for the treatment of these conditions. The two conditions, over-acid and putrefactive, had long been recognized, but what was needed was a reliable method of differentiating them.

Investigations in Vulvovaginitis by Means of the Female Urethroscope.—Dr. JOHN F. SINCLAIR of Philadelphia, Pa., read this paper. He declared that the great majority of medical men had slowly but surely come to regard vulvovaginitis as a serious infectious disease, not usually venereal in origin, but in the vast majority of instances due to the presence of the Niesserian organism. It was primarily with the view of improving the methods of prophylaxis that the present study was undertaken. The characteristic tendency of the disease toward periods of latency was so misleading that new and improved methods of vaginal examinations were sought. Leopold and Rubin, in January last, reported their experience with the electric lighted female urethroscope in searching for evidences of vulvovaginitis in children. Their method seemed to be an improvement on the use by Koplik in 1893 of Skene's urethral speculum for this purpose, so they had determined to test its efficiency. During the present year eighty-three infants admitted to the Babies' Hospital of Philadelphia had been examined with the female urethroscope and the bacteriological findings noted. Only the negative cases were admitted to the general wards, all positive and suspicious cases being isolated for further study. They had used the dry swab, the moist swab, and the platinum loop in taking the smears; the last had given the best results, the moist swab being somewhat less satisfactory, and the dry swab much inferior. They had also used a 1-1,000 solution of bichloride of mercury, injecting it deep into the vaginal vault with a pipette provided with a small rubber bulb and then recovering the solution and subjecting it to careful bacteriological examination. This method had not proved as satisfactory in their hands as when employed by Van Gieson. This might be due to their faulty technique, as Hamil and Kolmer spoke highly of the method. The complement fixation test was employed in ten cases and the results of this series was detailed in a chart. These were so far as the author knew the first complement fixation tests made on infants which were accompanied by notes of endoscopic examination of the cervix and vaginal vault. That 55 per cent. showed a positive reaction to the test was also of interest, as former investigators were unable to report any positive reactions. The source of infection was sought for, and an effort made to fix upon the date of onset, when this was possible. Complications and sequelæ were noted when present. Of the 83 cases examined 16, or 19 per cent., were found to be infected with the gonococcus at the time of admission to the hospital, or to present highly suspicious evidence of such infection. Seven cases which were negative upon admission subsequently developed vaginitis of specific origin. Five of these had been in the hospital from five weeks to thirteen months, and had shown no evidence of vulvovaginitis on repeated examinations. They were sent to a convalescent home in the country between June 3 and June 26, and no vaginal discharge was noted until July 20, when one of the babies was reported to have gonorrheal ophthalmia, and examination disclosed a specific vulvovaginitis. From this time till July 29 four additional cases of gonococcus infection were discovered. Of the remaining two cases one was positive on August 13 and the other baby which was negative when admitted did not present positive signs of vulvovaginitis until August 13. Nine of the cases well illustrated the well-known tendency to latency in this disease and suggested the thought that one of the great questions in regard to proper prophylaxis had to do with early recognition of the infectious agent in these latent cases. Of the total number of cases found in the first two groups 21.74 per cent. would have escaped detection without the use of the electric lighted female urethroscope. Only 30 per cent. of the cases in the group showed any visible sign of discharge upon admission. The source of infection was a most difficult one to determine and in none of their cases had it been definitely settled. The date of onset could only be accurately recorded in those cases beginning *de novo* in the convalescent home or hospital. The complications noted were ophthalmia, an exanthematous condition of the vulva, buttocks, and thighs, and proctitis, each of these occurring but once. Treatment consisted of irrigations of permanganate of potassium 1-8,000, and local applications of argyrol in 20 per cent. solution. When the discharge became scanty a solution of hydrochloric acid 1-10,000 was substituted for the solution of potassium permanganate. Irrigations with both of the solutions were discontinued with the disappearance of the discharge and were thereafter only employed on the days when a discharge was again present. To be effective prophylaxis must begin with a campaign of education in the homes where infants were born and raised as well as in all manner of institutions which had to do with the various phases of child welfare. Day nurseries, infant and orphan asylums, hospitals, shelters, public baths, recreation centers, and even the school houses were prolific sources of infection, and would continue to be until adequate medical supervision was exercised and individual cases were isolated until free from specific infection. In all institutions where children were received each child should be examined upon admission for clinical and bacteriological evidences of gonococcal infection and promptly removed or isolated if the findings were positive. Proper isolation in institutions demanded the employment of special nurses who should not come in contact with other children. The lay helpers should be free from gonorrheal infection and this should be determined by the bacteriological examination and the complement fixation test. Systematic examinations of all inmates of such institutions should be made at convenient intervals in order that latent cases might be early detected and isolated before becoming centers of infection.

Boards of Health should be empowered by law to make gonorrheal infections reportable and to exercise their authority along lines similar to those which they now employed in dealing with tuberculosis. Medical attendants, especially gynecologists and genitourinary surgeons, should inform their patients clearly as to the nature of the disease and the danger of communicating it to innocent babes and children, and should give them minute instructions as to how they might safeguard those about them. Special clinics for the treatment of vulvovaginitis should be established in all large cities as they had been in Boston and New York.

Dr. RICHARD M. SMITH of Boston, Mass., said they had been working on this subject endeavoring to work out a line of treatment, and he wished to call special attention to the value of the complement fixation test. They had had several instances come under their observation where children were kept out of school and treated for vulvovaginitis when they were found later to have had a mixed infection. The complement fixation test would settle such cases as these.

Active Immunization in Diphtheria by Toxin-Antitoxin Mixture.—Dr. WILLIAM H. PARK of New York described the experiments that had been made with toxin-antitoxin mixtures in the laboratories of the New York

Department of Health and Willard Parker Hospital. He recalled that many of their methods of immunization and treatment were the result of accident. The use of antitoxin was discovered by accident and the use of the toxin-antitoxin was the result of an attempt to economize in the use of guinea pigs. After giving the guinea pigs toxin they gave them more antitoxin than was necessary, so that they might use them over again and they soon found that the guinea pigs had developed a certain degree of immunity. This action had been noted as far back as 1895, when they gave horses diphtheria toxin and then more antitoxin by one-half than would neutralize the toxin. In Boston Dr. Smith had found that not only his guinea pigs had immunity but that the young of these immunized pigs had a certain degree of immunity. Hitherto, in most of their immunity experiments they had been using horse serum which was an alien antitoxin and was eliminated in about four weeks from the human system, so it had been suggested that if they developed antitoxin in the human system the immunity should remain for a greater length of time. Working along these lines Behring a year ago injected a number of children with toxin-antitoxin mixture and actually immunized them against diphtheria, and this led them to carry out the same line of investigation. Dr. Park presented charts showing the results of their experiments with guinea pigs and horses. In making this study they found themselves confronted with two dangers; the danger of using too large an amount of toxin when the animal speedily died, or with a lesser amount became paralyzed; or, on the other hand, the danger of giving too large an amount of antitoxin when no immunity resulted. They designated that amount of toxin which produced active symptoms of diphtheria and death as 100 per cent, and then gave smaller percentages, 90, 80, 70, and so on down to 40 per cent. They found that as the amount of toxin was decreased the number of deaths and paralyses decreased. When from 60 to 70 per cent. of the fatal dose was administered the greatest degree of immunity was secured together with the greatest degree of safety. Different proportions of antitoxin were also employed, and it was found that the proportion that gave the greatest immunity was an amount a little greater than was necessary to neutralize the dose of toxin. In a series of experiments on horses it was found that 0.66 of a unit of toxin to one unit of antitoxin produced the largest amount of antitoxin in the blood and the greatest degree of immunity to the disease. In their experiments with children they found that about four-fifths of the children receiving the toxin-antitoxin injections, after ten days, developed from one-half to two units of diphtheria for each cubic centimeter of blood. This persisted for a number of months in gradually lessening amounts. In one series of fifteen cases there were five that developed no antitoxin in the blood; and of these, two developed diphtheria; they were then given antitoxin without any serious results and made rapid recoveries from the disease. One of the children in this series had one-tenth of a unit of antitoxin normally, and in fourteen days this child developed four units of antitoxin. The children who had antitoxin normally in the blood developed greater amounts of antitoxin than those who had none normally. None of the children with antitoxin normally in the blood developed diphtheria. In the scarlet fever wards, of 433 children receiving 1,000 units of antitoxin as a prophylactic dose on admission to the hospital, 20 developed diphtheria; all were given another dose of antitoxin and in no instance had there been any evidence of anaphylaxis, while in every case the diphtheria was controlled. In scarlet fever Behring found that active immunity broke down in several instances. Dr. Park then compared the mortality and morbidity curves of diphtheria in New York City since 1893. These curves showed that while the mortality of diphtheria had been reduced from 1.30 per 1,000 population in 1893 to 0.21 in 1912, the morbidity curve had fallen but very little if any. The morbidity in 1898 was 3.42, rising in 1903 to 4.85 and in 1904 to 4.65, and falling in 1912 to 3.61. This showed the need of some procedure which would lessen the incidence of diphtheria, and the question arose as to whether active immunity would give enough benefit to be worth the trouble when active immunization conferred immunity on about three-fourths or two-thirds of the children receiving injections for a period of about one year. It was possible that there was a need for active immunization in cities where diphtheria was endemic, but in outbreaks of diphtheria in institutions and families passive immunization was undoubtedly the better method in the present state of their knowledge regarding active immunity.

Dr. E. H. Place of Boston, Mass., said that, in regard to the production of active immunity, Dr. Smith had suggested the idea, but no one had had the courage to attempt it in the human being. As to the incidence of diphtheria, it was not evident that there had been any reduction in this respect. Although the morbidity curve was slightly lower it should be remembered that culture diagnosis had come into use and had exerted some influence on the morbidity curve. All sought some means of bringing about active immunity as this under the present conditions of living seemed to offer the only hope of controlling and limiting the incidence of the disease.

Dr. Park said that he might add that the results of their work on active immunity had not made them feel at all discouraged in attempting further investigations and they were planning to use this method on thousands of cases and to follow them up for several years.

The Position of the Stomach in Children.—Dr. James Warren Sever of Boston, Mass., said that he had examined a large number of stomachs of infants and children of various ages and physiques by means of the bismuth meal and the *x*-ray in the effort to determine the average location of the stomach in the erect position of the individual. In the literature on this subject much was found that would have to be discounted, if not altogether discarded, in the future, as they became more cognizant of the subject. He believed that they had been led to lay too much stress on the condition of so-called visceral ptosis, congenital or otherwise. Dr. Sever quoted a number of authorities as to the position of the stomach and pointed out the great diversity of opinion in regard to the normal location of this viscus. In the series of cases under consideration 83 children were examined, 60 girls and 23 boys. These children varied in age from four to eighteen years, the average being ten or eleven years. The weight, state of nutrition and general body development were also observed, as well as the attitude and the size, shape, and capacity of the thorax, and the costal angle. No attempt was made to outline the stomach by palpation or by inflation with gas, as this was felt to be unsatisfactory. The crests of the ilia were used for purposes of comparison. The average of the series was well up in size and weight to Holt's averages. Of the girls, 47 were well developed and nourished and thirteen were poorly developed and nourished. As far as they had been able to observe, general condition and body weight, with or without much adipose tissue, had very little to do with the position of the stomach. There could be no established rule on this point. In this series the capacity of the thorax was measured relatively by the chest expansion which showed a good average. In some of the cases a long flat narrow thorax was noted, but there was quite apt to be a stomach relatively high in these cases as in others with a normal thorax. No relation could be established in regard to the shape or capacity of the thorax with the degree of ptosis present or to be expected. The costal angle in these cases was generally normal or broad. They had taken the so-called index of Bescher and Lenhoff, the determination of which was supposed to give an adequate idea as to the relative capacity of the upper abdomen, but this had proved rather a failure as a means of estimating the probable position of the stomach. Cases with the highest indices showed no other evidences which could suggest ptosis, and others with low or moderate indices showed all degrees of ptosis. There could be no definite lines or relations established between the index and the shape, development, or capacity of the thorax, or shape of the costal angle. As to the position of the stomach itself in these cases, it was noted that, taking the crests of the ilia as landmarks, twenty-five showed the lower border of the stomach opposite the fourth lumbar vertebra, nine showed it at the level of the crests, and in 49 instances the lower border was well below the crests of the ilia, often in the pelvis, often as much as three or four inches below the crests. The finding of a uniformly low position of the stomach in such a large proportion of the series could mean nothing but that that was where the stomach belonged. He believed that such a low position was normal, and that in the future the second lumbar vertebra would have to be discarded as the normal landmark of the lower border of the stomach. In studying the *x*-ray plates, the size and shape of the stomachs was notable as well as the positions. The shape varied considerably, the most persistent type being that of the sink-drain variety. There were very few stomachs presenting the so-called normal cow's horn shape, and none of these were in the position usually regarded as normal. Many of the stomachs were seen in the middle line, but many were also seen to the left, apparently resting well within the iliac fossa. Ideas in regard to the position of the stomach would have to undergo a change. A low stomach in a child did not mean a pathological ptosis.

Dr. Maynard Ladd of Boston, Mass., said that all their work had been done on infants under nine months of age and done with reference to gastric motility rather than to the position of the stomach, but he believed that the position of the stomach in these younger children was higher than they had been accustomed to think. In twenty-five cases that he had examined there were none in which the lower border of the stomach reached anywhere near the crest of the ilium.

Dr. Abraham Jacobi of New York said that Dr. Ladd's remarks were in order. In infancy the position and shape of the stomach changed rapidly. In the newborn the stomach was in nearly a vertical position and by the end of one month it was in an oblique position, the lower border being in front of the tenth dorsal vertebra. It then gradually descended. It was to be hoped that Dr. Sever would take up this subject and observe the position of the stomach at the different months and years of infancy and childhood. The shape and position of the stomach in infancy was influenced by the food, whether the infant was breast fed or artificially fed. In looking up the literature he had found that the first demonstration of the localization of the stomach was made in 1825, and at that time the stomach was pictured as in a vertical position at birth and soon afterward.

Dr. Arthur R. Kimpton of Boston, Mass., said that he had had occasion recently to do two autopsies, one on a child three weeks of age and the other on one of four days. In the first case a diagnosis of pyloric stenosis had been made and a palpable tumor could be definitely made out, so the pyloric stenosis was not spasmodic. This stomach was in the oblique position higher up than the text books showed. The illustration presented was interesting as showing a picture of pyloric stenosis. The child's stomach was normal in size and the tumor looked like a new growth rather than a hyperplasia. The second case was not one of pyloric stenosis, but of congenital absence of the large intestine. In this subject the stomach was extremely high up and in an oblique position. The large intestine was about the thickness of a lead pencil and was filled with inspissated, putty-like material. The obstruction occurred about an inch from the ileocecal valve. In such cases one should look for the obstruction close to the cecum rather than in the large intestine.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-ninth Annual Meeting, Held at New Orleans, La. October 23, 24, and 25, 1913.

The President, Dr. Albert E. Sterne, Indianapolis, Indiana, in the Chair.

(*Continued from page* 1007.)

Technique and Results of Anoci-Association.—Dr. Harry G. Sloan of Cleveland, Ohio, said the best results would be obtained when we were able to protect the patient's central nervous system from all insults, whether these arose from psychic, traumatic or anesthetic factors, for the condition of the central nervous system was the cornerstone on which the ultimate outcome of each surgical case rested. The depletion and exhaustion of the central nervous system were readily accomplished, whereas its convalescence and return to normal function were notoriously slow; hence prophylaxis was of the greatest importance. Soon after waking on the day of operation the patient received a hypodermic injection of morphine and scopolamine and thereafter was disturbed as little as possible by nurses and friends. He was encouraged to doze off. On reaching the operating room he was at once anesthetized with nitrous oxide, in order to spare any unnecessary delay. In order to cut off from the brain the afferent nerve impulses from the field of operation, they blocked each successive plane of the operative field with novocain before it was invaded by the scalpel. All tissues were handled with the utmost gentleness, especially those viscera whose nerve supply it was impracticable to block. Gentle manipulation produced the least amount of tissue injury, and in turn necessitated the minimum amount of healing. Clean cut tissues contributed to the postoperative comfort. Trauma by destroying local immunity predisposed tissue to infection. The tissue trauma should be as slight as possible. First, the skin and the subcutaneous fat along the course of the proposed incision were blocked with 1-400 novocain solution; 10 c.c. Record hypodermic syringes were used and both the surgeon and the first assistant infiltrated the tissues at the same time so as to expedite matters. The aim was to infiltrate between the superficial and deep layers of the skin with the first line in such a manner as to cause a pig skin appearance. Putting the skin on tension facilitated this and when the proper plane was found the needle was progressively pushed along beneath the skin parallel to the surface while the injection was being made. In this manner a 10 cm. skin incision could be infiltrated by making only three skin punctures. The pig skin effect was much more easily obtained in some skins than in others on account of the varying cohesion of the two layers. The infiltrated line was massaged to spread the anesthetic and then immediately incised. Each tissue plane was blocked in a similar manner before the knife invaded it. Operating under local anesthesia alone was a valuable practice for learning effective local blocking. In such a case any careless move would call forth a protest from the patient. As a result of an abundant experience with conscious patients, the surgeon when operating on the anesthetized patients would automatically plan the infiltration and his handling of the viscera in the manner which would cause the least pain were his patient conscious. Wherever it was possible, they blocked the sensory nerves which supplied the operative field. An abdomen opened in such a manner, as described, showed perfectly relaxed walls because no sensory impulse had reached the cord to call forth the protective stiffening of the muscles. Since there was no increased intra-abdominal pressure the intestines in sliding up and down with the respirations would not protrude from the wound. The cut in the abdominal wall gaped open as it would in a cadaver. In order to achieve such a result, however, the blocking must be absolute, for careless infiltration would not turn the trick. This demanded practice, but practice would make perfect. Wherever practicable they blocked the whole nerve supply of the viscus on which they were operating; in this way they could isolate the uterus, appendix, bile passages, etc. Unless nerve conduction was interrupted in the cord, it was well nigh impossible to obtain perfect relaxation beyond the block in the muscles overlying an inflamed peritoneum or in a cancer-studded viscus which could not be included in the block. By blunting the keener faculties of the patient during the day of operation he was spared the anxious uncertainty that naturally occupied his thoughts at such a time. The induction of nitrous oxide anesthesia entailed no more discomfort than would dozing off in his own bed at home. In the hands of an expert this was one of the safest anesthetics known. By the use of a local anesthetic, the amount of general anesthetic required was reduced to one-third or one-half the amount ordinarily used. This was true of both nitrous oxide and ether. The post-operative comfort of patients who had been subjected to this technic was probably the most convincing evidence of the value of this procedure. A rapid convalescence and a rapid return to normal condition after an operation were in direct relation to the amount of damage done to the central nervous system.

Dr. W. F. Parham of New Orleans said he had been carrying out the method of Dr. Crile which had distinct advantages in the prevention of shock and the after comfort of the patient. Dr. Crile had given strong evidence of the effect of trauma upon the cells. He did not see how, with the careful method which he carried out in determining whether there was any such effect upon the nerve tissue or not, he could be in error, so that from his standpoint he would accept the statement from Dr. Crile as proved. He had recently been able to withdraw a kidney under local anesthesia entirely. He had brought the kidney up through a small incision, opened the pelvis of the kidney, removed a good sized stone from the pelvis, sewed it up, and then resected a cyst as large as a walnut from the lower pole of the kidney, put the kidney back into the cavity, and sewed up the wound with practically no pain. He had preceded this local injection by scopolamin 1/150th grain, and morphia, 1/6 grain. If that could be done, and it had certainly been done in a sufficient number of instances to prove its practicability and its advisability in many instances, then the addition of an anesthetic which was harmless in character, which would abolish the psychic effect, was a combination which made operative work about as nearly perfect as it was possible to make it at the present time.

Dr. E. Denegre Martin of New Orleans said that anyone who watched Dr. Crile work for any length of time was impressed by the fact that in his operations no unnecessary damage had been done. His effort had been to shorten the time of operations, to perfect his technic so far as he could, to traumatize the patient as little as possible, and to affect the patient as little as possible by the use of the ether, and he had succeeded in making

them more comfortable by shortening the operation, and they were less nauseated from the use of ether.

Dr. W. M. Perkins of New Orleans stated that in the matter of anoci-association great emphasis was laid on the patient's tranquility and upon the patient's confidence in the physician or surgeon who was to do anything to him or for him. That particular part of the paper should be emphasized, and especially for the benefit of those who did hospital practice. Patients psychologically would be treated very often in hospitals and if there was anything that they did not get in the way of cell exhaustion, it was only by luck.

President's Address: The Civic Importance of Some Phases of the Neuroses with Suggestions as to Their Control.—Dr. Albert E. Sterne of Indianapolis pointed out that of the many medical questions of civic importance probably none had acquired greater prominence than that of drug addictions. By reason of the baneful effects, not only upon the individual user, but upon his family and upon succeeding generations as well, by reason of the enormous proportions to which the various habits had spread, by reason of the crying necessity for authoritative control, and most important, by reason of the comparative ease with which this control could be attained, if the right measures be pursued, this drug question easily outstripped the rest in importance to society, and the opium question, the morphine question and the cocaine question had attained tremendous magnitude. Slaves of the one or the other or all of these drugs were numerous in every community, whether urban or country. Their total reached millions. Individual health or precongenital defect in loss in earning power formed an economic civic problem of the highest order. In its ramifications it touched many social conditions. Its association with the vice situation brought it startlingly into the foreground. It was safe to assert that 80 per cent, probably 90 per cent, of commercial white-slaves and their hangers-on were users of drugs. Many had become public prostitutes through drug addictions, more than had become drug habitues after inauguration into the body traffic and no small percentage had been designedly let into the thralldom of drug effects in order to make them easy victims of the tenderloin. This was particularly true in the larger cities to which ignorant immigrants swarmed, or to which many country girls were lured. If we, as physicians, were earnestly engaged in fighting disease conditions, personally and communally, if we were striving to prevent disease, to uplift humanity, and to teach the quality of man with the animal kingdom, to advocate quality rather than mere quantity of the human species, then it was our business to hit this drug monster with every atom of strength that we possessed. There was not a single community in this country or anywhere else in the civilized world which had not suffered from the effect of this great social disorder, concealed though it be as far as possible. Unlike the alcohol question, which paraded itself openly and thrived on publicity, the drug question sneaked, hiding as long as it could, save in those instances of common habit among a group of individuals or a given class of workers. The ratio of usage of drugs was as great or greater among the wage earners as among the wealthier and far greater among the very lowest social grades. In the South the number of drug users was uncountable. Race riots had been not infrequently attributed to the effects of these crazing poisons. Various States had legislated or sought to legislate and legitimatize the traffic in habit-inducing drugs. Indiana last year passed a law regulating the sale and use of these drugs, but the law was too faulty to be of much use. It was drawn by druggists, wholesale and retail, and never was designed to wholly prohibit trade in these nefarious stuffs. In Ohio a similar law was being urged. In several other States an analogous situation prevailed. This whole question was not one limited to any city, State or States, but was country wide and could be solved only by the federal government. Restrictive legislation and control by States would help to some degree, but unless some laws were obtained and were enforced by all states anything like adequate results would be mere speculation. As long as dispensing drugs of this sort remained lucrative, there would be found some means of supplying the demand, unless the matter could be absolutely controlled by federal authority which had the machinery already in action wherewith to effect proper control. He would emphasize the national regulation of all habit-forming drugs of every type, but especially those of opium and cocaine derivation. It took cognizance of the fact that only through federal action could any real result be gained and quickly gained. Concisely his plan was: *First*, the establishment of a national warehouse or central depository for imported opium and cocaine, and like raw drugs. *Second*, the establishment of regional or district depositories either for a group of States, or, if deemed advisable, for each State either for raw material, or manufactured products, or both. *Third*, the appointment of authorized pharmaceutical agents to convert the crude products into commercial form. These three departments would constitute the business plan, the proper operation of which would enable almost perfect control of raw material and finished product.

Child Culture the Function of Organized Medicine.—Dr. Henry B. Favill of Chicago stated that improvement in the conditions of future generations must be accompanied by an improvement in quality. The burning question is "How can the human stock be improved?" The relation of crime, insanity, pauperism, degeneration and social degradation to individual and hereditary defects had been proven. The control of the unrestrained breeding of defectives was immediate and urgent. This, however, was only a small part of the problem. The real question was not how to prevent the bad, but how to develop the good. The difficulty was that our knowledge of heredity was not as yet sufficient to enable us to control conditions. As we had not the facts on which to base any plan of control the most that could be accomplished at present was the creation of a public sense of conscience and responsibility, at the same time making every effort to increase scientific knowledge regarding the factors involved in heredity and eugenics. This was a field in which physicians must be able to qualify as experts. As a whole, the medical profession had not hitherto risen to the situation. Legislation could not proceed in advance of public opinion, and public opinion would not allow an invasion of private rights without overwhelmingly positive evidence being presented. This evidence must be secured and properly presented to the public by scientific physicians, if a public feeling of social responsibility was to be developed. Child psychology and proper methods of pedagogy were also involved. The prime question in any life was the character of its growth. The personality of the child was a determining factor in its development. Teachers could not be expected to solve the problems involved without assistance from physicians. Parents were in need of assistance from both physicians and teachers. We must make ourselves competent advisers to the parent and the teacher, in order to develop in each child the best of which it was capable. Health was a function of character. Under civilized conditions the maintainance of health became a question of self-restraint. Sanitary science could control mass conditions, but great progress in the physical welfare of the race would not be made until individuals were thoroughly trained in ideals as to health standards and their obligations to others. The evolution of the child was of the utmost importance in the solution of health problems, and physicians were not justified in saying that they would deal with the child's body and that some one else must mold its soul. Viewing the child and its development from any point, the conclusion was inevitable that the problems involved must be solved by physicians as a class. Again, the question presented itself, "Are we qualified for this responsibility?" It was a deplorable fact that in medical schools in this country, instruction in personal hygiene was almost unknown, and instruction in psychology was unheard of. The only explanation of this tremendous defect was that the profession had not as yet realized its responsibility in these directions. The greatest contributions of the medical profession of the future to human welfare would be the furtherance of child culture. The Council had undertaken to ascertain the exact public health situation in this country by inaugurating a survey of all public health agencies. This involved a survey of the public health work being done by the national government and a comparison of federal health work in this country with that of other civilized nations, as well as the development of practical plans for the establishment of a National Department of Health that would be second to none in importance in the government. Of still greater importance in this country was the State health work. Yet no one knew what was being done by the various State boards of health, because there was no standard or basis of comparison. The Council had undertaken a detailed and painstaking study of this question. A trained sanitarian of the highest rank was about to make a personal study of every State board of health to discover the work, powers, equipment and support of the health department in different States. After this had been completed a similar survey of the municipal health work was planned. Aside from official health activities, there were in this country many organizations springing from the private initiative and supported by popular

subscriptions. The importance of these organizations could not be overestimated. While the Council was carrying on these investigations in the existing health conditions, it had also started definite measures for the education of the public. A press bureau had been organized, which sent out to five thousand newspapers every week a press bulletin dealing with important public health subjects. The newspapers had recognized the fact that there was no sinister purpose or private interest behind this effect and they were using freely the material thus sent out. A speakers' bureau had been established, through which one hundred and thirty of the leading physicians of the country were offered to local organizations for addresses on public health without expense to the local body. The speakers donated their time, the Council paid their traveling expenses and the local organization furnished the meeting place. A bureau of literature was also preparing and sending out pamphlets on public health questons, written for the instruction of the people. Many special committees were at work on special subjects. A medicolegal bureau had been established to study public health laws in this country and others, and to draft, with the assistance of prominent educators, social workers, lawyers, judges, governors, and others, model laws for the protection of the public health. We recognize that in this work the legal point of view must be common. If asked what had public education to do with child culture, the answer was: "Everything." We could not mold the future on criticism. We could not educate and perfect children without intelligent co-operation of the present generation. The more intensely we saw our duty to posterity, the more profoundly we realized the necessity for sane conservative advance at present. The improvement of the future generations and the salvation of the people from disease was possible if the medical profession would take the lead and if the people would support its efforts.

Endocarditis with Special Reference to Its Etiology; Ulcerative Appendicitis in a Rabbit Produced by the Intravenous Injection of the Streptococcus Rheumaticus.—Dr. Robert H. Babcock of Chicago said it was his desire to emphasize the tonsil as the most frequent atrium of infection in rheumatic fever and endocarditis of whatever type. Unfortunately this relationship was not sufficiently appreciated, and mainly perhaps, because in childhood an acute tonsillitis may be so mild as to be overlooked, but ever since the work of Meyers in Germany years ago called his attention to the connection between follicular tonsillitis and rheumatism and endocarditis, he had made it a rule to investigate the condition of the tonsils in all cases of acute or chronic valvular disease coming under his observation, and he did not hesitate to assert that he invariably discovered evidence or obtained a history of previous tonsillar infection. The main reason perhaps why the etiological influence of follicular tonsillitis was not recognized more often was as pointed out by Rosenow, that the tonsillar involvement was very apt to precede the rheumatism by a number of days or even weeks. And as Rosenow said this was owing to the fact that time was required for the hemolytic streptococcus causing the tonsillitis to become converted into the rheumatic streptococcus. When at length this had been accomplished, this latter strain was taken up by leucocytes and carried directly into the blood. By this stream conveyed to the joints or to the capillaries of the valves they there set up the characteristic inflammation, and we saw the phenomena of articular rheumatism and endocarditis or in the case of a child only an endocarditis without joint involvement. In many cases he had discovered slight, but to his mind convincing, evidence of appendicial mischief and had attributed these stomach attacks to acute exacerbations of a chronic appendicitis. Generally the family physician or the parent had been unwilling to accept the diagnosis and the case had been allowed to go on. But in the following case an acute appendicitis was diagnosed by more than one physician though recourse to operation was not had. A young man whom he had seen in consultation some years before and who had aortic regurgitation developed a sharp attack of inflammatory rheumatism and reinvolvement of the already damaged valves was feared. Therefore, he was asked to see him in consultation with two other physicians. The tonsils were actively inflamed. Under treatment the case was progressing favorably when he developed unmistakable symptoms and signs of acute appendicitis for which a competent surgeon was called. Owing to the gravity of the cardiac condition no operation was thought advisable by the surgeon. After a time this as well as the other rheumatic symptoms abated and at his advice the tonsils were removed under ether. A year later this young man was driving his automobile and appeared in fine health excepting, of course, his aortic lesion. In the light of this specimen here exhibited we could understand the occurrence of the appendicitis in this case and should be in position to recognize such a complication or accompaniment in future cases of acute rheumatism or rheumatic heart disease. He considered the etiology of the endocarditis due to the *Streptococcus viridans*. This organism which Rosenow believed was a strain or modification of the pneumococcus, since by appropriate cultural methods he had transformed it into the pneumococcus, existed in the throat and was frequently found on diseased tonsils. It did not itself occasion tonsillitis, but found an unhealthy tonsil good soil for its growth. Consequently, it could be taken up by the leucocytes and carried into the blood stream to lodge in the capillaries of the heart valves in the same manner as were the germs of rheumatism. If the capillaries were fairly abundant, as in the young, the bacteria might be attacked by the phagocytes and destroyed before they had time to grow and multiply. But if the capillary supply to the valves was poor, as was the case with sclerotic valves from former endocarditis, then leucocytes could not get at and destroy the streptococci which, therefore, grew rapidly and produced massive vegetations as in the specimen presented and in the slides submitted for inspection. Two conditions were generally requisite therefore, a throat infection or an atrium of infection elsewhere, and a chronic valvular lesion. Of the latter it appeared to be aortic insufficiency, that was particularly liable to this form of ulcerative endocarditis. What now was the lesson to be drawn from these specimens and these cases? In the first place, we should take care of the throats of children by the removal of adenoids and the correction of any other defect that predisposed to throat infections. Never regard any sore throat or tonsillitis in the young as trifling and whenever a child displayed languor, slight fever, etc., examine the throat. In particular parents should be taught the danger of throat infections and the necessity of frequent inspection of the throat. Finally, in any person with valvular disease who had recurring sore throats or rheumatic pains strict attention should be paid to the care of the throat, and if the tonsils were diseased, even though not enlarged, they should be taken out, not merely clipped. Tonsillectomy skilfully performed under ether was less dangerous than was the risk of endocarditis of the deadly kind shown in this second specimen. He had had a considerable number of children and adults with valve lesions and bad tonsils subjected to this operation, and as yet had not seen unfortunate results in a single instance. We should not pass over recurring attacks of so-called indigestion with fever in a child with an endocardial lesion as merely a "stomach attack," but bear in mind the possibility of appendicitis in association with or as a result of rheumatic infection and tonsillitis and direct particular attention to the appendix. If convinced that it was responsible for these attacks of digestive and febrile disturbances, have it removed, if possible. A chronically infected appendix might serve as the atrium of infection for this terrible foe to patients with valvular disease, the *Streptococcus viridans*.

Dr. Willard J. Stone of Toledo, Ohio, discussed the clinical significance of diastolic pressure variations, with especial reference to hypertension and cardiac overload.

Functional Testing of the Cardiac Power.—Dr. Charles Spencer Williamson of Chicago drew these conclusions: (1) "In diseases of the cardio-vascular apparatus, the examination of the quietly resting patient gives us no clew as to the functional efficiency of his heart, except there be present manifest signs of cardiac insufficiency. (2) In the present state of our knowledge, the most satisfactory method of arriving at a knowledge of the functional efficiency of the heart, is by subjecting the patient to exercise tests, and in a doubtful case no diagnosis should be regarded as complete without such tests. (3) None of the methods which have been as yet devised, and which depend on variations in pulse, rate and blood pressure, are free from considerable sources of error, and none of them can be regarded as furnishing a numerical estimate of the cardiac strength. (4) In spite of the inadequacies and inaccuracies of these various methods, it is possible for the purposes of practice, to obtain a very accurate estimate of the functional heart power by submitting the patient to an accurately measured, but familiar exercise, such as climbing a certain number of steps, and by observation of the pulse, respiration and blood pressure, together with the quickness of the return of these to the normal. The severity of these exercises should be strictly individualized, and in every case, adjusted to the patient's general muscular development and condition. (5) For more scientific work, the only method which is capable of giving numerical results is that of obtaining the size of the heart before and after exercise, as deter-

mined by the orthodiagraphic method or some of its modifications."

Thrombosis and Embolism.—Dr. Walter L. Bierring of Des Moines, Iowa, described a series of unusual circulatory accidents occuring in acute infections.

Case I. Gangrenous appendicitis, mesenteric thrombophlebitis, pyelophlebitis of the liver, acute endocarditis, simultaneous embolism of the left middle cerebral and left axillary artery.

Case II. Suppurative cervical lymphadenitis, operative trauma left facial artery, embolism left middle cerebral artery, right hemiplegia.

Case III. Exophthalmic goitre, acute influenza, chronic infectious endocarditis, embolism with occluding thrombus of right posterior and anterior tibial artery with resulting ischemic gangrene of right leg.

Case IV. Male, 39 years of age, acute tonsillitis, thrombosis of left posterior tibial artery; ischemic gangrene of left foot and leg; embolism of right middle cerebral artery; (partial) left hemiplegia; exitus.

Case V. Male, 57 years of age. Acute follicular tonsillitis, cervical lymphadenitis, femoral thrombophlebitis, local abscess formation, general fatal septicemia.

Case. VI. Male, 21 years of age, acute tonsillitis, bacteriemia, acute parenchymatous nephritis, edema, uremia, thrombosis of the right internal jugular vein and right cavernous sinus.

Case VII. Young girl, aged 17 years. Acute pleurisy, central pneumonia, thrombophlebitis of right and left jugular veins, acute right and left cavernitis. Duration of illness four days.

In this series of circulatory accidents, the acute infectious process in four instances was an acute tonsillitis, and one example of acute pleurisy and pneumonia, influenza (lymphadenitis), and appendicitis. As regard localization, the posterior tibial artery was involved in two cases, the middle cerebral three times, the axillary artery once, one example of femoral thrombophlebitis and two of cerebral sinus thrombosis. In two cases multiple embolism occurred in the same patient. In summarizing this series of cases, which were all instances of acute infection accompanied by general bacteriemia or septicemia, tonsillitis, and apparently acute infection of the upper air passage, played a prominent role. This gave to acute tonsillar infection an importance that might not have been recognized heretofore, and supported the conception that it was an expression of general septicemia, and most of all emphasized the need of rest as the main essential in its treatment.

Dr. James Birney Guthrie of New Orleans said that for a number of years he had been an exponent of the light percussion method of outlining the borders of the heart. On one occasion, after having carefully outlined the heart of a patient in bed who was suffering with a marked degree of cardiac insufficiency, and having drawn on the chest wall a projection diagram, he was interrupted for a few minutes, and then he returned and repeated the procedure. To his surprise he found that the outline had changed, and that the right heart border was pushed out 2 cm. Investigation as to the cause of this phenomenon showed that the patient had coughed rather violently in the interval, and in so doing had dilated the heart. This patient he regarded then as a most interesting and unusual case of heart weakness. A number of his colleagues were brought in to see this case and concurred with him as to the existence of cough-dilatation. The dilatation reached its maximum after three cough efforts and in this particular case lasted five minutes during which time there was a gradual return of the original outline. For some time he believed that this case and similar ones which he found subsequently were extreme cases of cardiac weakness. He discovered them in a colored service made up largely of cardiorenal cases. This view, in the light of subsequent work, he no longer held, but had come to look upon the procedure of outlining the heart by percussion or X-ray before and after cough timing the return to the original size of the outline, as a most valuable index of the integrity of the heart muscle. The healthy heart dilated on coughing to a degree perceptible during X-ray examination, but not appreciably by percussion. The time factor was quite as important as the measurement of the outward displacement of the right heart border. The graver the heart weakness, the longer the dilatation lasted. The longest cough-dilatation time observed so far had been fifteen minutes and the shortest five seconds. This statement was based on careful examination of over one hundred cases. It was probable that this range of cough-dilatation time would be extended on further observation.

Dr. Albert E. Sterne of Indianapolis reported a case of chorea, arthritis, and endocarditis in a girl whom he saw in consultation. A month or so before he saw her she had fallen down stairs and cut her forehead on the base-plate of a stove. The injury seemed trivial. The attending physician cleansed it but the wound did not heal, and in spite of every measure at the hands of an excellent surgeon the wound kept suppurating. She developed in the course of the second week after the injury polyarthritis. In the course of a few days, after the joint invasion, she developed a profound and severe form of chorea of the ordinary type, at which time he saw her in counsel with her physician and the surgeon who had attended her. These cases usually developed severe infectious endocarditis, and in this case, in the course of a few days the endocardial lesion occurred. At the time of his first visit the heart sounds were perfectly normal. Under careful treatment this child seemingly did very well, but she did not regain her strength; the joint condition practically disappeared, the chorea subsided and the heart murmurs lessened, but did not entirely disappear. In about four weeks after the time the heart lesion first manifested itself the joints again became inflamed; the chorea again became severe; the heart sounds again became indistinct and the child died of all the symptoms characteristic of thrombosis and embolism of the several sinuses.

Dr. T. J. Halsey of New Orleans asked Dr. Stone whether he had made an attempt to correlate the diastolic and systolic findings on blood pressure. The pulse rapidity might have an enormous influence on the diastolic pressure from the fact that with the more rapid time we had a shorter diastole and a slighter and shorter interval in which blood pressure had fallen.

Dr. F. M. Pottenger of Monrovia, California, said that in considering the tonsil as a port of entry or a culture medium and in advising the removal of tonsils he had sometimes wondered whether or not in removing them we were not taking away a source of protection to the patient. He had had the tonsils of his own children removed, but at the same time he felt probably we were doing wrong in taking the attitude we did toward the tonsil as a whole.

Dr. Walter L. Bierring of Des Moines, Iowa, said it was a matter of great interest to note how the clinical experience of such an extensive clinical observer corroborated the work of Rosenow. It was still more interesting to recognize the fact which Dr. Babcock had been emphasizing for years, namely, that the relationship existing between focal infection, particularly of the biliary or intestinal tract and its influence upon the heart muscle and upon diseases of the endocardium, was being corroborated by the work of Rosenow. In this etiologic unity which Dr. Rosenow had established between various offsprings of the pneumococcus, he had illustrated how acute infection of the tonsils, the endocardium and the appendix were all the same. He had gone still further and by modifying the organisms had produced experimentally cholecystitis with the same organism, and in another dog had produced typical round ulcer of the stomach.

Dr. Willard J. Stone of Toledo, Ohio, said regarding the pulse rate, the systole and diastole and pulse pressure had been taken with the patient at rest as far as possible. He thought the only condition in which we were apt to have increased heart rate, so far as it effected a difference in pressure, would be in connection with shock or hemorrhage. It was perfectly apparent that in estimating the systolic or diastolic pressure we failed to consider the venous pressure.

Dr. Babcock said in answer to Dr. Pottenger's question, we were not justified in recommending the removal of healthy tonsils whatever their exact function might be, but when a tonsil was no longer healthy, when it was diseased, he believed to safeguard the patient the tonsils should be enucleated.

The Possibility of Differentiating Between Active and Quiescent and Healed Tuberculosis by the Character of the Reaction to the Cutaneous Tuberculin Test.—Dr. F. M. Pottenger of Monrovia, California, pointed out that a positive clinical history, suspicious signs within the chest, and a maximum reaction to tuberculin within the first twenty-four hours, gave grounds for making a diagnosis of active tuberculosis. With a questionable clinical history, questionable signs on physical examination, a reaction to tuberculin reaching its maximum after twenty-four, or particularly thirty-six hours, he believed we were safe in saying that we were dealing with a partially quiescent lesion.

Miscellany.

Needed Financial Basis for the Medical Profession.—According to statistics, there are now practising in the United States and Canada about 150,000 physicians. In that territory there are between 3,000,000 and 4,000,000 people constantly ill, and unnumbered millions on the border-line of illness. Eugene Lyman Fisk, Medical Director, Postal Life Insurance Company, thinks that overcrowded as the profession is supposed to be, it is questionable whether the supply of competent physicians would exceed the demand if these sick people turned for relief to the men trained to do the work, instead of relying on almanacs, cookbooks, soothsayers, or any other mysterious medium of relief, except the doctor, until they finally appear at his door demanding that he instantly restore their diseased tissues and organs to normal condition. Assuming that preventive medicine continues to reduce this morbidity, the balancing factors derived from closer contact with the public may result in improving the economic condition of the physician. The average physician goes about his work unmindful of these remote possibilities, happy if he can in any way lessen the suffering in his community. It is, however, the physician's duty to take thought of all proper ways by which his profession may be placed upon a financial footing that will enable it to render the most efficient public service. Is it not important that the scientific men to whom are committed the health and lives of families be placed upon an economic basis at least equal to that of a skilled mechanic? An underpaid and oftentimes never paid "last resort" medical profession is not in line with public welfare. There should be, however, no yielding to the commercial spirit of the age.—*Lancet-Clinic.*

Medicine and the Pulpit.—W. Sampson Handley points out that there are many men who, like St. Luke, have abandoned medicine for the ministry. An eminent example is Canon Arnott, now, and for the past twenty-eight years, rector of Beckenham, who is a Fellow of the Royal College of Surgeons, a distinguished pathologist, and the author of a work on cancer. In entering the ministry of the Church he realized a youthful ambition, deflected for a time to medicine by parental wishes. He rigidly abstains from any exercise of his old craft of surgery, whether by way of advice or practice, and this appears to be the safe general rule of those who leave the profession. His busy life in a large parish with four churches has left him little time to keep up his old and still vivid pathological interests. But he admits that while medicine has no direct value in his present field of work, the old scientific training, the long hours spent in microscopic work, the power of sympathy with suffering, the realization of the inexhaustible study and experience needed for anything like dogmatism in the ways and by-ways of nature, the humility necessary before the baffling problems of life and disease and death—all this is of incalculable value in his present profession. He speaks, too, of the knowledge of men and affairs which medicine gives, and of the intimate acquaintance with the seamy side of life to be gained perhaps better in a hospital surgical out-patient practice than anywhere else in the world. Such is Canon Arnott's personal estimate of medicine as a liberal education.—*Lancet*, October 4, 1913.

SURGICAL TREATMENT OF DIFFUSE SUPPURATIVE LABYRINTHITIS.*

By PHILIP D. KERRISON, M.D.,

NEW YORK.

PROFESSOR OF OTOLOGY, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

The main facts and established theories of labyrinthine physiology are now so generally known and accepted as no longer to require argument. When, however, we come to a consideration of clinical problems and particularly of the vexed question of surgical treatment, we find our discussions bristling with opposing statements, and that many problems await solution. If this statement seems exaggerated, we have only to ask ourselves the following questions:

1. Shall we operate in the acute stage of suppurative labyrinthitis? and, if so, upon what indications?

2. Shall the clinical evidences of latent suppurative labyrinthitis be regarded *per se* as an indication for operating upon the labyrinth?

3. Are there cases of chronic, or latent, suppurative labyrinthitis in which the radical operation for chronic middle suppuration, without draining the labyrinth, may be admissible.

4. What shall be regarded as a complete or adequate operation in the majority of cases of diffuse suppurative labyrinthitis?—*i.e.* what mechanical result shall be regarded as the surgical end in view?

5. Which of the classical operations subjects the patient to a minimum of risk while securing to him the best chances of recovery?

Apparently, the questions which interest us today are those of differential diagnosis, treatment, the correct interpretation of surgical conditions, etc., rather than of theory. I shall try, therefore, to limit my discussion strictly to certain practical surgical questions which all of us are obliged to consider in connection with the cases coming under our care.

Before taking up the question of surgical treatment, it may be well to recall briefly certain facts bearing upon the gravity of the lesion:

According to Hinsberg,[1] one in every 100 cases of middle-ear suppuration leads to suppurative invasion of the labyrinth. According to the earlier investigations of von Stein,[2] the percentage of cases leading to labyrinthine infection is even greater: *i.e.* about 2.2 per cent. All competent observers agree that suppurative labyrinthitis results far more frequently from the chronic than from the acute forms of suppurative otitis media; and not a few have believed that labyrinthine infection as a result of acute purulent otitis media is a rather remote possibility. In opposition to the latter view, Habermann[3] has maintained that suppurative labyrinthitis is a not very infrequent complication of acute suppurative otitis media. This view has had the support of the later investigations of W. Brock[4] of the University Clinic of Erlangen. Brock has collected from the literature thirty cases, and added thereto four cases coming under his own observation in which the labyrinth became infected during the course of an acute purulent otitis media. To these thirty-four cases the writer can add at least one case from his own practice in which a destructive type of diffuse suppurative labyrinthitis occurred as an early complication of an acute suppurative otitis media.

As throwing some light upon the relation of the mode of infection to the subsequent course of the disease, one should bear in mind the small but instructive series of cases recorded by Jansen[5] in 1908, in which labyrinthine infection was the immediate result and sequence of accidental injury to the stapes during the radical and other tympanic operations. These cases taught an impressive lesson in the high mortality rate, nine out of nineteen having ended fatally. While the cases of labyrinth infection due to stapedial injury collected from other sources (*e.g.* Hinsberg's collected series) have not given so large a mortality, the accident is rightly to be regarded as one very seriously jeopardizing the patient's life. The writer personally knows of two cases in which the annular ligament of the stapes was torn during the radical operation. In each case the patient developed suppurative labyrinthitis and died within a week of diffuse leptomeningitis.

An interesting fact brought out in Brock's analysis of cases relates to the pathway of infection in cases of labyrinthitis complicating acute suppurative otitis media. Of thirty-one cases investigated, in twelve infection took place directly through the oval window; in thirteen, by other routes, the stapedial foot-plate and ligament remaining intact, while in six the exact mode of invasion remained in doubt. According to these figures, so far as the path of infection could be determined, the oval window provides the point of attack in nearly 50 per cent. of cases complicating acute purulent otitis media—a percentage certainly far greater than in cases secondary to chronic middle-ear suppuration. This is an important fact which will be referred to later as having a direct bearing upon the surgical indications in certain cases.

Sifting a little further the facts at our disposal, we know that of cases of labyrinth infection due to surgical injuries of the labyrinthine capsule, those due to dislocation of the stapes or rupture of its annular ligament are far more dangerous to life than are those caused by accidental opening of one of the semicircular canals—*e.g.* the horizontal. In

*Read by invitation before the Clinical Congress of Surgeons of North America, Chicago, November 14, 1913.

cases of suppurative labyrinthitis secondary to chronic middle-ear suppuration, the path of infection in the great majority of cases is not through the labyrinthine windows but through a tract involving the horizontal canal or passing from the infected antrum or mastoid cells indirectly through the petrous bone. In cases of labyrinthitis complicating acute middle-ear suppuration, on the other hand, the oval window, according to Brock, is the point of actual invasion in nearly 50 per cent. of cases. This conclusion rests not only upon his careful analysis of conditions observed post mortem, but also seems the logical sequence in acute middle-ear lesions where the tympanum houses the chief focus of infection and in which the denser parts of the labyrinthine capsule would hardly have time to undergo necrosis. Reasoning now by analogy with the recognized gravity of surgical injuries to the stapes or its annular ligament, it seems a reasonable deduction that those cases of labyrinthine infection complicating acute suppurative otitis media and reaching the vestibule through the oval window will be found to furnish a particularly high percentage of fatalities.

Indications for Labyrinth Operation.—As to the indications for operating, there is no field of surgery in which dogmatism is so unwarranted as in the case of the infected labyrinth. The question of operating in any case depends so largely upon the surgeon's interpretation of symptoms that it is difficult to formulate any rules that may not lead to serious error. There are, however, certain conditions which in themselves constitute so grave a menace to the patient's life or his comfort in living as to constitute a more or less definite call for surgical intervention. Among such may be mentioned the following:

(1) Labyrinthine infection following quickly upon surgical injury of the stapes. I have personally known of two cases in which this accident has been followed almost immediately by symptoms of diffuse labyrinthitis, this in turn giving rise to a remarkably rapid and fatal leptomeningitis. The labyrinth was not operated upon in either case. To be of any value in such a case, surgical intervention must be prompt—*i.e.* before meningeal infection shall have had time to take place.

(2) Suppurative labyrinthitis complicating acute purulent otitis media, and accompanied by high fever, rapid pulse, headache, etc. It is obvious that this condition may be pathologically analogous to those resulting from stapedial injury. Unless the fever, headache, and pulse rate show very early and progressive tendency to subside, prompt drainage of the vestibule would seem to be called for.

(3) The acute stage of a suppurative lesion of the labyrinth being passed, the evidences of a latent suppurative labyrinthitis plus symptoms of chronic middle-ear suppuration calling for relief, would in my opinion constitute a fairly definite indication for an operation on the labyrinth.

(4) Physical evidences, found during the radical operation, of intravestibular suppuration, as shown by pus escaping, or granulations protruding, from the oval window or from a defect (fistula) in the promontory, or the presence of a fistula leading to the vestibule through the horizontal canal—such findings would naturally leave no question as to the necessity of surgical intervention.

As having an important bearing upon the indications for operating and upon the prognosis in cases operated upon, I wish to say a word as to the most favorable stage of a suppurative labyrinthitis for opening the vestibule. There can be no question that the latent stage of the disease is the period in which the vestibule may be opened with least risk. Nearly all the deaths following a labyrinthine operation which have come within the range of my personal knowledge have occurred in cases operated on during the acute stage. I have, myself, operated in a number of cases of diffuse suppurative labyrinthitis during the latent stage, all of which have made perfect recoveries. I believe that the uniformly favorable results in these cases were due very largely to the fact that I was able to postpone operation until the acute stage was well passed.

Anatomico-Surgical Features of the Labyrinthine Capsule.—Differentiating it from other parts of the temporal bone and from all other bones of the body, the labyrinthine capsule presents the following structural features:

(1) It is composed of peculiarly hard, dense bone. According to Gray of Glasgow,[6] its Haversian canals are smaller than are found in any other bones of the body. This extreme density of bone undoubtedly confers comparative protection from rapid suppurative attack from without. Intralabyrinthine infection having occurred, *e.g.* through the labyrinthine windows, it seems fair to assume that the same influence would oppose in some degree the early and rapid extension of the lesion through bone from within outward. This obviously adds to, rather than lessens, the gravity of intravestibular infection.

(2) Within the bony spaces of the labyrinth there is complete absence of the diploic tissue so liberally distributed throughout other parts of the temporal bone, and which forms so favorable a starting point for osseous necrosis. The provision of free drainage should therefore suffice to check the lesion in cases in which intracranial infection has not already occurred.

(3) The inner walls of the vestibule and of the labyrinthine spaces communicating therewith present, for the most part, smooth and even surfaces which should offer considerable resistance to the rapid spread of a suppurative process from the membranous labyrinth to its bony encasement.

It is clear that the anatomical conditions described above should be taken into account in any attempt to define the scope and limitations of labyrinthine surgery. In suppurative labyrinthitis is it our duty as in mastoid surgery to expose, investigate, and remove all structures possibly infected or likely to become diseased? Or is our task merely to provide adequate surgical drainage? Personally, I am convinced that in a majority of cases the provision of free drainage from the vestibule is all that is required and all that it is wise to attempt.

Division of All Cases of Acute Suppurative Labyrinthitis into Two General Groups.—According to clinical experience there is apparent justification for separating all cases of acute suppurative labyrinthitis into two general groups: 1. The first group includes (*a*) cases secondary to chronic middle-ear suppuration, and (*b*) those which develop as a late complication or sequela of a protracted attack of suppurative mastoiditis. A very large proportion of such cases pass uneventfully—*i.e.* without intracranial involvement—to the latest stage of suppurative labyrinthitis. 2. To the second group belong (*a*) cases of sudden labyrinthine infection due to a surgical injury to the stapes or its annular ligament, and (*b*) those coming on as an early complication of

acute purulent otitis media. Whether resulting directly from stapedial injury or as a rapid spread of infection from an acute middle-ear suppuration, the point of invasion is, in a large percentage of cases, the same—*i.e.* the oval window. In either case the pathways of infection to the meninges are comparatively open and unguarded, and the prognosis proportionately grave.

The practical significance of this classification must be clear; for if we may assume that the immediate risk to the patient's life of a labyrinthine lesion secondary to chronic middle-ear suppuration is of comparatively moderate degree, and tends to become less as the acute vestibular symptoms subside, then it becomes clear that the wisdom of early operation is open to question.

On the other hand, in cases of labyrinthine infection directly resulting from surgical injury to the stapes or developing as an early complication of an acute suppurative otitis media, the danger of leptomeningitis is far greater, and the need of early surgical intervention more clearly indicated.

The purposes of this paper do not call for descriptions of operative technique. It is of the greatest importance, however, that the surgeon should have a correct conception of the operative indications in the two classes of cases above outlined. While in both free drainage of the vestibule is the chief desideratum, the lesions are in many cases so widely separated, both in their local manifestations and in the risks to the patient's life, that it would be surprising if some variations in the method of treatment were not called for. I should like, therefore, to say a word as to the rationale of the operative treatment (1) of *latent*, and (2) of *acute* suppurative labyrinthitis.

Surgical Treatment of Latent Diffuse Suppurative Labyrinthitis.—Locally the latent stage of suppurative labyrinthitis invariably includes practical destruction of the membranous labyrinth, or at least destructive changes so advanced as to cause permanent loss of the vestibular function. Further than this, the lesion may vary considerably in the extent of damage to the bony capsule. In my own limited operative experience, the following changes have been observed: (1) Complete destruction of stapes with granulations protruding through a necrotic and enlarged oval window. (2) Destruction of stapes plus defect (fistula) in promontory. (3) Wide destruction of horizontal canal showing original path of vestibular infection. (4) In one case, a large portion of the bony capsule was separated as a sequestrum. (5) In another, no loss of continuity in the capsule was demonstrable, the bone being merely thickened and therefore giving an impression of unusual density. (Diagnosis in this case was made on past history of characteristic vestibular attack plus absolute loss both of vestibular and cochlear functions.)

Obviously some variation in operative technique may be called for by these variations in the extent and direction of necrotic tracts in the bony capsule. Thus with absence of involvement of the facial nerve and with a demonstrable but circumscribed tract of necrosis through the horizontal canal, or with the path of vestibular invasion not macroscopically demonstrable, the Hinsberg operation would seem to me the simplest, most direct, and therefore, perhaps, the safest operation. On the other hand, with widespread necrosis of the capsule, facial paresis or paralysis, and with granulations occupying the position of a necrotic facial ridge, I can conceive that the Neumann operation might provide the point of attack exposing the nerve to least risk of permanent injury.

The point I wish most particularly to emphasize, however, with regard to all cases of latent, or chronic, suppurative labyrinthitis is this: that the acute stage having passed without evidences of meningeal involvement, we may assume that the natural pathways of intracranial infection—*i.e.* the vestibular and cochlear aqueducts and the minute nerve channels leading from the labyrinth to the internal auditory canal—are to some extent safeguarded by inflammatory thickening of the membranous structures contained therein. In a word, the lesion at this stage describes a functionally dead membranous labyrinth confined within bony spaces temporarily walled off from the meninges, though surrounded by areas of osseous necrosis of variable extent. The operation calls, therefore, for very careful and thorough removal of all diseased bone from the osseous capsule, plus the provision of free drainage from the infected vestibule. Beyond this the safety of the patient demands the greatest care to avoid injury to the modiolus. Dr. Richards[7] of New York was the first to call attention to the danger of injuring this structure. If our purpose in operating is mainly to prevent intracranial infection, the modiolus should not be disturbed, for therein lie the innumerable foramina for the filaments of the cochlear nerve, the opening of which may determine a rapid spread of the infection to the meninges.

Surgical Treatment of Acute Suppurative Labyrinthitis.—Some five years ago, reports of cases of suppurative labyrinthitis operated upon during the acute stage were not uncommon. In addition to these were many cases operated upon but never reported. While a majority of them probably recovered, the number of fatalities was also impressive. Today the number of such reports is comparatively small. Otologists are happily coming to recognize the fact that in the great majority of cases *it is safer not to operate until all signs of vestibular irritation have completely disappeared.* To this general rule there are two possible exceptions, viz. (*a*) cases of labyrinthine infection directly following a surgical injury to the stapes, and (*b*) cases of suppurative labyrinthitis developing as an early complication of acute suppurative otitis media.

As a reason for placing such cases in a separate category we must bear in mind this fact, viz., that whether due to an injury to the stapedial ligament or to a sudden extension from an infected tympanum, the point of invasion is in a large proportion of cases the same, *i.e.* the oval window. In either case we would have to deal with the sudden infection of a previously healthy vestibule, or, in other words, with a possibly rapid accumulation of pus within a bone cavity from which the natural channels of intracranial communication are unguarded by previous inflammatory change.

Our problem is, therefore, whether we shall operate promptly in order to forestall meningeal infection or delay operation in the hope that the acute stage may pass without intracranial involvement. Undoubtedly, this happier sequence of events will occur in a certain proportion of cases. We must consider, however, that after meningeal inspection shall have taken place, the outcome, with or without operation, is usually death. I am inclined to believe, therefore, that in any large series of this particular class of cases early operation will result in a reduction of the percentage of mortality.

Operative intervention having been determined upon, we shall do well to bear in mind two facts, viz., (1) that, aside from the defect or lesion at the oval window, the bony capsule is usually not diseased, and (2) that we must enter a peculiarly unprotected field in which any unnecessary manipulations may actually conduce to meningeal infection. Reasonable operative speed and the reduction of the operation to the simplest possible technique are therefore important factors. Drainage of the vestibule is all that the condition calls for and all that should be attempted. When we have uncapped the vestibule above, and provided through drainage below by removal of the stapes and outer wall of the promontory, we have done all that is possible in preventing meningeal infection in these cases. Any extension of the operation beyond this is an error which may be paid for with the patient's life.

Fig. 1.—Radical operation, preliminary to operation upon labyrinth. a, Prominence of horizontal semicircular canal; b, diploic tissue above horizontal canal.

Labyrinthitis Complicated by Leptomeningitis.—There is admittedly still another class of cases requiring operation during the acute stage, viz., cases of acute suppurative labyrinthitis accompanied by evidences of meningeal infection so unmistakable and pronounced that surgical intervention becomes the last resort in an effort to save the patient's life. So far as I have been able to draw any conclusions from the cases coming under my observation or from the results recorded by others, such cases almost invariably represent an already established leptomeningitis. At least no such case has come to my knowledge in which a labyrinth operation has been the means of arresting the progress of the meningeal lesion. Such cases, with or without operation, almost invariably end fatally. They provide a field urgently calling for careful investigation and study.

Fig. 2.—Same bone, with diploic tissue above horizontal canal removed.

Fig. 3.—Same bone with horizontal semicircular canal opened

but they do not, in my opinion, properly fall within the scope of a paper dealing solely with the treatment of uncomplicated suppurative labyrinthitis.

The Operation.—Naturally the preliminary step to opening the labyrinth is the radical operation, the excavation being rather larger than in ordinary cases of chronic middle-ear suppuration. In most temporal bones—all, in fact, except the sclerotic or semi-sclerotic type—there is found just above the prominence of the horizontal canal a considerable mass of deploic tissue (Fig. 1). In preparation for opening the vestibule, this diploic tissue should be thoroughly removed. This is easily accomplished by any suitable curette and leaves a depression, or recess, of considerable depth, its height varying with variations in the level of the tegmen antri (Fig. 2). The outer part of the floor of this recess is formed by the hard, dense bone constituting the superior wall of the horizontal canal. We begin the actual work upon the labyrinth by scraping away this hard bony prominence from above downward until the fine, thread-like horizontal slit representing the open canal is seen (Fig. 3). To eliminate the danger of facial nerve injury, we should use only a very sharp instrument by which the bone may be scraped away without exerting a pressure which might fracture the delicate bridge of bone containing both the horizontal and facial canals. The writer has designed for this purpose a curette which holds its edge better than the ordinary spoon curette and which has seemed in his hands to facilitate the work in this field. The horizontal canal, opened in this way, presents an anterior expansion, or enlargement which represents its ampulla, or anterior vestibular opening. This occupies a position vertically above the oval window. Applying now the curette just behind the ampulla, and again using care not to exert pressure upon the facial bridge, the vestibule

Fig. 4.—Vestibule uncovered above; promontory removed below. Tympanic probe passed behind facial ridge and through opened vestibule.

is easily opened by scraping away the extremely thin layer of bone which remains of its superior wall.

The promontory is next in part removed by pressure of the same curette upon the small bridge of bone connecting the niches of the round and oval windows. Removal of the outer shell of the promontory *without curetting the cochlear spaces thus exposed* is usually as far as we should go. A small bent tympanic probe may be passed from the cochlear space upward behind the facial bridge and through the uncovered vestibule (Fig. 4), or vice versa. This provides perfect drainage and in a very large percentage of cases is all that the condition calls for.

The writer is of the opinion that the technique of the labyrinth operation as described by most writers is unnecessarily elaborated. While the technical difficulties are admittedly considerable, they can be reduced, and the patient's safety enhanced, by a careful search for the simplest and safest method of reaching the vestibule, and then by resolutely eliminating from the operation every surgical step which the condition does not actually call for.

Before closing my paper I would like to say a word in regard to what seems at the present moment to be a very much unsettled question—*i.e.* the question of operating upon the mastoid without opening the labyrinth in cases of chronic middle-ear suppuration complicated by latent suppurative labyrinthitis. When I was in Vienna five years ago, the school there had already formulated the rule that in no case of latent diffuse suppurative labyrinthitis should the radical operation be performed without at the same time draining the diseased labyrinth. In a lecture there at that time I heard the arguments in support of this theorem stated somewhat as follows: (1) That in a very considerable percentage of cases the presence of a latent focus of suppuration within the labyrinth would defeat the purposes of the operation, *i.e.* the discharge from the ear would not be permanently arrested; (2) that there were in some cases certain indefinite but recurring symptoms referable wholly to the morbid process within the labyrinth, which would not be relieved; and (3) that to perform a radical operation upon an individual suffering from latent diffuse suppurative labyrinthitis without at the same time draining the vestibule actually augments the danger of meningeal infection, and places his life at greater hazard. While these facts, if accepted, would constitute a logical basis for the rule in question, the rule itself does not seem to have gained universal acceptance in this country. It is claimed by some of my colleagues, for whose work I have the highest respect, that they have performed the radical operation without opening the labyrinth in a number of cases presenting the negative symptoms of latent suppurative labyrinthitis, and without untoward results, *i.e.* the patients have recovered and the wounds healed satisfactorily as in a case of uncomplicated middle-ear suppuration. Such experiences have naturally influenced them to call in question the value of a ruling which calls for so many seemingly needless explorations of the labyrinth.

To my mind this is an exceedingly important question in regard to which we should not indulge in hastily formed conclusions.

Let us consider for a moment a hypothetical case. Let us suppose a case of chronic middle-ear suppuration which while under our care and observation has undergone an unmistakable attack of diffuse suppurative labyrinthitis. Let us suppose further that all acute symptoms and evidences of vestibular irritation have completely disappeared leaving the involved ear absolutely deaf to all sounds and absolutely irresponsive to the caloric test. Should some condition now develop in mastoid or tympanum demanding surgical intervention, would any of us venture upon a radical operation without also draining the labyrinth? If I am right in believing that none of us in such a case would leave the labyrinth unopened, then it seems clear that we must still recognize the sound surgical principle underlying the dogma that in the actual presence of a suppurative process within the labyrinth no operation upon the mastoid is safe which does not provide surgical drainage of the labyrinth.

As to the successful results obtained without draining the labyrinth, it seems to me that the best educational value of such experiences will be developed if we are stimulated thereby to a careful restudy of the late clinical phenomena of latent suppurative labyrinthitis. In such an investigation questions which might well be made the subject of special research are: (1) Does a suppurative focus within the labyrinth, though quiescent, remain for all time a menace of intracranial infection? (2) Does a latent suppurative process within the labyrinth tend in any degree to be self-limited? and (3), if so, is there a time limit, after which we may operate with comparative safety without opening the labyrinth? (4) Finally: In chronic middle-ear suppuration is absolute functional inactivity of the labyrinth a reliable indication of labyrinthine infection? Until time and the patient sifting of further evidence shall have shed their light on these questions, we shall do well to think twice before we permit our sanction of new theories which may later be proved at the cost of human life to have been founded upon error.

In passing, I wish to propose for your future consideration this somewhat pertinent question: In a case of chronic middle-ear suppuration, showing absolute loss of both cochlear and vestibular functions, does the opening of the labyrinth add materially to the risks of the radical operation? In skillful hands, I personally do not believe that it does.

In conclusion I would like to refer briefly to four surgical cases which seem to have some bearing on the subject under discussion.

Case I.—For the privilege of citing this case I am indebted to Dr. John D. Richards of New York. The patient, a woman, had suffered from chronic middle-ear suppuration of many years' standing. The radical operation was performed for the usual purpose, *i.e.* of terminating a suppurative process and bring about cessation of discharge. In spite of personal postoperative care, the discharge was not controlled and satisfactory, or at least complete, epidermization could not be obtained. Dr. Richards, than whom I know of no keener observer of macroscopic bone changes, assures me that there was nothing in the appearance of the bony capsule of the labyrinth, as seen during the operation or afterward through the canal, to indicate labyrinthine necrosis. Ultimately, in order to correct a condition for which no other cause could be assigned, the labyrinth was investigated. The vestibule was found to be filled with pus, and as soon as the outer shell of the promontory was removed, areas of necrosis in the bony labyrinth became apparent.

Such a history permits two deductions, viz., (1) that so far as this particular case was concerned, draining the labyrinth at the first operation would have been the safer procedure, and (2) that had complete epidermization been possible and have taken place, the danger of intracranial infection would have been enormously increased.

Case II.—This case occurred in the hospital practice of Dr. A. B. Duel of New York. The patient, a woman, presented the usual physical signs of long-standing suppuration of the right middle-ear, plus the characteristic symptoms of a latent suppurative process within the labyrinth. During the radical operation careful search was made for a labyrinthine fistula or other signs of necrosis of the labyrinthine capsule. No physical evidence of such a defect being demonstrable, the labyrinth was not opened and the radical operation was completed in the usual way.

After several months of careful postoperative treatment, the wound remained unhealed. She was, therefore, subjected to a secondary operation, at which the wound was laid open and all visible areas of diseased or questionable bone were removed. Following this second operation, exactly the same sequence of events occurred. Complete healing could not be brought about. Finally, to terminate this trying condition, it was decided to open and investigate the labyrinth. The vestibule was found to contain pus.

I have had an opportunity of examining this patient within the past ten days, and her ear is dry and apparently healed.

The two cases above cited would seem effectually to dispose of the thory that a suppurative lesion of the labyrinth may always be detected during the radical operation through macroscopic evidences of necrosis in the labyrinth capsule.

Case III.—This case was reported by Dr. Wendell Philips before the January meeting, 1913, of the otological section of the New York Academy of Medicine. The patient was a sufferer from unilateral chronic middle-ear suppuration of long standing. In addition there were evidences of latent diffuse suppurative labyrinthitis, the ear being absolutely deaf and caloric reactions being completely absent. For the relief of this condition, it was determined to try the effect of a radical operation without disturbing the labyrinth. Following closely upon the operation, the patient developed a leptomeningitis from which he died.

Case IV.—This case, which has already been reported in full, refers to a man of sixty, who came under my care in 1909, suffering from chronic middle-ear suppuration of the right ear, dating from childhood. While no history of an acute labyrinthine attack could be obtained, it was assumed that at some time in his life he had suffered such an attack, since his right ear was totally deaf to all sounds and the caloric reactions were absolutely wanting. The necessity for operation was found in the presence of both pain and tenderness over the right mastoid. Arguing that the invasion of the labyrinth had probably occurred many years previously and that the labyrinthine lesion had very possibly undergone spontaneous resolution, I decided to do a radical operation and open the labyrinth only if macroscopic evidences of necrosis (fistula) were present. No such obvious defect was found, and the radical operation was completed in the usual way. The patient left the hospital on June 7, with instructions to return regularly to the clinic for postoperative treatment. From that time until I went away on my vacation, the ear continued to discharge, and the patient complained at times of indefinite pain and discomfort in the right ear. Late in September of the same year, during my absence from the city, the patient was readmitted to the hospital complaining of severe head pains. A secondary operation by a hospital colleague did not relieve the condition, the patient dying suddenly on September 30. Autopsy revealed a cerebellar abscess of the size of a hazel nut and surrounding purulent leptomeningitis. In searching for the path of infection the labyrinth was opened and found filled with pus.

To my mind the death of this patient was due to my error of judgment in not opening and draining the functionally dead labyrinth at the time of the radical operation. In partial excuse may be mentioned the fact that he came under my care more than four and a half years ago when our interpretation of labyrinthine phenomena rested upon a thinner ground-work of knowledge than to-day. Until I learn of some method by which, in a functionally dead labyrinth, the presence of a quiescent but potential focus of infection can be definitely excluded, it is an error which I shall not repeat.

RADIUM AND ROENTGEN THERAPY IN CANCER.*

By ISAAC LEVIN, M.D.,

NEW YORK.

CHIEF OF THE DEPARTMENT OF CANCER RESEARCH OF THE MONTEFIORE HOME. ASSOCIATE IN CANCER RESEARCH COLUMBIA UNIVERSITY.

The treatment of malignant tumors with radium, mesothorium, and Roentgen rays presents undoubtedly a most potent addition to our none too rich store of methods for combating the disease.

Is radium or Roentgen therapy a true *cancer cure* as the term is understood by a lay reader of a newspaper article? The best answer to such a query will be an analogy drawn from another chapter of modern therapeutics. The subject is chemotherapy of trypanosomiasis and spirillosis and more particularly the treatment of syphillis with salvarsan.

The discovery of salvarsan by Ehrlich is certainly the greatest achievement in therapeutics of our time. The therapeutics in syphilis presents a much simpler problem than in cancer, since the former is a parasitic disease, in which the nature of the parasite as well as the correct methods of diagnosis are well established. Salvarsan, when introduced into the circulation of the patient, kills the *Spirochetæ pallidæ* without injuring the normal tissues of the organism of the host. Should the salvarsan treatment be instituted during the first couple of weeks after the appearance of the initial lesion, when the Wassermann reaction is still negative and the disease is localized, one or two injections of the drug may destroy all the parasites and actually cure the patient. In these cases salvarsan acts as a true *therapia magna sterilisans* as postulated by Ehrlich for a specific chemotherapeutic agent. But in practice such a result is obtained only in a small number of cases. If the spirochetes entered the circulation before the treatment was instituted then a small number of the parasites escape the action of the salvarsan. This most usually happens with the spirochetes which enter the central nervous system, where salvarsan is apparently unable to reach the parasites. The few remaining spirochetes multiply and form, as Ehrlich has shown, a new strain of parasites which resist the sterilizing action of the drug. The disease not only relapses, but may become refractory to the action of salvarsan, and one must then resort to the old methods of treatment of the disease. Moreover, in the later stages of the disease there develop severe lesions in vital organs as, for instance, the nervous system. The treatment with salvarsan instituted at this period of the disease may result in the destruction of all the parasites circulating in the organism of the patient and still the lesions of the various organs remain uninfluenced. It is clear

*Read at the meeting of the Section of Medicine of the New York Academy of Medicine, October 21, 1913.

then that salvarsan is a true specific therapeutic measure against syphilis, but it is not a *syphilis cure, i.e.* it is unable to cure definitely every case subjected to its influence.

The difficulties of effecting a cure with even a specific remedy in parasitic diseases are enhanced in the case of cancer. All the clinical manifestations of a malignant tumor are due to the unlimited proliferation of the cancer cells in the region of the primary tumor or in the local recurrences and to the transport and subsequent proliferation of the cancer cells in distant parts of the organism in the case of metastatic tumors. This view holds good whether we adhere to or deny the parasitic theory for the explanation of the pathogenesis of the original transformation of a normal cell into a cancerous one. Consequently, a specific therapeutic agent in cancer must attack the cancer cells without injuring the adjacent normal cells of the organism. On the other hand, while the true etiology of cancer is still unknown, it is quite evident that the disease begins as a local condition. All the recurrences of metastatic tumors are caused by the proliferation of the cells transported from the original tumor. This interpretation of the mechanism of the disease must be borne in mind in the study of therapeutics of cancer.

In order to appreciate the similarity between the action of a chemotherapeutic agent like salvarsan and the rays of radium or a Roentgen tube a brief explanation of the psysics of the rays is indispensable. The discovery by Henry Becquerel in 1896 of radioactive substances, which closely followed the discovery of .r-rays by Roentgen in 1895, radically changed our conceptions of the properties of matter and energy, and of the laws of chemistry and physics. Until then pure elements were considered to be inert matter the constitution of which could not be changed by any known physical or chemical agent. An atom of pure element was supposed to be indivisible. The radioactive substances (radium, mesothorium, and others) present a group of pure elements (metals), which constantly and spontaneously, without the aid of outside energy of any known kind, disintegrate and throw off new atomic elements and at the same time retain their original chemical structure. In the case of radium such disintegration may continue for hundreds of years without diminishing perceptibly the quantity of metal. It takes nearly 2000 years for a milligram of radium to lose half of its strength. This disaggregation, or *radioactivity*, as it is called, manifests itself by the emission of invisible rays. These radiations are capable of passing through plates of metal and other substances opaque to ordinary rays of light; they further act on a photographic plate in a manner similar to Roentgen rays and ionize the air, *i.e.* they transform the air in a good conductor of electricity, and what is most important for the present discussion, they influence in a certain characteristic manner the cells of plant and animal tissues, which they penetrate.

The radioactive substances emit different types of radiations, which can be distinguished by the following two methods. By observing whether the rays are deflected in a magnetic field and by comparing the relative absorption of the rays by solids and gases. Examined in these ways it has been found that there are three distinct types of radiation emitted from radioactive bodies, which have been termed by E. Rutherford α, β, and γ-rays. The α-rays have very little capacity for penetration, and are readily absorbed by thin metal foil or by a few centimeters of air. These rays represent particles of matter charged with positive electricity the size of an atom of hydrogen, which are thrown off by the radioactive substance with an initial velocity which is equal to about one-fifteenth the velocity

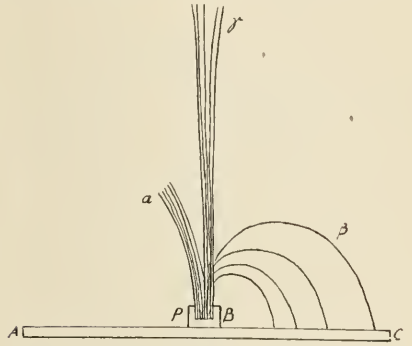

Fig. 1.—Showing the deflection of the α and β-rays by a magnet.

of light. When its motion ceases, *i.e.* the energy transmitted to it by the atom of radium at the moment of expulsion is exhausted, it is transformed into an atom of inert matter called *helium*, which is a new element. When these rays are brought in contact with the skin they produce superficial burns.

The β-rays are on an average far more penetrating in character than the α-rays, and consist of particles of matter charged with negative electricity. The particles represented by β-rays are 2000 times smaller than the hydrogen atom, and are thrown off by the radioactive substance with velocities equal to the velocity of light.

The γ-rays are extremely penetrating—more so than the most penetrating β-rays—and are not deviable by a magnetic field. Their true nature is not yet definitely settled. The majority of physicists consider them to be waves of ether similar to light or electricity, but some investigators are of the opinion that the γ-rays also consist of minute particles of matter. Fig. 1 illustrates the effect of a magnetic field on a pencil of rays from a radioactive substance giving out the three kinds of rays. Some radium is placed in the bottom of a narrow cylindrical lead vessel R. A narrow pencil of rays consisting of α, β, and γ-rays escapes from the opening. If a strong uniform magnetic field is applied at right angles to the plane of the paper and directed toward the paper the three types of rays are separated from one another. The γ-rays continue in a straight line without any deviation. The β-rays are deflected to the right, describing circular orbits the radii of which vary within wide limits. If the photographic plate AC is placed under the radium vessel the β-rays produce a diffuse photographic impression on the right of the vessel R. The α-rays are bent in the direction opposite to that of the β-rays, and describe a portion of the arc of a circle of large radius, but they are rapidly absorbed after traversing a distance of a few centimeters from the vessel R.

The rays emitted from the radioactive substances present a very close analogy with the rays which are produced in a highly exhausted vacuum tube when an electric discharge passes through it. The .r-rays are analogous to the so-called channel

rays, which have been shown to consist of positively charged particles of matter projected with great velocity. The β-rays are the same as the cathode rays, while the γ-rays resemble the Roentgen rays. In a vacuum tube (*x*-ray tube) a large amount of electric energy is expended in

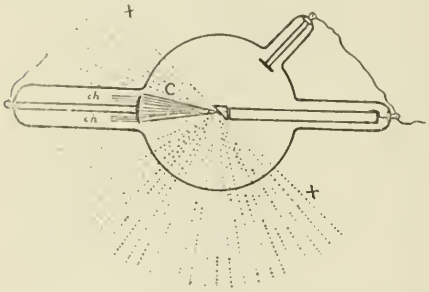

Fig. 2.—Ch = Channel rays; C = Cathode rays; X = Roentgen rays.

producing the rays, but in the radioactive substances, as stated above, the rays are emitted spontaneously and at a rate uninfluenced by any known chemical or physical agency. The α and β-rays from the active bodies are projected with much greater velocity than the corresponding rays in a vacuum tube, while the γ-rays are of much greater penetrating power than Roentgen rays. Fig. 2 illustrates the relationship of the different rays in the *x*-ray tube, and Fig. 3 shows graphically the difference in the penetrating power of the different rays of radioactive substances and of the Roentgen tube. We see that the γ-rays are the most penetrating, and consequently the radioactive substances are superior in their action to the Roentgen rays. Moreover, the source of the γ-rays of a radioactive substance can be placed nearer the effective area than the source of the *x*-rays. On the other hand, the γ-rays of radium and mesothorium are identical in their qualities and penetrating powers, consequently there is no difference in the action of the two metals.

The sharp dividing line which was thought to exist between the action of chemical and physical agents begins to disappear. Many biological phenomena in animal life, which were thought to be chemical in nature, are explained to-day on the basis of physical properties of organic substances (viscosity, surface tension, etc.). Apparently both

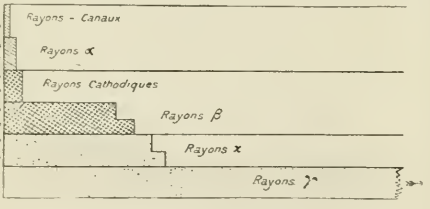

Fig. 3.—Showing the different degrees of penetration of the various rays.

radium and Roentgen rays are minute particles of matter suspended in the air in the same manner as particles of salvarsan are suspended in the fluid. It is easy to demonstrate that the rays can penetrate through the whole body of an organism. If a radium or Roentgen tube is placed on one surface of the body, and a fluoroscope screen on the other, the latter will become fluorescent. The physicists observed very early in their experimentation with radioactive substances that they produced burns and ulcerations on the hands of the investigators. It was therefore self-evident that the rays must produce a certain biological effect on plant and animal cells. A great deal of experimental and clinical work was done on the subject, and a general conclusion can be drawn as a result of it that the different cells and tissues of the organism react differently to the rays. For instance, the liver cells are more susceptible to the rays than the gall duct cells, and the tubules of the kidney react stronger than the glomeruli. The liver as a whole is more susceptible than the kidney. The pancreas is still less susceptible. The most resistant tissues are the connective tissue and the muscles. Highly interesting and of practical importance is the action of the rays on the testicle and the ovaries. The rays affect the spermatozoa—forming epithelium, and the Graafian follicles; azoospermia may occur in a man and a cessation of menstruation in a woman without any other lesion in the organism. This highly selective action of the rays has its limitations, and if a sufficiently large quantity of the rays is used every cell in the organism may be destroyed. The large percentage of rays are the α and soft β-rays. Since they have a small penetrating power, they are all absorbed by the superficial layers of the skin, and there injure every cell they meet, acting as an ordinary caustic. On the other hand, the γ-rays represent only a small fraction of the whole radiation, and penetrate very far, consequently the rays are greatly diluted, each cell absorbs comparatively little of the rays, and the selective action becomes very apparent.

Old and highly differentiated cells are more resistant to the action of the rays, while the young embryonic cells, and cells in a state of active proliferation, are very susceptible. It is therefore clear *à priori* that the rays must exert a selective influence on cancer cells.

Indeed, radium and Roentgen rays were employed in the treatment of cancer nearly since the time the rays were discovered. The first attempts failed and the action of the rays did not seem to differ from the action of any other caustic. Dominici, Wickham, and Degrais in France showed recently that the failures were due to faulty methods employed by the investigators. The quantity of radium used was so small that the γ-rays had no effect at all, and the soft rays acted as a caustic. Their new method consists in employing large quantities of the radioactive substances and applying them for a much longer period of time. The other very important addition to their technique is the method of filtering off the soft caustic α and β-rays, which would be very injurious with the large quantities of radium used. Layers of aluminum, silver, gold, or lead, 0.5, 1.0, or 2.0 mm. thick, placed between the radium and the skin, absorb all the soft rays. These metal filters, under the influence of the absorbed soft rays, produce in their turn so-called *secondary rays*, which are irritating to the skin, and have to be filtered off by layers of paper, cotton, or rubber.

With this improved technique truly remarkable results have been obtained during the last couple of years by French and mainly German surgeons and gynecologists. The results in cancer of the uterus are so striking that experienced and con-

servative clinicians like Kroenig of Freiburg, Bumm of Berlin, Doederlein and Klein of Munich expressed an opinion that radiotherapy may be indicated even in operable cases.

Since the greatest amount of work done recently has been in carcinoma of the uterus, it is best to describe the results of radium therapy upon this condition. As soon as treatment is undertaken pieces of tissue are removed at stated intervals for microscopic examination. A few days after the beginning of the treatment one notices extensive degeneration with formation of vacuoles in the cancer cells accompanied by a proliferation of connective tissue, which surrounds the constantly diminishing islands of cancer tissue. Ultimately the cancer tissue is completely replaced by connective tissue, and at the same time the examination of the normal tissue of the uterus surrounding the carcinomatous growth shows that the cylindrical epithelium of the cervical glands remains intact. There are cases on record where an inoperable carcinoma of the uterus was treated with radioactive substances, the uterus was subsequently removed and no signs of carcinoma were found on gross or microscopical examination. Such results surely indicate a powerful selective action.

Kroenig and Gaus seem to be the most enthusiastic advocates of radium and Roentgen therapy in cancer, and in their latest publication they offer the following indications for this method of treatment:

1. When a cancer is yet operable, but can be easily controlled by sight and touch, then one should first employ radiotherapy, and if not successful, then operate.

2. When the case is still operable and not easily controlled by sight and touch, then operate, provided the postoperative mortality is low and the chances for an ultimate result good; otherwise employ radiotherapy.

3. When the case is inoperable then radiate.

4. Whether a case has been apparently cured through an operation or radiation a prophylactic radiation should be employed from time to time in order to prevent a recurrence.

In justification of their advice to radiate even operable cases they presented the following statistical chart, compiled from the material of various clinics:

Carcinoma of	Primary operative mortality. per cent.	Ultimate results. per cent.
Upper lip	0	30.7
Breast	4	18
Lower lip	4.3	17
Vulva	5	1
Body of uterus	8	47
Rectum	18	12.4
Tongue	19.3	16
Cervix	19.3	18
Vagina	30	4
Stomach	34	3
Gall-bladder	35.3	0
Colon	48	12
Small intestines	55.5	4.3
Esophagus	100	0

This chart shows that the primary operative mortality in cancer is very high, ranging from 20 to 40 per cent., while the percentage of ultimate radical recovery is low—from 4 to 30 per cent. The carcinoma of the body of the uterus is the only exception, with 47 per cent. of radical cures, but this condition is in their estimation so easily handled with radiotherapy that in about three weeks' treatment no carcinoma can be found on examination.

In order to place a true valuation on the radiotherapy in cancer a comparison with salvarsan may be again in place. A true radical cure of cancer with every cell destroyed is as rare as the *therapia magna sterilisans* in salvarsan therapy. One must not forget that the initial lesion in syphilis during the first few days does not penetrate any deeper than an epithelioma of the skin, and the latter can be radically cured by radiotherapy. But in the deeper conditions by no means every case responds as promptly and as well. I have seen cases of carcinoma of the uterus where the action of the radium was marvelous, and I have seen again cases which seemed to be identical clinically and microscopically, and still did not respond to the action of radium. I have also seen cases where the patient after treatment with radium appeared to be clinically well and the microscope showed only a few islands of carcinoma cells remaining. The treatment was discontinued for a couple of weeks, and the patient returned with a local recurrence of the carcinoma.

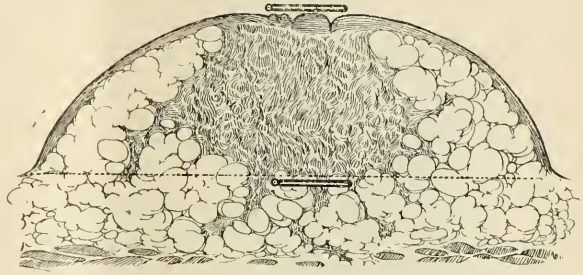

FIG. 4.—Radium treatment of carcinoma of the breast, before and after operation.

Radiation undoubtedly accomplishes as much as the knife in certain localized superficial conditions like the epitheliomata of the skin and ulcus rodens. It may even have certain advantages over the operative treatment inasmuch as it may reach microscopically small islands of cancer cells which the knife would have left behind. Furthermore, it does not open the lymph and blood channels and allow freed cancer cells to enter the circulation as an operative incision may do. On the other hand, the size and extent of the tumor growth may be such as to preclude the possibility of its being influenced in its entirety by the rays. Should the main mass of the tumor be removed surgically then the rest can be easily influenced by the rays.

Figs. 4 and 5 present schematic drawings of a carcinoma of the breast and one of the uterus. One radium tube is shown over the skin of the breast, and this tube will not be able to influence the whole of the tumor. Another radium tube is shown on the wall of the chest after the tumor has been removed surgically. This tube will have to influence the remaining islands of carcinoma, which is surely easier of accomplishment. The rays may also be brought in better contact with all the parts of the tumor by inserting the tube in the center of the growth, but a preliminary radical removal of the tumor is certainly a better procedure. In the case

of a cancer of the uterus the tube can be placed in nearer contact with all the parts of the tumor, as is seen on the illustration, and in a certain number of cases all the cancer cells within the uterus may be destroyed. But even in this case a few islands of cancer cells may remain and give rise subsequently to recurrence.

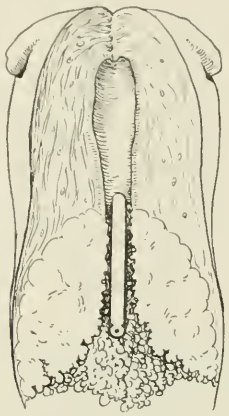

FIG. 5.—Radium treatment of cancer of the uterus.

In view of all these considerations the advisability of radiation as an only method of treatment of inoperable cases of cancer appears to me to be very questionable. In the present state of our knowledge I must emphasize strongly that the radical operative removal remains the paramount method of treatment in cancer whenever practicable. But in certain cases it may be advisable to radiate before the operation. The cases reported that were made operable through a preliminary radiation indicate the advantage of such a mode of procedure. Certain cases have also been reported where the radiation did not diminish the size of the malignant growth and still the condition seemed to have become more benign and the life of the patient was prolonged from a few months to a few years. A preliminary radiation may then improve the ultimate results of the operation. The same reasoning indicates clearly the absolute necessity of prophylactic radiation following every operation for a malignant growth. Inoperable cases belong undisputably to the domain of radiotherapy. But here another extreme must be guarded against. Cases with metastases in the liver or lungs and general dissemination should not be turned over as an *ultimum refugium* for radium therapy. This will serve only to discredit the method of treatment and demoralize scientific work. Barely 20% of the cases referred to me for radium treatment are suitable. The attending physician or surgeon should begin to consider radium early in his treatment of cancer cases, and not when the patient is moribund.

The radioactive substances are the most powerful chemical agents of any that we know at present, and a wildly proliferating cancer cell is the most treacherous enemy to handle. Too small a dose of radium may irritate and increase the growth of cancer, instead of arresting it. Too large a dose may necrotize the cancer tissue too rapidly and produce perforations into vital organs (esophagus, stomach, colon, etc.), or erode the blood vessels and produce a fatal hemorrhage. Very large doses may produce, also, alarming general symptoms—fever, nausea, and even collapse. Correct and scientific methods of radium and Roentgen therapy, methods which will lead to real progress in the future treatment of malignant growths, imply the correct selection of cases, correct dosage and filtration of the rays, and constant clinical and microscopical control of the patient under treatment. In other words, the physician who takes up radiotherapy as his life work and wants to protect himself and his patients against great disappointments and serious mishaps should not only be well acquainted with the physical and biological properties of the rays, but must also be a trained clinical surgeon and a pathologist.

To recapitulate: The radium and Roentgen rays are no more of a cancer cure than salvarsan is a syphilis cure, but these rays are therapeutic agents deserving at least as much consideration as surgery. Over-enthusiasm is as injurious to scientific work as over-pessimism is. Sober joint research in this field of the physicist, biologist, and the clinician, will surely be fruitful of far-reaching results in the therapy of malignant tumors.

119 West Seventy-first Street.

RADIUM IN THE TREATMENT OF CANCER.

By WILLIAM H. DIEFFENBACH, M.D.,

NEW YORK.

A RÉSUMÉ of eleven years of experience with radium employed in efforts to control neoplasms will, at the present time, be acceptable in view of the constantly increasing interest in the application of this remarkable element in the treatment of cancer.

In 1902 the late Dr. Henry G. Piffard induced the writer to invest in a tube of 1,800,000 activity radium bromide for experimental purposes in his clinical work. This tube has been supplemented from time to time by the following:

No. I. 100 milligrams of 200,000 activity radium chloride in a glass tube.

No. II. 225 milligrams of 500,000 activity radium chloride in a shellac mass.

No. III. 10 milligrams of 1,800,000 activity radium bromide in a glass tube.

No. IV. 10 milligrams of 1,800,000 activity radium bromide in a hard rubber disc with a mica window.

No. V. 5 milligrams of 1,800,000 activity radium bromide in a glass tube.

No. VI. A number of coated placques and bougies covered with a film of 25,000 activity radium bromide which were tested over large surfaces and in orifices of the body. These coatings were devised by Hugo Lieber, New York, to whom credit is herewith accorded. These activities were figured according to the uranium oxide scale and have not been re-valued according to the Curie scale in vogue to-day. They are given in detail to enable others to estimate relative dosage when employing radium in their own practices and will be referred to by numbers when reference is had to them in the recital of cases.

In 1905 the writer had collected sufficient data and experience to warrant his paper before the First International Congress of Radiology and Ionization held at the World's Fair at Liège, Belgium, of that year, where he represented the United States Government as official delegate by appointment of the late John Hay. This paper, "A New

Method for the Application of Radium in Neoplasms," was published in the transactions of the Congress, 1905, and also in the *Archives d'Eléctricité Médicale*, and is believed to have given impetus to the French school in developing the technique of coated discs and placques, as is evidenced by the work of Wickham and De Grais, Dominici and others, which first assumed importance since the delivery of above lecture. The résumé for the period of 1902-1905, as reported above, was as follows: "We can report absolute present success in cases of flat epitheliomata, small patches of lupus vulgaris, epithelioma of the lip and tongue—all of which must await the usual term of years before danger of recurrence has passed. In several cases of epitheliomata involving large surfaces, final results are still subjudice, in others failures resulted."

In spite of a large percentage of failures, especially in fungating epitheliomata involving large surfaces, the writer was convinced of the inhibitive action of radium rays upon pathological cells, as shown in frequently recurring favorable results, which, like white stones, showed the way along the path to success. To this period belongs a case of epithelioma of the concha (Figs. 1 and 2).

Fig. I.—Case of epithelioma involving concha. Before treatment.

Case I.—Miss L. M. G., aet. 63, came for treatment in 1905. Diagnosis: epithelioma. Patient had been advised to have operative removal of the concha as the lesion was growing rapidly. Eighteen hours of raying with No. VI coated discs resulted in disappearance of the lesion, leaving a perfect cosmetic result. This patient has been seen on and off for the past eight years and no recurrence has been noted.

In 1906 Mr. Hugo Lieber, New York, produced solutions of 25,000 activity radium dissolved in gelatine, the object being to use an animal product as a vehicle for disseminating radium within tissues by means of injections. This method was tested in a large number of cases of inoperable and inaccessible tumors. Incision into tissues, including laparatomies, with subsequent injection into tumors and burying glass tubes and coated rods in same for varying periods was carefully tested in non-operable tumors. The writer claims the credit in conjunction with Dr. W. T. Helmuth of New York of having had a laparatomy performed for the express purpose of securing access to an inoperable sarcoma of the groin and injecting the same with solutions of radium gelatine. Recital of this case will be valuable, for after two years an autopsy was secured and a careful microscopical study was made of the remnants of the injected tumor.

Case II.—Mr. E. C. H., aet. 59.—In 1909, the patient was referred for *x*-ray treatment for an inoperable tumor of the right inguinal region, which could be mapped out superficially and was fully eight inches in diameter, reaching downward into the pelvis. After a period of three months of raying with no marked diminution of the tumor, the writer suggested an exploratory laparotomy and the subsequent injection of radium into the tumor, if at all practical. Although no promise of improvement could be vouchsafed, the patient was willing to have the experimental work done, and the surgical work being performed by Dr. W. T. Helmuth, the writer prepared one ounce of gelatine containing 20 milligrams of 25,000 activity radium bromide (Lieber method). This solution, after exposure of the tumor and excision of a small particle for diagnosis, was injected into the tumor in four separate areas and a purse-string suture placed about the superficial opening caused by each needle thrust. The abdominal wound was then closed and the patient treated expectantly. The action of the absorption of the radium produced irregularity of myocardial contractions and physiological stimulants were required to tide over this attack, which lasted for 36 hours. The patient made an uneventful recovery and returned home in two weeks. Contraction of the tumor, which Dr. L. Heitzmann had pronounced round cell carcoma, ensued, and within four months but a small mass was palpable in the lower portion of the inguinal region. The patient gained in weight and insisted that he was well enough to resume business. It was suggested to him to have a second laparatomy and have the small mass still persisting removed surgically. This was declined.

Fig. II.—Case of epithelioma of concha after eighteen hours' exposure to 25,000 activity radium rods. No recurrence after eight years.

The patient was seen from time to time for *two years* in apparent good health, but during the last month of his life developed edema of the lungs, which was ascribed to metastasis—with exitus lethalis.

A post-mortem was granted and the following report given by Dr. Louis Heitzmann: "The tumor removed from the right inguinal region of Mr. E. C. H. at autopsy was irregular in outline and contracted from the hardening fluid, when received in my laboratory. It was then fully 2½ inches in length by almost two inches in width in its widest part, and had a thick capsule, which, however, varied considerably in thickness in different parts. On sectioning, one end of the tumor was found to show degenerative changes, being yellowish in color; this extended about three-fourths of an inch into the body of the tumor, becoming less and less marked. At the periphery this degenerative change extended over the entire length, and about two-thirds of the width. At the other end of the tumor the degeneration was not present, but only a thickened capsule. The chief mass or body of the tumor presented a variegated appearance, black areas alternating with white or grayish ones, to a varying degree, the former predominating near the surface, although not throughout the entire tumor.

"Microscopical examination of the capsule of the tumor showed dense fibrous connective tissue, near the surface, almost devoid of blood vessels, but looser in the deeper portions, containing a few blood vessels. In many places the cicatricial tissue has become considerably infiltrated with fat globules, the so-called fatty infiltration as distinguished from fatty degeneration. Besides this, a varying amount of pigmentation is also present and some of

the fibers are secondarily degenerated, breaking down the granules, a commencing necrotic change. Immediately beneath the capsule a large area of hemorrhage is present everywhere. This contains not only blood corpuscles and fibrin, but considerable pigment, and the pigment found in the capsule is undoubtedly derived from this. The hemorrhage has infiltrated the tumor proper, and becomes less marked the nearer we come to the body of the tumor.

"The tumor itself is a melanotic small round-celled sarcoma. It consists of numerous small, round, coarsely granular and nucleated corpuscles, partly in close contact with each other, separated only by a structureless basement membrane, partly separated by a small amount of fibrous connective tissue. Many of the nuclei show slight karyokinesis, while others have undergone karyorrhexis. In the majority of corpuscles, pigment granules are present in small numbers, due apparently to cellular activity, and causing the tumor to become more malignant and more liable to produce metastases. Masses and small clumps of pigment are scattered throughout the tumor and here and there red blood corpuscles in small groups are also present. The tumor is moderately vascular, the walls of some of the blood vessels being infiltrated with sarcoma corpuscles. While necrobiosis (karyorrhexis) is seen within the cells, true necrotic changes, as seen at the periphery, are not found in the body of the tumor. In many places large strands of fibrous connective tissue run through the tumor. These are dense in character, similar to the tissue present in the capsule. Here and there the connective tissue is infiltrated with round cells, while in other places it can be seen to have undergone more or less complete disintegration. The impression is thereby given that the connective tissue throughout the tumor was much more abundant and became secondarily destroyed and changed to sarcoma corpuscles.

"The periphery of the tumor showing degeneration to the naked eye was found to have undergone more or less complete necrosis, so much so that in many fields of the microscope only an indistinct, blurred granular mass is left. In other places the sarcoma corpuscles commence to disintegrate and become necrotic. Other degenerative changes are also present in the mass of necrosed tissue, notably thin plates of calcareous infiltration, but also some pigmentary degeneration. In some parts of this necrosed mass the connective tissue is still abundant and dense in character, while in other parts it is more or less completely destroyed. Taking all the features into consideration, it appears that cicatrization had set in, but had not become complete, so that while parts of the tumor had become destroyed and necrosed, others escaped destruction. These latter took on an active growth and partly again destroyed the cicatricial tissue."

This interesting report clearly showed how radium rays given for a long period acted upon tissues and confirmed the observations made upon superficial tissues where cicatrization with the formation of a white scar is the usual end-result of a massive radium dosage.

The results of treatment of a number of neoplasms by injections and local application of tubes and disks were read before the American Electro-Therapeutic Society in the fall of 1910 and published in full in the *Journal of Advanced Therapeutics*," June, 1911, under the title: "Radium, what it is; what it has accomplished and where it has failed." The report of the lesions treated included: Keloids, nevi, pigmented moles, angiomata, urethral caruncle, epitheliomata, fibromata, all of which were reported amenable to radium rays. To quote further from the above article: "Inoperable cancer of the breast: a number of cases were treated—we have three patients living after respectively, four, three, and two years—the rest of the patients were lost track of or are known to have died. Inoperable epithelioma of the oral cavity, including cancer of the lip and tongue; there have been ten cases, of whom six are living and four dead. Since the reading of this report this list has been added to largely with about the same percentage of successes and failures. Inoperable carcinoma of the neck we have had eight cases, of which two are living and six are dead. This percentage of successes and failures has also been retained in patients treated since 1910. The earlier the lesion is treated and the more prolonged and massive the dosage the better have been recent results. Inoperable carcinoma of the liver: injections were tried in four cases. All these patients died, although one patient after injection lived for eight months. Inoperable cancer of the spleen: there have been three cases—of the stomach, one case; of the bladder, two cases (1910)—all these patients died. Inoperable carcinoma of the rectum was treated in a number of cases; all of these patients died, with the exception of one, under supervision of Dr. C. H. Wintsch, Newark, N. J., who lived for three years, and the other apparently successful case is still living after six years. Sarcoma of the thigh, two cases, of which one case is living after two years—the other one died. In addition to the inoperable cases of cancer of the breast, a large number of recurrent cases have been treated with Roentgen ray and radium tubes and injection. Of these our records show a percentage of cure of one in three; the sooner these patients are received after recurrence is noted, the better the prognosis. Of primary operable cases, three patients have been treated. In all these cases the patients had refused operation, and they are alive after three, two and one and one-half years, respectively. In uterine cancer, inoperable and recurrent, our experience has been quite extensive. The final results in nearly all cases were negative. Several recurrent carcinomata involving the vaginal tissues were kept alive for two years, one case of recurrent carcinoma is still alive after five years and performs her duties as a professional nurse." This patient still remains well, three years later (1913).

Since instituting prolonged raying with radium, results have improved in uterine cancer and the apparent cures thus far secured have been added to.

The conclusions of the above paper were as follows: "It will be noted, therefore, that the use of radium in malignant conditions involving large areas leaves much to be desired; but judging from the excellent results secured in small areas we are justified in attempts made in inoperable cases to produce on a large scale what has many times been produced in small lesions. The injection method with diffusion of radium throughout the affected tissues offers hope for success and it remains for us to determine the dosage and repetition of the dose in order to secure fibrosis in the tissues we desire to render inert or destroy." The following deductions were drawn in above report: (1) Radium in sufficient dosage is a specific in small aberrant growths, including warts, moles, keloids, leucoplakia, nevi, angiomata, lupus, and epitheliomata. (2) It cannot cure any of above lesions if the dosage is insufficient or does not penetrate the entire substance of the tumor—hence its failures in cases of deep-seated epitheliomata. The combination of surgery and the removal of all involved tissues possible and immediate radium treatment offers hope for success in many cases otherwise considered inoperable. (3) Injections of radium or introductions of radium tubes or rods into large inoperable tumors have been successful in but a few cases of sarcoma and carcinoma thus far. If the technique of dosage, repetition of same and the activity of radium to be employed is further developed, there is reason to hope for increased success in this class of cases, for the same principle of cure secured in small lesions should theoretically be applicable in larger ones."

Since this paper was compiled, 1910, opportunity has not been wanting to follow out this line of procedure. The recital of a case of inoperable cancer of the bladder treated in 1911 and still alive, will illustrate the desirability of prolonged primary, massive dosage.

Case III.—F. C., aet. 69. This patient, on and off, had suffered from hematuria and had the misfortune to break his catheter in the deep urethra while performing his usual cystic lavage. Drs. Bukk G. Carleton and Sprague Carleton were called in consultation and with difficulty removed the broken tube. Some days subsequently hematuria set in very profusely and various treatments failing to check the bleeding, a suprapubic incision was made by Dr. Carleton and the bladder incised. Both physicians found a large fungoid mass almost filling the bladder cavity, and after deliberation concluded that operation was not feasible, the age and condition of the patient being considered. A prognosis of fatal termination of what both surgeons considered as inoperable carcinoma was made. With this prognosis before him the writer suggested the use of radium in the case, and with the aid of Dr. Carleton, No. III tube was placed in the end of a catheter and introduced into the bladder cavity with the intention of leaving it in place for some days, of removing it if symptoms demanded it. After *three full days* of radium exposure, hemorrhage ceased and the radium was removed. The patient, almost exsanguinated, soon showed signs of improvement, but after one week hemorrhage set in again. The process was now repeated and the same tube inserted for three days more (Dr. Carleton's notes have it four days) when bleeding ceased and has not recurred. Almost two years have elapsed since the treatment and the patient is living in apparent good health, although still voiding his urine suprapubically in a rubber container.

This, it is believed, is the first authentic report of malignant involvement of the bladder apparently cured through suprapublic cystotomy and massive radium radiation, and we desire it to be so noted. In October, 1912, another patient with malignant bladder was treated in conjunction with Dr. Walter G. Crump of New York and Dr. Stella Q. Root, Stamford, Conn. In this case a suprapublic incision was made by Dr. Crump and No. III tube applied over a small hemorrhagic area for three hours, being packed directly into the center of the mass. The patient has been reported free from hemorrhagic recurrence since that time.

In the treatment of inoperable or recurrent uterine, cervical, and vaginal carcinoma, the technique in the past few years has been to have the nurse prepare a gauze tampon into which are sewed tubes Nos. I, II, and V, in the form of a tripod, so as to reach as many surfaces as possible. The technique consists of introducing this tampon against the lesion and in small lesions have a 24-hours exposure. When hemorrhage is marked, 48-hour and 72-hour exposure is given. In all cases hemorrhage has been controlled, and in several cases no recurrences have been noted after two years, since the use of the prolonged massive dose. The foot of the bed is raised in these treatments in order to keep the tubes with the radium in place. Repetition has been given every two to four weeks, depending upon a return of active symptoms. This massive dosage is recommended to the profession most earnestly for the palliation and possible cure of this large class of otherwise hopeless cases. The limitations of combined surgery and radium treatment are difficult to define. A case illustrating this point will be cited:

Case IV.—The patient, aet. 59, presented a papillary epithelioma of the left labium (second recurrence) about the size of a large lemon, with involvement of the glands of both inguinal regions. This patient was treated in conjunction with Dr. E. Lothrop of Buffalo and Drs. W. G. Crump and A. E. Austin of New York. Dr. Lothrop, assisted by Dr. Crump, following preoperative radium treatment of the tumor and groins for several weeks, excised the tumor mass and inguinal glands and cauterized the open wound with actual cautery. This was followed by the implantation into the large incisions of tubes I, III, and V on one side, and discs II and IV on the other side, the radium being kept in the wounds for three days. The discs were subsequently shifted at three-hour intervals along the whole periphery of the incision of the labial, and inguinal tissues until the whole area was covered. The lesion has now, after almost one year, shown no recurrence and the patient is apparently well. The diagnosis by Dr. L. Heintzmann was villous carcinoma (papillary epithelioma) with involvement of lymph nodes of both groins. Studies made by Dr. Heitzmann upon the action of radium on the tumor mass show degeneration with fibrosis in the main mass of the tumor treated and deserve a separate report.

Whenever possible, pathological studies were made of tissues subjected to radium rays, and the following report is submitted as conclusive of the power of radium rays upon cellular development.

Case V.—Patient aet. 66, with epithelioma of the right thumb-distal phalanx. Radium was applied in this case, using discs II and IV for one hour, dosage once a week for three months, when a friend interfered and insisted upon surgical removal. The report of the pathological study of Dr. Heitzmann follows: "The tumor of the thumb which had been treated with radium proved to be an epithelioma with ulceration almost completely degenerated and partly necrosed. Nowhere throughout the entire tumor could any non-degenerated epithelial nests or alveoli be found and in only a few places in the center of the new formation was it at all possible to diagnose the original character of the tumor. The changes were more or less universal and consisted in hyaline degeneration, necrosis, hemorrhagic extravasation, pigmentation, and inflammation, with a thickening of the walls of the blood vessels and a partial or almost complete obliteration of many of the smaller blood vessels. In the diffused layers of epidermis where ulceration has not taken place, proliferation and inflammation with a partial necrobiosis of many epithelia could be seen. In many of the ulcerated portions of the epidermis a complete general degeneration or ulceration was visible. The connective tissue of the derma was considerably infiltrated with inflammatory corpuscles and here and there variously sized areas of hemorrhage with masses of pigment were present. The blood vessels were without exception hyperemic, many completely engorged with blood corpuscles, the walls of some had undergone hyaline degeneration and were considerably thickened. The sudoriparous glands showed inflammation and proliferation. The subcutaneous connective tissue was also infiltrated with inflammatory corpuscles, and in many parts of the muscle tissue inflammation and hyaline degeneration were present, extending in a few places almost to the bone. The tumor itself, throughout its entire extent had undergone inflammation with degenerative and necrotic changes, so much so that many of the cancer epithelia had become destroyed and broken down to illy defined granular masses. In a few places in the median and deep seated portions of the tumor a few distinct cancer nests and pearls were present, but even here commencing degeneration was found. Nowhere in any part of the specimen could any evidences of regeneration and new formation of connective tissue be discovered, the changes being only degenerative in character. The inflammation had extended down to the ball of the thumb, where no evidence of the presence of a tumor could be found, the tumor and the ulceration taking up the second and small part of the first phalanx."

Pathological reports on sarcoma, carcinoma, and epithelioma which had been subjected to radium treatment and subsequently excised, show conclusively that contrary to the reports of some observers, radium has *no selective action* on any particular kind of malignant cell. A massive dose will produce inflammatory degenerative changes in *any tissue*, to be followed in due time by fibrosis and a clean white scar on superficial tissues. If repetition of dosage is indulged in when not required, destruction of the newly formed scar tissue, with necrosis, will supervene.

The dosage and technique employed and gradually evolved during the past 11 years is as follows:

(1) In superficial lesions, adults, one to two hours' radiation with Nos. I, III, and V filtered through adhesive plaster and covered with several layers of ganze; Nos. II and IV filtered through ordinary tinfoil and covered with ganze, bringing the disks about ¼ inch distant from the lesion. The tubes and disks are fastened with adhesive straps and the patients are preferably placed in a recumbent position to prevent shifting of the applicators. In infants a shorter exposure, especially *in nevi*, is imperative, as an adult dose will produce necrosis. As a rule, one-half of the adult exposure is the correct dosage. Repetition of dose is best given in four weeks—if the lesion has been poorly covered it is best to risk overdosing and repeat within 10 to 14 days, rather than permit the further development of the neoplasm. The principle of dosage to be remembered in all cases is that *short exposures stimulate, large, massive doses inhibit cellular growth.* This has been demonstrated on seeds, ameba, and on living tissues and admits of no dispute.

(2) In deep-seated lesions in adults, from two to fours hours of Nos. I, III, and V filtered through adhesive plaster; Nos. II and IV filtered through tinfoil and eight to sixteen layers of ganze. Frequently it is necessary to introduce the tube directly into the tumor. The glass tubes are then enveloped with adhesive plaster and the ends sewed up with silk and forcibly introduced into the tumor mass, the silk threads being left out so as to control the position of the tube or tubes. In large fungating tumors these tubes have been kept in for 24 hours and weekly repetition of treatment has been given at other or distant portions of the growth.

(3) In uterine, cervical, and esophageal and rectal lesions much depends upon the size and involvement of the lesion. In inoperable uterine cancer a tampon, with two or three tubes, is kept in place for from one to three days (as already described), in rectal conditions a coated bougie, 25,000 activity, is kept in contact with the lesion for as many primary hours as possible, a maximum of 60 hours in one case having been required to check hemorrhage. Cocaine applications are often required to permit introduction of these bougies.

(4) The technique of burying tubes or disks depends largely upon the size and extent of the lesion to be treated. A minimum of 48 hours (in my judgment, based on failures with shorter exposures) is required for moderately large lesions where the tubes or disks can be introduced deeply and if no adverse symptoms (toxemia, myocardial irregularity) are noted, an extra day's treatment will be beneficial rather than harmful.

Complications and Sequelæ.—Complications and sequelæ are particularly to be guarded against when injections are employed. The direct absorption of the emanations of radium produce arrhythmia and stimulation is required to tide over the attack. When long exposures are given toxemia has been noted in many cases. The hot pack or prolonged warm baths (20 to 30 minutes at 98° to 100° F.) or the Murphy drip are then resorted to for eliminative purposes. Remedies will be given symptomatically depending upon each individual reaction.

In conclusion, the writer desires to express the conviction that the battle against malignant growths is not as confined and hopeless as is generally pictured. In many inoperable or advanced lesions the combination of surgery with radium radiation will prove successful.

1748 Broadway.

CHORIOEPITHELIOMA — WITH REPORT OF A FATAL CASE.*

By W. MORGAN HARTSHORN, M.D.,

NEW YORK.

A CHORIOEPITHELIOMA may be defined as a neoplasm apparently due to an unrestrained proliferation of chorionic epithelium.

It is predisposed to during the child-bearing age in females. Frank has also reported twenty-two cases of testicular chorioepithelioma. The youngest case in females was that of a girl of 17 years reported by Ahlfeld, while the oldest, aged 52 years, is reported by Holleman.

Recent parturition, ectopic pregnancy, abortion especially if a hydatid mole has preceded, are among the exciting causes given. Ladinski reports in 128 cases: 51 followed hydatid mole; 42, abortion; 28,

FIG. 1.—From curettings, showing masses of giant and syncytial cells.

labor at term; 4, premature labor; 3, tubal pregnancy.

The time of onset was, after pregnancy, 5 weeks; after placenta mole, 8 weeks; after abortion, 7 weeks.

In Teacher's records of 188 cases, 73 followed uterine mole; 36, abortion; 49, labor at term; 7, from tubal origin.

Marchand considers nutritional and chemotactic influences at fault in the causation of the growth, and states that the earlier in pregnancy they develop the more malignant their course. Veit regards the maternal tissues as the starting point which he thinks begins before pregnancy. Softening of the uterine wall and the death of the fetus have been assigned as causes. Schmorl declares that generally a diseased placenta, probably hydatid, has preceded.

*Case reported to the Sloane Hospital Alumni Association, October, 1912. Paper read before the New Haven Medical Society, April, 1913.

Fortunately it occurs rarely. Of 27,000 patients treated at the Sloane Hospital, one case of chorioepithelioma had been admitted previously to that here reported. I found records in the literature of 350 cases.

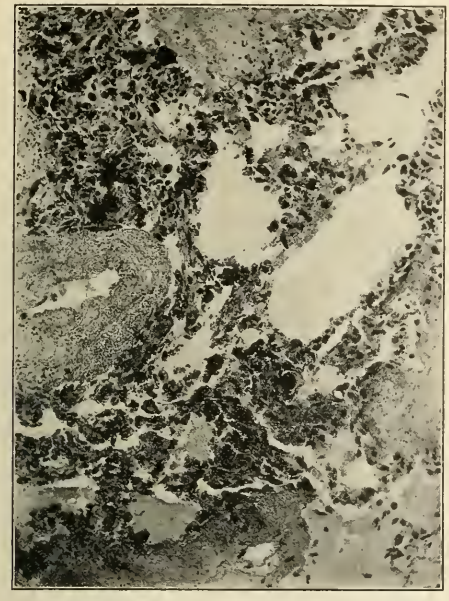

Fig. 2—From curettings, showing cells of the same character as in Fig. 1.

In 1889 Sänger first called attention to two unusual conditions following abortion. The tumor in these cases he called "Deciduoma metastica malignum." In 1892 he reported another case which he regarded as a sarcoma of the uterus; reddish tumors in the uterine wall with metastases in the lungs and elsewhere. This he termed a "Sarcoma deciduocellularis uteri." In 1877 Chiari had described a similar growth as a carcinoma. Pfannenstiel called the growth endothelioma. Marchand first insisted upon its fetal origin in the chorionic villi.

It will be remembered that the chorionic villi consist of a groundwork of connective tissue supporting the fetal blood-vessels. These villi are covered by two layers of cells. The inner layer consists of a single row of sharply defined polyhedral cells with oval nuclei; the cell bodies are clear and rich in glycogen, the Langhans cells. The outer layer consists of a homogeneous cellular mass studded with nuclei; for this reason it is called the syncytial layer. This layer throws off knobs which on cross-section resemble giant-cells. In addition, the chorionic epithelium also comprises so-called chorionic wandering cells which are probably derived from the syncytial layer and penetrate for longer or shorter distances the myometrium at the placenta site.

In an hydatid mole, which is often the precursor of a chorioepithelioma, these two layers reveal pronounced proliferation. The villi are enormous in size and are covered by masses of loose syncytial and Langhans layers. Whether this proliferation is primary and causes the hydropic swelling of the villi, or is secondary and due to the irritative influence within the villi, is still a matter of speculation. (Moschkowitz.)

Ewing groups chorioma, as he styles it, under several distinct classes: (1) Syncytioma; (2) chorioadenoma; (3) choriocarcinoma—(*a*) typical; (*b*) atypical; (4) transitional syncytioma.

1. Syncytioma—a neoplasm with more or less infiltration of the myometrium, or a tumor which does not tend to perforate the uterus or to form metastases. Large syncytial wandering cells may be found in the walls of the sinuses and also in the musculature. In the early stages the prognosis is good. Curettage generally cures.

2. Chorioadenoma. In this form, while metastases may occur, they sometimes undergo spontaneous regression. These polypoid tumors may distend the uterine cavity, perforate the organ and extend into the veins. There must be a curettement to determine their histological character, and where there is extensive involvement with metastases hysterectomy is indicated. Here the prognosis is not hopeless.

3. Choriocarcinoma, similar to the malignant *typical* chorioepithelioma of Marchand. They are characterized by the absence of villi, extensive proliferation, and pronounced metaplasia of Langhans and the syncytial cells. Here the prognosis is distinctly bad for the mtastases may invade the lungs, spleen, and other organs. He classifies it thus because of its (1) rapid and greater malignancy; (2) histological characteristics of carcinoma; (3) transmission by the lymph as well as by blood-vessels.

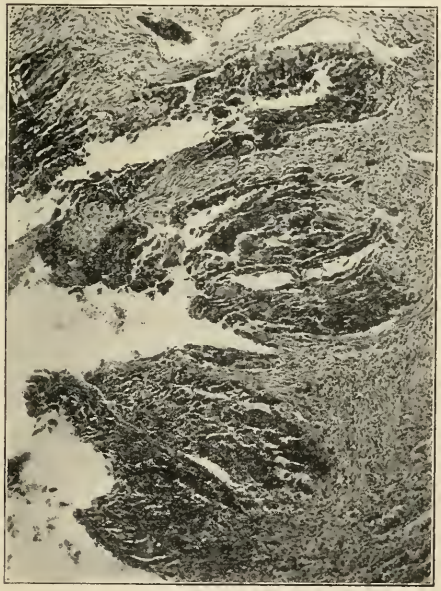

Fig. 3.—From curettings, showing an extension of the tumor cells into the uterine stroma.

Of the *atypical* chorioepithelioma described by Marchand, Ewing states that the uterus is much enlarged, there is extensive infiltration of the muscle and sinus walls with giant and mononuclear cells derived from the syncytium. There may be one

mass of several globular masses. Microscopically there are masses of giant and syncytial cells (wandering cells). Definite Langhans or villi are missing. There is involvement of the muscularis and walls of the sinuses with exudate and inflammatory cellular tissue. The prognosis is not unfavorable as there are no progressive metastases.

4. Transitional syncytioma, classified between these types. In this there is marked increase in the syncytial (wandering cells), with decrase in those of Langhans. Pick differentiates two forms: (1) Typical, in which the syncytial masses build a network in the meshes of which lie Langhans cells; (2) Atypical, the tumor substance is formed mostly of giant wandering chorionic cells.

Frank brings out the fact that all attempts to distinguish histologically between the malignant and the benign forms have been unsatisfactory. Gottschalk believed that chromatin changes in the nuclei enabled him to differentiate between non-malignant and malignant chorioepithelioma. Von Velits' theory of regressive changes and paucity of karyokinetic figures in Langhans cells as signs of non-malignancy has not been accepted. Most pathologists agreed with Marchand that the resistance of the maternal tissues alone influences the final result.

The growth is generally located in the region of the fundus of the uterus, corresponding to the placental site.

The most important symptoms following the development of chorioepithelioma are hemorrhage or constant sanguineous discharge, anemia, cachexia, and metastases in the vagina, lungs, and elsewhere. These grow with great rapidity; in one case observed by Dr. Frank Mathews it seemed that new metastases would appear in the vagina over night. Their presence in the lungs can be determined by an obstinate cough long before physical signs appear. Pick believes that malignant metastases may arise from benign moles and that the severe form may come from embolic normal cells while the uterus remains unaffected.

Ladinsky concludes that significant symptoms are, after a history of recent parturition or abortion, especially if a hydatid mole has preceded: (1) Profuse hemorrhage, irregular intervals with reoccurrence after curettage, sanguineous discharge between hemorrhages; (2) large, hyperplastic uterus and cervix with patulous os; (3) pain in the pelvis, anemia, and cachexia; (4) nodule in the uterus in the early stages; (5) metastases.

Diagnosis.—Microscopical examination of specimens obtained from curettage, or better, from direct section of the uterus, is the only positive way of making an early diagnosis.

Treatment.—Palliative or expectant treatment is indicated until the diagnosis has been established by the methods mentioned. After the diagnosis is made a complete hysterectomy should be done with resection of all vaginal metastases. Even after radical interference the prognosis is not hopeful.

Teacher reports in 99 cases in which hysterectomy had been performed:

		Deaths	Recoveries	%
Following	Hydatidiform mole	9	38	78.5
	Abortion	16	20	55.5
	Term	10	9	47.3
	Tubal	1	1	

In 36 deaths, 11 occurred within a few days after operation; 5 had intervals of several weeks of good health; 25 died after 6 months; 3 remained well one year.

Dorland and Metz report 70 cases with a mortality of 90 per cent. In 87 of Teacher's cases not operated upon, 83 died, 2 recovered, and 2 cases not accounted for.

Ladinski reports the mortality as being 59 per cent. Metastases were found in other organs in 47 cases. The causes of death were: Hemorrhage and exhaustion in 20 cases; perforation of the uterus in 4 cases; operation, shock, and sepsis in 2 cases.

Death—	After mole	After abortion	After labor at term
Shortest	3 days	2 weeks	4 weeks
Longest	2 years	18 months	9 months
Average	6 months	5 months	4 months

Fleischman has collected seven cases of recovery after probable metastases in the lungs. Schmauch reports thirteen cases of recovery after vaginal metastases. Von Velits, in 1904, reported eight cases of recovery after curettage, and several men have reported recovery after partial removal of the tumor.

Nineteen cases of primary ectopic chorioepithelioma have been collected, eleven of which were fatal, with general metastases and proliferating syncytium and Langhans cells.

I wish to report the following case:

Mrs. C., 29 years of age, was confined for the first time in May, 1910. Her family and personal history was negative, her pregnancy uneventful. The labor, a breech presentation, terminated by a breech extraction at the end of twenty hours. The child was a well developed and vigorous boy. Her second pregnancy began in March, 1911. Her history was negative up to that time. When seen in November she said that during the first week in October, while out of the city, she had been attacked by a severe pain extending across the abdomen and around the left hip. She attributed this, and a slight bloody discharge accompanying it, to overstrain. At this time she was in bed for one week.

Upon examination she appeared perfectly well, the fetal heart was strong, rate 160, heard loudest in the left lower quadrant of the abdomen, presentation vertex. On December 10 I saw her again and upon examination found that the position was apparently the same, heart distinctly heard in the left lower quadrant, rate 150. Repeated urinary examinations were negative.

Her labor began on the evening of December 20, pains fairly strong, membranes unruptured, dilatation two fingers. Fetal heart not heard; head well engaged. After the rupture of the membranes the mouth and chin could be easily felt, chin anterior and to the left. Labor progressed slowly, and finally the face was born with chin anterior. The fetus was macerated and the placenta upon its delivery showed what appeared to be large areas of fatty degeneration. Unfortunately it was not saved. The puerperium was normal in every way; the breasts were left without binders and caused very little discomfort. The patient was discharged in the third week, apparently in excellent condition. The cause of fetal death I could not explain, but ascribed it to the degeneration of the placenta and to the face presentation.

On January 16, three days after my last visit, the husband telephoned that his wife had had such a severe hemorrhage that she had fainted. Apparently she had lost a great deal of blood, as she was seriously prostrated, pale, mucous membranes anemic, pulse 120. Her temperature was normal. After rest in bed, sedatives, and ergot she appeared much better the next day. The night following she had another hemorrhage, which, while not as profuse as the first, was very alarming to the family. The uterus, which upon final examination had been well involuted, now could be felt above the symphysis, boggy and filled with soft clots. Realizing the necessity of an operation and the possibility of a serious pathological condition of the uterus, Dr. Wilbur Ward was called in consultation, the patient curetted, and the possibilities of malignant disease considered. The tissue was not examined pathologically as it so strongly resembled retained placenta. For several days after the curettage the patient flowed considerably, so

much so that I asked Dr. Ward to see her again. In the meantime a very obstinate cough had developed. When he examined the uterus he found it again soft and boggy, the fingers above the symphysis, filled with clots and débris. There was also a suspicious soft nodule on the right vaginal wall.

A second curettage was done and the specimen sent to the college for examination. Dr. William Clark reported it to be a chorioepithelioma and advised me to show the slide to Dr. Frank Mathews, who at once confirmed this diagnosis. That same afternoon he also saw the patient and found two soft nodules where one had been felt previously. He agreed with Dr. Ward that an immediate operation might possibly save the patient's life. She was accordingly transferred to Sloane Hospital and operated upon by Dr. Cragin, to whom I am indebted for the privilege of reporting the subsequent history of the case and for the use of the hospital records.

Admitted to Sloane Hospital February 10, 1912.—*Physical examination:* General condition poor, skin and mucous membranes anemic. Heart, rapid, sounds good quality, Clear. Lungs, slight dullness left apex, no adventitious sounds. Perineum, good condition. On the right lateral fornix a nodule size of a hickory nut found, not cystic, apparently not attached to the deeper structures. On the left lateral fornix there is a nodule smaller in size. Cervix, posterior, admits tip. Uterus, bulges into the anterior fornix, is about two or three fingers above symphyses, is boggy, freely movable. No thickening in the ligaments.

Operation by Dr. Cragin, February 10, 1912.—Panhysterectomy; salpingo-oophorectomy, double; transplantation of left ureter, intentionally resected for metastases which involved the ureter.

Pathological Report.—Diagnosis, chorioepithelioma of uterus with metastases. *Gross appearance:* Specimen consists of part of vagina, whole of uteurs, tubes, and ovaries. The uterus measures 10½ by 7 by 5 c.m. Each tube appears normal in size and 9 c.m. long. The ovaries are of normal size. On opening the uterus the wall shows several round tumors imbedded in it. They are red in color and moderately soft and spongy. There is a similar growth in the posterior wall of the vagina. There is a separate piece of tissue 2½ by 3 c.m. removed from the ureter. *Microscopical appearance:* Section shows a group of large multinuclear cells (syncytial masses) and smaller polyhedral cells with well stained oval nuclei invading the uterine stroma and blood vessels. There is considerable interstitial hemorrhage in the region of these cells. Section of the ureter mass shows syncytial cells lodged in an artery. There is increase of connective tissue with round cell infiltration. *Postoperative History:* February 11.—Fairly comfortable, some nausea. February 12.—Packing removed, codeine phosphate given. Calomel in small doses followed by magnesium sulphate and enema with slight result. February 14.—Abdominal wound dressed. Gauze found to be saturated with foul smelling discharge, considerable pus from wound. Cleansed with saline solution, dry sterile dressing. February 16.—Considerable drainage through vagina, foul, greenish, watery discharge. February 18.—Abdominal wound packed with antistreptococcus gauze. February 18.—Great deal of leakage from the bladder. February 22.—Has a slight cough, shows distinct signs of failing. February 23.—Examination of lungs shows throughout both sides fine subcrepitant rales, more pronounced on the left and posteriorly; no signs of consolidation. February 26.—Patient very much out of breath upon slight exertion. Signs in chest more pronounced. Rales are coarser, especially over the left side. February 27.—Coarse bubbling rales over both lungs. Respiration became progressively worse and more labored during the evening; although dyspnea was severe, there was no orthopnea. At 4:30 A. M. there were unmistakable signs of edema of the lungs. From then on the patient gradually sank, dying at 8 o'clock.

February 27, 1912.—Autopsy by Dr. Packard: Body of a well-nourished and developed young woman, moderate amount of adipose tissue. Skin pale and firm. Pupils in middilation. The left leg is slightly larger than the right and is edematous. No external markings upon the body. In the midline below umbilicus is a gaping incision 15 by 5 c.m. The muscles have united, leaving the skin ununited. The wound is fairly healthy. Peritoneum is normal. There are a few fairly firm adhesions around the wound. The uterus and adnexa have been removed. Pleuræ, free except for a few delicate fibrous adhesions posteriorly and on the sides in both cavities. Small amount of fluid in each cavity. Lungs, studded with nodules varying in size from 0.5 to 3 c.m. in diameter. These are of a red color and are moderately soft and friable. They show hemorrhages into their substance. On cutting the lung tissue the tumors are seen everywhere. The uninvolved lung tissue is soft and crepitates. The bronchial nodes are enlarged and deeply pigmented. Posterior to the root of the left lung is a dark red mass, easily torn and firmly adherent to the parietal pleura. Heart, normal size. Valves show no vegetations on their leaflets. There is considerable postmortem clot. Spleen, normal in size, color, and consistency. Kidneys, normal size, pale in color, markings fairly well preserved, cortex of normal thickness, capsule strips easily. Bladder, an opening 3 c.m. in diameter is seen in the bladder at the point of entrance of the left ureter. This opening leads into a large pelvic abscess occupying the site of the removed uterus. The end of the ureter is attached to the bladder by a suture. Pus and decrotic tissue are found about the rectum, and there is an opening admitting two fingers into the vagina. The vagina shows necrotic tissue within two inches of the external opening. No tumor growth is found in this region. Pancreas, hard and fibrous. Section shows a dense surface. Weight 100 gms. Liver, right lobe enlarged somewhat, surface coloring normal; no abnormal conditions found upon section. Gall-bladder, normal. Stomach, intestines, and suprarenals, normal. Head not examined. Left leg not examined.

Anatomical Diagnosis: Chorioepithelioma. Metastases of the lungs. Pelvic abscess.

Conclusions.—From this brief review of the recent literature upon this subject the following conclusions should be emphasized:

1. Chorioepithelioma is, as a rule, a highly malignant blastoma which usually follows pregnancy.

2. Inasmuch as it most commonly arises after hydatid degeneration of the placenta, patients afflicted with this malady should be carefully watched for a long period after the expulsion of the uterine contents.

3. Persistent bleeding following abortion or pregnancy should be regarded with suspicion. In such instances the curettings should be subjected to pathological examinations

4. Although chorioepithelioma is, as a rule, highly malignant, the prognosis is not hopeless; a few cases recover even after general metastatic involvement.

For a complete bibliography the reader is referred particularly to the articles by Ewing, Frank, Stone, Ladinski, Pick, Marchand, Teacher, and Risel, from which quotations have been made. I am especially indebted to Dr. Eli Moschcowitz for his valuable suggestions.

50 Central Park West.

ACUTE PHLEGMONOUS CHOLECYSTITIS:

REPORT OF A CASE WITH GANGRENOUS ENTERITIS.

By ALBERT E. ROUSSEL, M.D.,

PHILADELPHIA, PA.

ASSOCIATE PROFESSOR OF PRACTICE AND OF CLINICAL MEDICINE, MEDICO-CHIRURGICAL COLLEGE; VISITING PHYSICIAN TO THE MEDICO-CHIRURGICAL AND TO THE HOWARD HOSPITALS, PHILADELPHIA; OFFICIER DE L'ACADEMIE, FRANCE, ETC.

The extreme rarity of the conditions mentioned in the title, either alone, and more especially combined, prompts the recital of the facts of the case as we know them and the detailed findings at necropsy. We are inclined to regard the case as unique, especially in view of the fact that after a most careful perusal of the literature on these subjects we find only those references mentioned herein, and in these we fail to find any absolutely similar cases. The case history reads as follows:

Case 4373.—Howard Hospital, J. M., male, æt. 48, of Irish birth, admitted December 27, 1910, with diagnosis of myocarditis complicated with purpura hæmorrhagica and gastritis. Temperature on admission 100.4° F., pulse 88, respiration 24. Five hours later the temperature dropped to 98° with a corresponding drop in pulse and

respiratory rate. Two hours later it rose to 98.6°; three hours later it dropped to 98.2°, then rose for the next 9 hours to 99.6° when the patient involuntarily voided 8 ounces of urine and had 3 involuntary stools. He died within the succeeding two hours.

The nurse's notes record the fact that upon admission the patient's hands and feet, hips and back were covered with red and purple blotches. A bedsore was present on the back. The left side of the face was swollen and there were reddish spots on the inside of the mouth and also on the tip of the nose and ears. The patient was very emaciated and extremely restless and talkative. Fractional doses of calomel were administered followed by Epsom salts with the result that the patient had four stools. The first two stools were large and brown in color and liquid in character. The subsequent stools were small, yellowish, liquid, and composed of apparently undigested particles. The patient was seen by me only two hours before his death and in addition to the above symptoms general abdominal rigidity was noticed. No previous history was obtainable. There was nothing to indicate the real nature of the process within the bowels. Other medicine such as caffeine citrate, salol, strychnine, convallaria, and potassium citrate were given at intervals, but the patient was unable to retain any medicine after about four hours. The one specimen of urine obtained showed upon analysis, dark amber color, alkaline reaction, specific gravity 1016, no sugar, no albumin, thin blood casts, triple phosphates, oxalates, mucus, and epithelium.

The notes of the autopsy as performed by Dr. Norman Gwyn, pathologist to the hospital, read as follows: Body of emaciated man about 5 feet 10 inches in height. Blood oozing from the mouth and nose, eyes edematous. Purpuric splotches over the hands, knees, outside of thighs and feet, some fresh and some old. Over the great toes (2.5 cm. x 5 cm.) and over the knees the spots are more discreet, some small spots on head of penis. Distinct ulcerations on lobes of ears and tip of nose, destruction of tissue on the feet. Large purple spot size of a hand on outside of left thigh, probably due to hypodermic injection. Red patch in epigastrium due to some application. Rigor mortis and livido mortis distinct. Left eye shows evidence of edema and distinct ecchymosis, no jaundice. Ecchymosis scattered through omentum. On lifting the latter the small intestine falls into view, is greenish gray in color, partly distended and partly collapsed. Transverse colon is collapsed and of same color. Two small knuckles of bowel, not discolored, project from either iliac region. These dark coils extended deep into the pelvis and flanks, giving the appearance of bowel filled with blood. The darkened area ends at the iliocecal valve, above it extends to the duodenum. The stomach is markedly distended and of the same green color but lighter. In the large bowel discoloration begins again above the caput coli and extends across the transverse colon, is empty and contracted. Rectum and sigmoid flexure empty and free from discoloration. No marked adhesion at splenic flexure or gall-bladder flexure. No hemorrhage in appendix, no fluid in abdomen. On exploring the small intestine immediately below the duodenum it seems to be covered with fine lymph, but its glistening appearance suggests condition of acute gangrenous inflammation. Nodes slightly enlarged. On exposing gall-bladder, which lies free at right angles, it is seen to be a shriveled structure 2 inches long, red and covered with a grey necrotic membrane with little crypt-like ulcerated areas. A distention at its neck and just beyond is evidently due to a contained gall-stone the size of a bean. Beyond this duct is clear. Spleen moderately enlarged and not suggestive of an infection process outside. On section, save for slight enlargement in malphigian bodies, it seems normal. Blood of mesenteric arteries and veins flows freely, particularly in lower part. As one ascends bowel no blood oozes out. On separating bowel, blood does not exude and bowel wall is greatly thickened; the general blackened condition must be ascribed to acute inflammation and gangrene. Left pleura clear, right pleura has adhesion at posterior apex, with a firm small nodule of evident healed tuberculosis; base also adherent. Both lungs crepitate, considerable congestion. Section of right lung shows moderate size cavity containing caseous material but no nodules and no consolidation. Pulmonary artery clear on both sides. Much edema and congestion at base of right lung; left lung clear. Left kidney larger than right, strips with slight difficulty. Cortex slightly swollen and suggests early stage of cloudy swelling. Right kidney also large, swollen and pale, and capsule strips with difficulty; cuts with some difficulty and on section is pale, dull, and suggestive of cloudy swelling. Both adrenals normal on section—no hemorrhages. Pancreas—section from tail is firm and pale. No hemorrhagic area or suggestion of fat necrosis. Head of pancreas shows no lesion, ducts clear, fluid flows freely. Small enlarged glands about middle of bile duct. Liver larger than normal, pale, evident seat of fatty deposit; covered with numerous stellate scars, probably the remains of old lesion. One section pale, morbidly fatty. Some slight distention of the bile ducts. Considerable ulceration in the stomach, mucous membrane red-gray in color. Firm plaques of atheroma in aorta. Small ecchimosis behind heart in pericardium. Heart not enlarged, 2 c.c. fluid in pericardium. Small chicken fat clots in auricle, auricular appendix free. Right heart free, pulmonary artery clear, valves free in right heart. Mitral valve free, aortic valve clear. Sclerosis around coronary openings. Heart muscle a little pale, not glistening. Bacteriological report of bowel secretions showed streptococci and colon bacilli.

In the case of phlegmonous enteritis reported by Ungerman (*Virchow's Archiv*, 1908, CXCIII, No. 3) the notes read as follows:

February, 1907. The patient was an out-patient, 60 years of age. Russian by nativity. He was suddenly taken ill with severe abdominal pain and prostration attended with slight icterus. He became rapidly worse and passed into a state of coma, dying on the third day. The patient had repeated high rises of temperature. On account of the scarcity of clinical data, there was no suggestion as to the locality or the character of the illness. There seemed to be a certain connection between the illness and the ingestion of two salt herring, but no information could be elicited concerning the quality or condition of the fish. The symptoms and physical signs seemed to point to a heavy diffuse exudative peritonitis, following perforation. Autopsy showed no evidence of intestinal injury or surface change of any other abdominal organs. There was a somewhat heavy swelling in the region of the pancreas, suggesting a pancreatic tumor. A close examination of the gland showed that it was not primarily infected. The head of the pancreas showed a mass of edematous infiltration, the remainder was even more strongly defective. The retroperitoneal edema which encircled the pancreas was the cause of the tumor-like resisting mass present in this vicinity. The chief part of the mass had most likely been the duodenum itself, the weight and stiffness of which was quite apparent upon opening the abdomen. The other organs were considerably injected and enmeshed in fibrous tissue, but had retained their normal size and consistence, and normal thickness of their coats. The duodenum, however, could not be encircled by the hand with compression, its wall was thickly covered with a doughy consistency of a cloudy greyish red color. Upon pressure there exuded a large amount of edematous fluid. This edematous condition also affected the anterior portion of the liver, reaching on one side along the side of the aorta near the highly inflamed and thickly covered lymph gland, high up on the other side to the mesentery. No thrombus was found either in the aorta or the mesenteric arteries. The wall of the stomach was not apparently changed. The gall-bladder was somewhat enlarged; the liver reached over the edge of the ribs in the mammillary line two fingers. It was somewhat cracked, and pale yellow with anemic surface markings. The spleen was normal in size and soft in character, the pulp being somewhat liquid. The genitourinary organs were normal. On opening the intestines the large intestine showed a smooth, pale, shining mucosa. The ileum and a large part of the jejunum had only a slight injection of the mucosa; the other coats were unchanged. A few centimeters under the duodenojejunal flexure there was seen a sudden thickening of the walls of the intestines. Upon completely opening the intestinal wall the mucous membrane presented a conspicuous appearance. In the region of the pyloric end of the stomach the mucous membrane was changed into a transparent, greyish-yellow or greyish-red coloration, the folds of which were closely compressed, so that between them there was a deep compression about 1½ cm. from the incision. The mucous membrane was separated from the muscular coat. The pyloric end of the stomach could only be recognized by the stronger muscular fibers. The surface of the almost gall-like mucous membrane appeared dull, and nowhere was there to be seen any swelling. An elevation rising out of the highly swollen parts was the papillæ of Vater, indicated by an intense red surrounded with a mucous membrane with dark yellowish bile pigment, but otherwise normal. In the region of the descending part of the duodenum the swelling was decided; above and below it was less intense, diminishing as the jejunum was approached. The swelling of the mucous membrane ceased

at the pyloric end of the stomach. The remaining mucous membrane of the intestinal tract was slightly reddened but otherwise normal. Upon separation of the ducts of Wirsung and Choledochus, a blind pouch as large as a finger was directly under the papilla of Vater, the same running along almost parallel to the ductus choledochus. Running in the direction of the hepatico-duodenal ligament there was a heavily swollen mucous membrane containing at the bottom two pointed bone splinters on either side; the smaller of the two was almost 1 cm. long and lay transverse on the lower border of the cul-de-sac. The other one, 1½ cm. long, was perpendicular to its long axis. Neither of the two splinters had penetrated into the wall of the diverticulum; the mucous membrane did not show any great injury, and there was no laceration or bleeding. About 15 cm. underneath the first diverticulum there was seen another one, somewhat smaller, built similarly, laying in the same direction, also completely covered with mucous membrane; no foreign bodies were found in it. By the examination of the horizontal incision through the wall of the duodenum, one could see that the brunt of the lesion was borne by the submucous coat. It was about 1½ cm., and while of a dull grey in parts it also showed a prominent, pus-like, yellow network, upon pressing which very purulent and dropsical fluid exuded. From the submucosa there branched off more or less broad, dull yellowish grey stripes through the muscular coat to the subserosa, which was thicker than normal, and here and there small purulent yellow dots were to be seen. The chest organs showed only old points of fibrous induration; otherwise there was no apparent change. The examination of the peritoneal exudate showed microorganisms mostly arranged in short chains and seen exclusively in the cuts through the altered intestines (doubtless streptococci). The histological picture showed inflamed mucous membrane everywhere. Also in the most altered regions were seen strands where there was a sparsely nuclear stain which points to an evident secondary necrosis, but no macroscopic ulcerous defect could be found. Directly under the epithelium in the strongly constructed tunica propria of the mucous membrane and Brunner's gland there was seen the greatest part of the larger lymph stream, with multinuclear leucocytes, pushed out in a condensed manner, and outside of the lymph channel lay scattered round and pus cells between bands of connective tissue. The submucosa consisted of a braided and dilated band of connective tissue between which there stretched out large and free lumina, and an enormous quantity of gathered dropsical fluid. In moderately regular places the membrane was covered to almost 1 cm. in breadth with pus cells towards the lymph channels. More dense and more diffuse gatherings of pus cells also covered the muscularis. The lymph channel of the subserosa was covered with pus organisms. The subserosa with its many changes reminded one of the changes in the submucosa; it was very loosely affected with many empty channels pushed through it; the lymph-vessels here were prominent and covered with pus cells and showed on the cut surface the appearance of small abscesses. There was a diffuse collection of pus bodies. The serosa in its strong accumulation of pussy exudate showed an acute purulent inflammation. The above described changes were similarly seen in the upper cut of the duodenum. In the region of the pylorus the clear, edematous swelling of the submucosa stood out, in its place was seen a large exudate which was equally distributed in all the crevices of the wall and which did not adhere so much to the lymph channels. Further on there were not seen any more of the cell-like infiltration of the stomach-wall, so that in the region of the circular linear inflammation there might have been room in the tunica propria for round cells and normal mucous membrane. In the same way the same affection was pulled over toward normal conditions on the other side towards the jejunum. The large diverticula, previously referred to, which showed themselves at the beginning of the incision, were more towards the base, consisting of a small band of muscular fibers showing, in passing over in the normal stomach wound, the similar edematous, pussy infiltration. Incisions into the edematous head of the pancreas showed an ordinary pressure of lymph channels. There was in the liver many accumulations of round pus cells in the mesh work of Glisson's capsule and in the shape of small handfuls between the cells on the edge of the liver. There was not seen any microscopic thrombus masses in any part of the portal vein. The retroperitoneal lymph vessel showed the signs of an acute hyperplasia, pronounced distention of lymph sinus with proliferated endothelial cells and leucocytes.

The incision was examined bacteriologically with Loeffler's methylene blue and Gram-Weigert stain. In all portions of the affected bowel regions, in edematous retroperitoneal meshing, in the inflamed lymph channels, in parenchyma of liver, and also in the peritoneal exudate were found the following microorganisms: A Gram positive coccus arranged in short chains of 4 to 8 bodies, plainly showed cutting through the wall of the duodenum. In the further broadening in the intestines was the same overflowing of pus cells in the lymph channels through the muscularis into the subserosa. The streptococci were very plentiful in the papillæ of Vater, diminishing from here on both sides. In the stomach wound is very little pus. Nowhere was there seen any other organisms. Only on the surface of the mucosa between the folds were seen Gram negative short rods. In some depths were seen only the streptococci previously described.*

J. T. Eskridge's field of observation in gangrenous conditions of the intestinal tract includes another interesting case (Tr. Path. Soc., Phila., 1880, IX, 18 to 21).

In this instance the patient was a woman, 40 years of age, and was ill for a period of 40 days before she succumbed. On autopsy, the liver, kidneys, and pancreas were found to be healthy. The spleen was small and covered with vesicles its interior was intensely reddened and granular. Microscopic examination showed chronic inflammation. The gastric mucous membrane was congested. The mucous membrane of the duodenum was almost black, ending abruptly about 12 inches from the pyloric end of the stomach in almost healthy mucous membrane; its walls were very dark and easily torn, and surrounded by a localized peritonitis. The gall-bladder contained a large gallstone. The uterus was inflamed and enlarged and its appendages normal. In this case, if we assume that the presence of the gallstone produced cholecystitis we have a case resembling that of this paper.

A case of acute disease of the colon resembling commencing gangrene, with gallstones, recorded by Minot (*Boston M. and S. Jr.*, 1871, VII, 96), has very many features of interest in this connection.

The patient was a man 81 years of age, and was suddenly attacked with severe pain in the left flank, vomiting, tenderness over the crest of the ilium, and died within 36 hours. On autopsy, the colon showed evidences of obstruction to the intestines. The gall-bladder was everywhere adherent to the liver and contained several hundred calculi, of which five were as large as filberts, and the rest varied from the size of a pea to that of a small shot. The other organs were normal.

Ulceration being a molecular form of gangrene it may not be inappropriate to mention in passing the case of extensive ulceration of the large intestine associated with gallstones, observed by R. H. Salter (*Boston M. and S. Jr.*, 1856, LIV, 57-61). The patient was a woman 68 years of age, and while generally healthy, she had been subject to attacks of indigestion and palpitation of the heart. Her last illness extended over a period of fifteen days. Autopsy showed atheromatous processes distributed throughout the course of the aorta and upon the aortic and mitral valves. The liver was large and fawn-colored with vascular points. The gall-bladder was distended with yellowish-green viscid bile and contained two round, yellowish-brown gallstones. The kidneys and spleen were normal. The mucous membrane of the lower part of the small intestine showed evidences of inflammation, but in the large intestine there were several areas of frank ulceration, one of which had perforated. Two fibrous tumors of the uterus were also found.

In the course of typhoid fever, perforation of the gall-bladder has been observed. In Ashhurst's case (*American Jr. Med. Sciences*, April, 1908) the patient eventually recovered, but in the case referred to by C. H. Lanviner (*Jr. A. M. A.*, June 6, 1912) the condition developed in the third week of the typhoid, and the patient died shortly after. This is mentioned merely to call attention to the simultaneous occurrence of necrotic conditions in these structures, although here the typhoid bacillus in the blood was probably the cause of the gall-bladder complication.

While it is difficult to find records of cases exactly similar to the case herein reported, we are able to find cases allied

*Phlegmonous enteritis is a very rare disease of the intestinal tract, according to Ungerman. There are only 7 cases in the available German records up to the time of Ungerman's observations. These are contained in the following: P. Deutelmoser: "Entertitis Phlegmonosa Idiopathica," Greifswald, 1905. Bellfrage und Hedennis: "Enteritis Phlegmonosa," in Virchow-Hirsh Jahrbuch, 1876, Vol. II. Goldschmidt: *Archiv für klinische Medizin*, Vol. 40, 1887. Askansay: *Zentralblatt f. allg. Path.*, Vol. VI, 1896.

in one or more particulars. Thus, for instance, we may refer to the three cases of acute cholecystitis complicating typhoid fever reported by E. M. Price (*Jr. A. M. A.*, May 15, 1909). In one of these at operation a small necrotic area was found in the fundus of the gall-bladder through which the greatly altered bile was discharging into the peritoneum. There were no duodenal complications.

W. Osler (Tr. Assoc. American Physicians, Vol. XII, p. 390, 1897) gives an account of a case of phlegmonous cholecystitis occurring in the course of typhoid fever. The patient was a married woman 37 years of age, who had an attack of typhoid fever and was now going through a protracted convalescence. She was taken with sudden pain in the region of the gall-bladder, jaundice, and chills. On opening the abdomen at operation the liver was seen to be enlarged, the gall-bladder projected below the right margin, and on its anterior wall a rupture was seen through which bile and purulent matter were oozing. The adjacent wall of the gall-bladder was quite necrotic. The patient died about twelve days later.

Sloughing of the intestine has occurred in the course of obstruction of the mesenteric artery, as is shown in the case observed by Allen (*Australasian Medical Journal*, 1882, n. s., V, 118). The patient was an old woman who was the subject of leg ulcers, diarrhea, and severe intestinal hemorrhages. Allen traces the causation of the sloughing of the intestine to the varicose veins of the legs, the latter incidentally producing obstruction of the mesenteric artery, thus precipitating the intestinal trouble and the fatal termination.

Mesenteric thrombophlebitis with hemorrhagic infarction is a very unusual type of localized intestinal gangrene and has been made the subject of especial study by P. Manclaire and F. Jacoulet (*Archives générales de Chirurgie*, Paris, March, 1908). These observers reviewed the literature on the subject and found fifty cases, including one in their personal experience, in which there was hemorrhagic infarction of the intestine from obliteration of either the artery or vein.

R. W. Wakefield (*Jr. A. M. A.*, Oct. 14, 1911) observed a case of gangrene of the ileum due to thrombosis of the mesentery. The onset was very sudden with intense abdominal pain and colic. Operation was performed and the patient recovered.

In Allbutt and Rolleston's "System of Medicine" (1908, Vol. IV, p. 239, "Diseases of the Gall-Bladder" by A. W. Mayo Robson) there is the statement that acute phlegmonous inflammation of the gall-bladder was observed and described by Courvoisier in 1890 under the name of acute progressive empyema of the gall-bladder, and seven cases of the condition are recorded in his writings at that time. Another reference is made to Potain (*Journ. de méd. et chir.*, Nov., 1882) who described a variety of empyema of the gall-bladder which rapidly assumed a malignant character with peritonitis and death, but in which there was no perforation.

Perhaps the most interesting of Allbutt's quotations are those having to do with the case reported by L. W. Hotchkiss (*Annals of Surgery*, 1894, XIX, p. 197). The patient was a boy 19 years of age who was admitted to the hospital with acute peritonitis thought to be secondary to appendicitis. There was no history of gallstones. An exploratory operation was performed at which the gall-bladder was found to be gangrenous. The patient died within 34 hours after the onset of the attack.

L. G. Courvoisier (Casuistisch-Statistische Beiträge zur Pathologie und Chirurgie der Gallenwege, Leipzig, 1890, p. 76) in a very elaborate contribution on the pathology and surgery of the biliary passages gives an account of ten fatal cases of acute cholecystitis which were typhoidal in origin, two with gallstones and phlegmonous infiltration of the gall-bladder walls, and seven with seropurulent exudate with occasional ulcers and necrotic areas. (These cases are also quoted by A. L. Mason from Courvoisier's work, in Tr. Assoc. American Physicians, 1897, Vol. XII, p. 28.)

Osler in his more recent works ("Modern Medicine," 1908, Vol. X, p. 819) expresses his view that the types of acute cholecystitis should be considered as catarrhal, suppurative, phlegmonous, gangrenous, and membranous. He believes that the varying lesions are due not so much to different microorganisms as to variations in the virulence of the same organism and other attendant conditions. He further states that a more advanced and rare stage of phlegmonous cholecystitis is spoken of as gangrenous cholecystitis. The small foci of necrosis that occur in suppurative cholecystitis are sometimes spoken of as localized gangrene, but he thinks "ulcerative cholecystitis" the better term. When a large section of the gall-bladder becomes necrotic the term "gangrenous cholecystitis" should be applied. This results from very virulent infection or interference with the blood-supply due to gallstone impacted in the neck of the gall-bladder or in the cystic duct, or to infectious thrombosis of the nutrient artery. The lesions resemble those of advanced suppurative or phlegmonous cholecystitis, with the addition of complete necrosis or gangrene of a variable portion of the gall-bladder. Usually this process begins at or near the fundus and spreads toward the neck; in some cases it begins about a gallstone more or less firmly embedded in the wall of the gall-bladder.

The cases of gangrene of the gall-bladder recorded by Richardson (*American Journal of Medical Sciences*, 1898, I, p. 630 and p. 644) are especially interesting. The first case occurred in the person of a married woman, 62 years of age, and began with severe abdominal pain. There was a history of occasional attacks of alleged gallstone colic over a period of seven years. Operation was deemed necessary and when performed the gall-bladder was found acutely inflamed, distended, black, and gangrenous, adherent to the contiguous viscera, and surrounded by a thin, offensive exudate. The right upper quadrant of the abdomen was the seat of a spreading peritonitis. The gall-bladder contained hundreds of minute gallstones suspended in a dark, offensive fluid. The patient died eight hours after operation from the original peritonitis and the superadded operative shock.

In Richardson's second case the patient was a man, 28 years of age, and a glazier by occupation. The condition began with a sudden griping pain in both groins followed by vomiting on the succeeding day. Acute appendicitis was diagnosed and an operation performed at once. The appendix was found to be normal but the gall-bladder was tensely distended and everywhere adherent. It was dark in color and had the appearance of acute gangrene. Death followed on the fourth day. Autopsy showed a general septic peritonitis and a gangrenous gall-bladder. There were no gallstones. The hepatic flexures of the colon were covered with fibrin and the lumen nearly occluded by adhesions.

W. C. McCarty, Rochester, Minn. (*Annals of Surgery*, May, 1910), in an article on the pathology of the gall-bladder refers to a clinical and pathologic study of 365 out of 657 cholecystectomies performed by the Mayos, and concludes that the lesions in the gall-bladder are not definite entities but degrees in a process of reaction to irritation. There were 33 cases of cholecystitis purulenta necrotica in this study. He states that during any stage of inflammation of the gall-bladder, obstruction to the cystic duct may be so great, or the pyogenetic infection so virulent that disturbance of the circulation or multiple abscesses in the gall-bladder may occur. The specimens are usually distended, dark blue or black, the contents pus or blood and usually not bile stained. Pericholecystitis acuta and chronica must be considered a sequel of any of the above mentioned degrees of inflammation. Even in the earliest degree of cholecystitis catarrhalis acuta, the process may extend to the serosa through the lymphatics, and it is not infrequent to see adhesions, usually to the omentum and transverse colon in this stage. He further states that he considers the gall-bladder, liver, duodenum, pancreas, and stomach are embryologically, anatomically, physiologically, and pathologically closely related and should be regarded as a gastroduodeno-hepatico-pancreatic system.

H. A. Hare ("Practice of Medicine," 1907, p. 675) describes acute cholecystitis and states that it may occur in a phlegmonous form.

A. A. Stevens ("Manual of Practice of Medicine," 1911, p. 94) admits the possibility of gangrene of the gall-bladder in impacted stone but gives no account of primary gangrene of that structure.

J. M. French ("Practice of Medicine," 1905, p. 486) in referring to phlegmonous enteritis states that it is very rare as a primary affection, usually being observed as a termination of strangulation, intussusception, pyemia, or malignant disease. This view is concurred in by most of the prominent clinicians. He further attributes the primary cases to the colon bacillus and states that the condition sometimes accompanies phlegmonous gastritis. In discussing acute infectious cholecystitis he mentions a phlegmonous variety but shows no relationship between it and phlegmonous enteritis.

R. C. Kemp ("Diseases of the Stomach, Intestines, and Pancreas," 1912, p. 599) states that phlegmonous enteritis is rare as a primary process. It is probably due to streptococci infection, the jejunum being most frequently involved and the condition cannot be diagnosed until after operation. It may be secondary to intestinal ulceration, to intussusception, or strangulated hernia.

Osler ("Practice of Medicine," 1912, p. 566) in his remarks on acute infectious cholecystitis acknowledges that there is a phlegmonous variety of the condition and quotes Richardson (whose cases are also referred to in this contribution) for the symptomatology of the affection.

Else (*Surgery, Gynecology, and Obstetrics*, Chicago, Dec. 1909, Nov., 1910) in discussing the pathology of the bile ducts, and gall-bladder states that microorganisms reach the gall-bladder from the intestines by ascending the common and cystic ducts, and very rarely reach the gall-bladder from the intestines by way of the portal vein. When they do the liver is first affected.

E. Williams, Patterson, Louisiana (MEDICAL RECORD, Nov. 20, 1909) records a case of acute gangrenous cholecystitis with gallstones in the cystic duct and perforation of the gall-bladder.

M. A. Tate, Cincinnati, Ohio (*Journal of Obstetrics and Diseases of Children*, Feb., 1911), also reports a case of gangrene of the gall-bladder.

Tyson ("Practice of Medicine," 1898) mentions the occurrence of phlegmonous cholecystitis but only as a complication or termination of impacted gall-stones.

The case reported by J. T. Eskridge (Tr. Path. Soc. Phila., 1881-83-84, XI, pp. 36-45) bears a slight resemblance to the case which makes the subject of this article, but in his case there was abscess of the liver, not a cholecystitis, and the intestinal trouble consisted of gangrenous inflammation of the cecum and appendix. The patient in this case was a factory girl, 27 years of age, and was the subject of inflammatory rheumatism. Her final illness lasted about one month and had reference to heart trouble. The autopsy showed remote and recent pleurisy, multiple abscesses of the lungs and spleen, small area of pericarditis over the left ventricle, dilatation and hypertrophy of the left auricle and ventricle, diseased mitral valves, thickened aortic valves, abscess of the liver, gangerous cecum with sloughing of the appendix, and numerous small abscesses of the liver, in addition to the single large abscess just noted. This was a distinctly surgical case, although the early symptoms had reference to the heart.

Anders ("Practice of Medicine," 1911) acknowledges five varieties of cholecystitis, namely catarrhal, suppurative, phlegmonous, gangrenous, and membranous. He states that gangrenous cholecystitis is rare and fatal. Regarding phlegmonous enteritis he states that it is a suppurative inflammation of the submucous layer of the intestines. It may be diffuse or take the form of a circumscribed abscess. Rarely it occurs as a complicating condition in septicopyemia and in malignant types of the exanthemata, resulting in the formation of abscesses that usually have their seat in the duodenum. Phlegmonous entertitis may be secondary to strangulated hernia or intussusception.

Musser ("Medical Diagnosis," 1896, p. 654) refers to acute phlegmonous inflammation of the gall-bladder and gives its symptomatology, but does not supply any information of value in differential diagnosis or etiology.

J. C. Wilson ("Medical Diagnosis," 1909, p. 953) under the head of phlegmonous enteritis says there are no distinguishing features of the disease and recovery does not occur.

Wood and Fitz ("Practice of Medicine," 1897) state that when the mucous membrane of the intestine is infiltrated with pus the condition is known as phlegmonous enteritis. It is a rare occurrence and may be the result of a primary infection of the wall as in malignant pustule. More often it occurs in consequence of ulcer, intestinal obstruction, strangulated hernia, or fecal impaction. Gangrenous enteritis occurs when putrefaction of the necrotic mucous membrane takes place. It is most often present in dysentery and is indicated by the discharge of discolored sloughs of extremely offensive odor with considerable blood.

Pepper ("An American Text Book of the Theory and Practice of Medicine," Vol. II, 817) states that phlegmonous enteritis is a rare affection which cannot be differentiated during life. It is usually secondary to strangulated hernia, intussusception, typhoid fever, tuberculosis, dysentery, and carcinoma.

Frederick Taylor ("The Practice of Medicine," 1911, p. 796) in discussing cholecystitis admits the possibility of a gangrenous termination of an inflammation of the gall-bladder, especially if it contain gallstones and one or more become impacted in the cystic duct.

Reynold Webb Wilcox in a recent work ("The Treatment of Disease," 1908, p. 471) refers to the possibility of gangrene of the gall-bladder with perforation, occurring in the course of acute cholecystitis due to infection with some one or more of the pathogenic bacteria. As a termination, he mentions that the process may be shut off by adhesions and thus form a localized abscess-cavity or it may result in generalized peritonitis.

H. Crouse (*New Mexico Med. Jr.*, Las Cruces, May, 1911) reports three cases of gangrene of the gall-bladder.

H. Riese (*Deutsche medizinische Wochenschrift*, Berlin, Oct. 19, XXXVII, 42 pp. 1901-1911) gives an account of a case of gangrene of the gall-bladder incident to perforation of a gastric ulcer.

A. R. Edwards ("Principles and Practice of Medicine," 1907, p. 655) admits the great rarity of phlegmonous enteritis and considers it solely of anatomic interest. He refers to Maragliano, who described a form probably due to the colon bacillus in which multiple purulent foci are found in the intestinal wall, frequently resulting in perforation.

L. Cheinisse (*Semaine Médicale*, Paris, March 10, 1909, XXIX, No. 10, p. 109) in a paper on phelgmonous enteritis refers to the writings of a Russian clinician who reported five cases of this rare affection since 1899. Cheinisse's paper is very exhaustive and reviews the history of these cases and those mentioned in the other literature of the condition. From this digest of the cases it would appear that the disease shows a predilection for the duodenum and first part of the jejunum and he implies that he believes traumatism is a prominent etiologic factor. Streptococci were isolated in all cases and in one staphylococci were found in addition. A preceding acute catarrhal enteritis was observed in some cases, and in Moisecy's four cases, there was concomitant sore throat or gastritis. In none was there phlegmonous cholecystitis. In all cases the peritoneal reaction was so great that it masked the symptoms of the underlying condition.

C. P. Childe (*Practitioner*, March, 1909) in an article relating to resection of large lengths of the small intestine gives an account of a case with gangrene of that structure.

E. H. Binney (*Australasian Med. Gazette*, Jan., 1908) reported a case of gangrene of the ileum.

Acute diffuse phlegmonous gastritis due to streptococcic infection with fatal termination has been observed by Richard W. Westbrook (*Jr. A. M. A.*, Feb. 26, 1910). This is merely noted in passing to call attention to the possibility of the occurrence of phlegmonous inflammation in any part of the gastrointestinal tract as an independent condition.

In passing it might be well to refer to the cases of epidemic croupous enteritis reported by G. Baermann and O. Eckersdorff (*Münchener medizinische Wochenschrift*, June 8, 1909, LVI, No. 23, pp. 1162-1216) since from the course of this affection it is likely to be confused with phlegmonous enteritis. These cases were observed in Sumatra, and the condition consisted of an acute intestinal affection with tempestuous onset with fever, leucocytosis, rapid pulse, violent colic, blood-stained stools, tenesmus, and speedy fatal termination. Ten cases are reported with autopsy findings. Pseudomembranes were found in the large and small intestine. Streptococci were found in large numbers.

It is well worth noting a certain relationship between pressure in the common duct and the abdominal circulation, which has been demonstrated, especially in connection with this case, in which we are endeavoring to show a relationship between the two gangrenous structures. Thus Ransohoff (*Annals of Surgery*, Oct., 1908) showed by experimentation a marked fall of blood-pressure when the common duct is explored by introducing the finger in the foramen of Winslow. He concluded this was due to pressure on the portal vein. If his conclusions be correct the backing up of the portal circulation might be responsible for the precipitation of necrosis in the intestinal tract. From an academic standpoint this seems reasonable, although we have no means of confirming this supposition.

In a previous paper* upon gangrene we referred to the influence of heart disease, especially endocarditis, in the production of the affection. While it may be drawing some upon the imagination to attempt to connect gangrenous conditions of the abdominal viscera with heart conditions, yet we find that Robert Babcock (*Jr. A. M. A.*, June 12, 1909, p. 1904) has collected a series of cases and quoted all the available literature up to that date showing a relationship between chronic cholecystitis and myocardial incompetence. The point of this is that should there be a true relationship between the pathology of the two structures it is active in all affections of either, and in that event it would be possible to find in phlegmonous cholecystitis some etiological factor in the heart.

*Spontaneous Gangrene. With the report of a case illustrating the ordinary senile type, resulting in spontaneous amputation, and a case of spontaneous gangrene affecting the several extremities successively in the course of acute primary infectious endocarditis. By Albert E. Roussel, M.D. International Clinics, Vol. III, twenty-second series.

Conclusions.—In analyzing the case we have here recorded we find a sudden onset with symptoms of myocarditis, purpura hæmorrhagica, and gastritis with a very rapid course terminating within a few hours in death. In the other cases we have quoted, there were also sudden onset, rapid course, and fatal termination, except in a very few instances. No other case showed evidence of myocarditis although in Eskridge's first case pericarditis and endocarditis were present and in Salter's case endocarditis and symptoms of heart trouble were observed. Babcock showed a relationship between chronic cholecystitis and myocardial disease mentioning a definite case in his own experience, but his case was not of a phlegmonous or gangrenous character. The purpuric spots mentioned in the case in this paper were not observed in any of the other cases.

The autopsy findings were, briefly, emaciation, edema, purpuric spots, ulceration of the lobes of the ears and tip of the nose, extensive gangrene of small intestine, extensive discoloration of the stomach and colon, cholecystitis with ulcerated areas, gray necrotic membrane, and one gall-stone, few areas of fat necrosis in the pancreas, cloudy swelling of the kidneys, pericardial effusion, healed nodule of tuberculosis in the right pleura, congestion of both lungs, active tuberculosis of the right lung, and ulceration of the stomach.

The emaciation may be explained by the tuberculosis although emaciation is not mentioned in the other cases, probably because of the very acute onset of the affection. It can therefore be dismissed as being merely incidental to the abdominal condition.

The edema may be attributed to the heart and kidney conditions and probably existed prior to the gall-bladder and intestinal condition.

The purpuric spots are difficult of explanation, as are also the ulcerations on the lobes of the ears and tip of the nose.

The pericardial effusion, the cloudy swelling of the kidney, and pulmonary and pleural tuberculosis may possibly bear a relation one to the other, but certainly do not bear any definite relation to the intestinal and gall-bladder disease.

Nearly all the other cases have shown a relationship between gall-stones and the gangrenous cholecystitis but here we have one small stone which does not appear to be more than incidental.

In view of the extensive inflammation of the entire gastrointestinal tract beginning with gastritis and gastric ulcer, passing into gangrene in the small intestine, and terminating in inflammation and discoloration in the colon, it is reasonable to presume that it was due to streptococcic infection that extended into the gall-bladder producing similar changes in that structure. We are encouraged in this view by the records of Ungerman, Cheinisee, Westbrook, Baerman, and Eckersdorff, which observers found streptococci in their cases. It will be recalled that the bacterial examination in the case recorded in this paper also demonstrated the presence of streptococci. The cases of gangrenous cholecystitis in the course of typhoid fever further corroborate the view that the affection began in the gastrointestinal tract first and extended by way of the common and cystic duct, otherwise an abscess of the liver would have been observed, especially if the infection had reached the liver through the portal system.

Gangrenous cholecystitis usually results from gallstones, as has already been stated, and gangrenous enteritis most often follows obstruction, strangulation, or intussusception, but the intestinal condition may follow in the course of general pyemia. If we are inclined to concur in this it requires but a small effort of our speculative powers to presume a mixed infection in the tubercular right lung of our patient, which aided by the crippled heart permitted a generalized streptococcic infection of the gastrointestinal tract.

We must therefore conclude that gangrenous cholecystitis may occur independent of impacted gall-stones or typhoid fever and may be secondary to a similar process in the intestinal tract. Also, it must be admitted that gangrenous enteritis independent of obstruction, intussusception, or malignant disease may occur as the result of some virulent infection, probably streptococcic, and may extend into the gall-bladder by continuity of structure. Further, such infection may gain access to the gastrointestinal tract directly or indirectly from localized foci. That the several organs of the chest and abdomen must be below par for the culmination of this process must be acknowledged, since all of the cases enumerated showed more pronounced changes in the gall-bladder and intestines, the more disturbed were the other viscera. In the face of these facts the condition must be regarded as a fatal disease.

2108 Price Street.

RADIOGRAPHY IN PULMONARY GANGRENE.

By EDMUND GROS, M.D.,
AND
MARTIN E. REHFUSS, M.D.,
PARIS, FRANCE.
PHYSICIANS TO THE AMERICAN HOSPITAL

The following case is one of considerable interest inasmuch as it illustrates the importance of a radiographic examination in the diagnosis of pulmonary gangrene and the great value of the latter in enhancing and completing the information given by radioscopy.

Mr. F. T. had a crisis of dipsomania on October 15, 1912, and in the midst of this crisis developed a mouth infection which was soon followed by a troublesome bronchitis. This bronchitis persisted in spite of careful treatment and was accompanied by a more or less mucopurulent expectoration. Finally, in the second week of February, 1913, he began to have abrupt rises in temperature with a slight fetor of the breath and the expectoration of buff-colored sputum which became more pronounced as time went on. The oral condition was carefully treated, inhalations given, and antiseptic intratracheal injections administered. In spite of the treatment the patient continued to emaciate, lose weight, and become distinctly weaker. He was in poor general condition, with sallow complexion and weak heart.

Physical examination at that time was practically negative and it is very interesting to note that about three weeks before the radioscopic examination was made the patient had hallucinations in which he claimed that he had been shot and that the bullet lodged just outside the apex beat. It was to convince him of the fallacy of this belief that he was subjected to *x*-ray examination.

Just before this examination a single sign was apparent; when the patient coughed a distinct and markedly blowing sound, almost like amphoric breathing but more acute and whistling in character, could be heard just outside and above the apex beat. This was heard only during cough, was distinctly gurgling, and confined to one spot.

Radioscopy was then performed by Dr. Beclere and he demonstrated a small lesion or opacity just above and outside the apex beat at the exact point which the patient indicated in his hallucinations. The following day another screen examination was made by Dr. Beclere and the

topography of the lesion seen on the previous day was confirmed, with the exception that in place of the opacity seen on the previous day was a central transparent zone about the size of a silver half-dollar as seen in the screen surrounded by an irregular opacity with the general contour presented on previous examination. No other lesion was visible at that time and auscultation revealed exactly similar conditions. Examination of the sputum revealed bloody mucopurulent sputum, no tubercle bacilli, many gram-positive diplococci and streptococci, many polymorphonuclears and altered red cells, no fibrous or elastic fibers; urine negative.

It was decided that operation was imperative and Dr. Beclere was emphatic as to the necessity of intervention, although Professor Gilbert, who was called in consultation, was less so.

Operation was performed by Dr. Du Bouchet under chloroform anesthesia. The 4th, 5th and 6th ribs were resected, and the lung was plainly visible while the two layers of the pleura were found adherent. An incision was made through the indurated portion which corresponded to the shadow on the plate—and this incision an inch and one-half long was made one inch from the anterior border of the lung right into the induration. After a gush of blood the foul odor observed on the breath was apparent and the gangrenous cavity was opened. The cavity, which was about the size of a hazelnut, was of a peculiar greenish color such as is seen in gangrenous bronchopneumonia. Adhesions were observed between the pleura and pericardium. Finally gauze impregnated with hydrogen peroxide was inserted into the cavity for its antiseptic and styptic effect.

The patient rallied somewhat after the operation and improved temporarily. A foul gangrenous odor came from the wound and the packing was of a dirty greenish brown color such as is seen in gangrenous appendicitis. After operation the sputum changed in character and was more abundant and distinctly blood tinged.

The circulation continued to be very poor and the second day after operation consolidation of the lower left lobe was detected. The patient's condition was such as to require almost constant use of strong stimulants, and despite everything he died several days after operation.

An autopsy was performed several hours later and the entire left lobe was seen to be in a state of red hepatization. The pleuræ were entirely adherent and a large infiltrating gangrenous cavity was found communicating with a bronchus. Connected with it were two other irregular cavities which had passed unseen in the midst of the hepatized lung. There were therefore multiple foci instead of one cavity. The pericardium was intact and in each chamber of the heart was a large preagonal clot which must have existed in part for at least twenty-four hours, absolutely white and containing only white cells, while the red agonal clot was present around it.

The interesting fact is that after each radioscopic examination radiographs were taken to record the appearances presented and while the first photograph corresponds exactly to the image seen on the screen, the second, which was not received until the day after death, shows not only the cavity and infiltrated tissue seen on the screen, but also delicately traced an exact shadow of the cavities or multiple gangrenous foci seen at autopsy. The knowledge of this fact would have interdicted operation.

The importance of the *x*-ray examination of the lung in cases of suspected gangrene cannot be overestimated and although circumstances which demanded it in this case were peculiar its value was self-evident. Radioscopic examination is capable of rendering the greatest service, but this case is but another evidence that the finer structural delineations which are unseen by radioscopy can be revealed very often by a good radiograph.

Since then a case has been reported by Dr. Beclere at the Société de Radiologie Médicale de Paris (*Bull. et Mem.* 39, 1912) in which a focus of pulmonary gangrene was revealed radioscopically and a small cavity suggesting pus with gas above was found. On shaking the patient the phenomenon of Hippocratic succussion was elicited and by various maneuvers before the screen it was possible to determine the approximate depth of the lesion—finally under radioscopic and radiographic guidance the operation was completely successful and the cavity drained.

This case is of interest therefore because it demonstrated (1) The direct connection with mouth infection and poor general condition and the absence of all physical signs until the cavity formed; (2) The value of radioscopy in accurately locating and showing the early infiltration and cavity formation; (3) The value of the radiograph in demonstrating the multiple foci of pulmonary gangrene which could not be perceived by radioscopic examination.

55 Boulevard du Château, Neuilly-sur-Seine.

Pineal Gland Extract in Obstetrical Country Practice.—Wolf tested this preparation in fifty-four cases. Strange to relate he does not state whose extract he employed. In fifteen cases he did not reach his patients until the third stage of labor, when he witnessed an excellent effect in retained placenta and hemorrhage. However, lest the results be temporary only, he followed with an ergot preparation. Aside from this series his results were also excellent in the remaining thirty-nine, apparently not inferior to those obtained by hypophysis extracts, although he admits that in eleven of these cases he was eventually compelled to use forceps.—*Deutsche medizinische Wochenschrift.*

Case of Myelitis Treated with Gymnastic Exercises.—F. Sylvan reports the case of a man, aged 36, who in January, 1910, got a bad cold and had severe pains in the posterior and lower thoracic region. After three weeks his legs began to drag and he gradually lost the use of both legs and had to stay in bed. He went into the Middlesex Hospital where he was treated for myelitis during six months. Soon after he went to the National Hospital and was treated as an in-patient for three months and as an out-patient for eighteen months, and he improved a little. In May, 1912, he started gymnastic treatment. The adductor muscles were contracted to such a degree that he could not get his knees apart, and could walk only with great difficulty. He often had a painful cramp in the left foot. On March 5, 1913, he could walk without difficulty, had no pain and no cramps and could separate his knees quite easily.—*Proceedings of the Royal Society of Medicine.*

Lichen Planus of the Tongue and Lips.—A. Whitfield reports the case of a young man who first noticed a small gray patch on his tongue at Christmas, 1912. This spread until the whole surface of the tongue was involved, and two months later he developed "eczema" of the arms and legs. When shown, the tongue was evenly gray in color to the naked eye, but with a lens this grayness could be seen to be formed by fine white stippling. The insides of the cheeks showed the common white "embroidery" of lichen planus and there was a similar condition of the dry mucous membrane of the lips. On the flexures of the elbows, the groins, the outer sides of the trochanter and the body of the penis (not the glans) there were numerous typical domed papules of lichen. Some, but not all of these, were circumpilar in origin and their grouping was rather unusual in character, being distinctly corymbose in arrangement. The author states that lichen on the mucous membrane of the cheeks is very common, but he thinks such extensive involvement of the tongue and the dry part of the lips is unusual. The rash is not very irritable and undergoes involution after a three weeks' arsenical treatment.—*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

New York, December 13, 1913.

THE EXPERIMENTAL INVESTIGATION OF INTESTINAL INTOXICATIONS.

A GREAT deal has been said and written within recent years about intestinal intoxication and toxemia, but comparatively little has been learned regarding the actual substances that bring about the systemic poisoning. A phase of this subject has recently been investigated by H. Eppinger and J. Gutmann (*Zeitschrift für klinische Medizin*, Vol. 78, Nos. 5 and 6), who set out to determine whether there are substances produced in the intestines which act like hormones on the vegetative nervous system. They note that Eppinger and Hiss have clearly defined one among the many so-called intestinal neuroses, namely, vagotonia, whose clinical manifestations result from a stimulation of the vagus center by certain toxic substances produced in the intestine. The severest forms of general vagus stimulation are seen in cases of meat and sausage poisoning, in which there may develop bradycardia, low blood pressure, diarrhea, vomiting, sweating, salivation, eosinophilia, and spasm of the ciliary muscle with miosis. These symptoms, which closely resemble those produced by pilocarpine poisoning, may also arise, though not to as pronounced a degree, in cases of endogenous intestinal intoxication. Particularly in spastic constipation may one frequently observe an analogous syndrome, in which hyperacidity, hypermotility, gastrospasm, bradycardia, and even extrasystole form the chief elements.

Barger and Dale have succeeded in isolating from ergotoxin one of the ergot derivatives, a substance, β-imidazolylethylamine, which is apparently identical with the decomposition product of histidin, which in turn results from protein disintegration. Histamine, which is another name given to β-imidazolylethylamine, produces when injected intravenously into most animals the typical symptoms of stimulation of the autonymous nervous system, namely, a lowering of blood pressure, with a simultaneous rise of pressure in the pulmonary artery, spasm of the bronchial musculature, bradycardia, uterine contractions, and diminution in the salivary and lacrymal secretions. Barger and Dale isolated a second base from ergotoxin, namely, p-oxyphenylethylamine, which may also be obtained by the decomposition of tyrosin, and is, therefore, named tyramine. This substance resembles suprarenal extract, both in its chemical and in its physiological properties. The above investigators also succeeded in isolating histamine from the normal intestinal mucosa, and suggested that it might be identical with secretin. Other bases have been detected in the human feces, for example, putrescin and cadaverin, both of which are protein decomposition products. Eppinger and Gutmann analyzed the feces of normal individuals and of patients suffering from various intestinal diseases, such as enteritis, proctitis, spastic constipation, paratyphus infection, etc., with respect to the amount of basic nitrogen excreted, and found that there is a marked increase in this excretion in the various pathological conditions of the bowel. The average increase is 100 per cent.

An interesting method of detecting minute quantities of β-imidazolylethylamine was evolved by the above investigators. They found that one or two drops of a 1 to 1,000 solution of the above substance, if rubbed into a superficial scratch on the skin of a human being produces in the course of five minutes a typical urticarial wheal. Histamine was the only one in a large series of bases tested that produced this cutaneous reaction. The next step was to determine whether the feces of patients suffering from chronic urticaria showed an excess in the amount of histamine present. Two typical cases of urticaria showed no such excess. The recent work of Mellanby and Twost is alluded to. These investigators isolated from the intestine a bacillus that converts histidin into imidazolylethylamine. This discovery tends to support the hypothesis that intestinal intoxication is primarily of bacterial origin.

There is another aspect of this subject, however, upon which Eppinger and Gutmann place special emphasis. Histamine has been shown to be an antagonist of suprarenal extract. May not the former, as well as its associated bases, act as a hormone on the vegetative nervous system? If so, the intestinal mucosa would exercise the function of an organ of internal secretion. The question cannot as yet be definitely answered, but is proposed as a fertile suggestion for future research.

ETHER-OIL RECTAL ANESTHESIA.

RECENTLY considerable interest has been manifested in this method of administering ether, and it seems necessary to sound a note of warning against the more or less indiscriminate use of the procedure by those who are not expert anesthetists. The idea of giving ether per rectum is not new. It is only the ether-oil combination which is the new development. During the past few months several anesthetists of this city have been using the ether-oil rectal anesthesia in selected cases, but they are not agreed as to the best kind of oil for admixture or the proper proportion of oil to ether, or as to the proper dosage of ether necessary to induce safe and sufficient anesthesia. Of the various oils, olive oil and liquid albolene have been used most extensively, and in proportions of two or three

parts of ether to one of oil. The dosage of ether has been adjusted in accordance with the weight of the patient, some allowing one ounce of ether to each 30 pounds, and others one ounce to each 20 pounds of body weight. The patient's age and general condition do not seem to have received consideration in determining the dosage, but one ounce of ether has been given arbitrarily for each 20 or 30 pounds of body weight. In practically all cases a preliminary hypodermic injection of morphine and atropine has been given.

It has been claimed that by this method anesthesia to surgical degree is quietly induced in from 15 to 45 minutes; that while some reflexes are not abolished (*e.g.* conjunctival), the abdominal wall is particularly well relaxed; that by withdrawing the remaining mixture shortly before the completion of the operation and injecting a pint to a quart of cold water into the rectum the patient can be restored to consciousness within 45 minutes; that there is less nausea and vomiting; that the method is particularly valuable in operations during the course of a bronchitis or in presence of chronic pulmonary lesions or when the patient is very obese; and finally that when properly administered the method is safe. These claims do not seem to have been substantiated by the experiences of other observers. The rectal anesthesia frequently has to be assisted by the administration of gas or ether or both by the inhalation method; while in many other instances the anesthesia has become alarmingly profound, either while the patient was on the operating table or after he had been returned to bed.

During the last few minutes of the operation it has been the custom to withdraw whatever remained in the rectum and thus, theoretically, prevent further absorption. LeWald and others have shown, however, that after the rectal injection of mixtures containing bismuth it is often possible to demonstrate, by means of the *x*-ray, that a considerable amount of the material has reached, or even passed, the ileocecal valve. As is well known, absorption takes place much more rapidly in the upper than in the lower portions of the large intestine. This is, of course, likely to happen when the ether-oil mixture is injected, particularly if the case be one requiring the Trendelenburg posture for a considerable time. Under these circumstances it would be impossible to withdraw all the remaining mixture and the patient would continue to absorb ether so long as any was present in the upper portions of the bowel. This may account for some of the cases in which the anesthesia has been reported as being prolonged for 24 to 36 hours, or even longer in a few instances. There have already been a few deaths following the use of this method of inducing anesthesia, although they may not have been due solely to an overdose of the anesthetic. In several cases, however, dangerously deep anesthesia has been induced, while in at least one case, where the patient barely escaped death, there is practically no room for doubt that an overdose of the anesthetic was the only factor concerned in the production of collapse.

This method is still in the experimental stage and should, for the present at least, be left strictly in the hands of expert anesthetists. The addition of oil seems to have removed the danger of necrosis of the rectal wall and consequent peritonitis, but no certain means of stopping absorption of the anesthetic immediately upon development of danger signals has as yet been devised. In view of the comparative safety of anesthetization by inhalation of gas and oxygen, or gas and ether, it would seem hardly necessary to return to the rectal method which has had two seasons of trial within the last thirty years and has been twice abandoned as dangerous to life.

POLITICS AND SANITATION IN THE PHILIPPINES.

We publish in another column a letter from Dr. Keen in reference to the report, emanating from an interview with Mr. Dean C. Worcester, that the new Governor-General of the Philippines contemplated the removal of Dr. Heiser from his post of Director of Health in the Islands. Dr. Keen deserves the thanks of the profession for his watchful care of its interests and of the interests of the public health, which are the same thing, and it is gratifying to note the fact, which his letter to the President elicited, that even Mr. Francis Burton Harrison is not entirely indifferent to medical opinion. We do not, however, feel altogether reassured by this gentleman's diplomatic denial of intent to demand Dr. Heiser's resignation. There are more ways of getting rid of an official than by actual dismissal. The proposed changes in the sanitary laws, of which our Manila correspondent makes mention in the letter published elsewhere in this issue, even if not so intended, will certainly result in vexatious hampering of the Director of Health, in depriving him of necessary authority, and in rendering much of his work ineffective.

The Governor-General is, we fear, a sanitarian of the same type as Mr. Poultney Bigelow, who some years ago derided Col. Gorgas for thinking he could keep off yellow fever and malaria by oiling stagnant water, screening doors and windows, or other such like superstitious practices. But, unfortunately, while Mr. Bigelow could only make himself ridiculous, Mr. Harrison has it in his power to undo all the incalculable good that has been accomplished by way of sanitation in the Philippines. The world rings with praise of Col. Gorgas, who richly deserves it; but work of the same kind has been done equally well and under great difficulties by Dr. Heiser, only he is on the other side of the world and the miracle he has accomplished is therefore less well known. What he has done will become apparent, however, if he is forced out or if his hands are tied by ignorant and unsympathetic associates; for once the sanitary measures now in force in that pest-threatened region are relaxed, there will surely some day be an extensive outbreak of cholera or the plague in Manila. In that event one would hardly envy the Governor-General if he had really played politics to the peril of the health of a dependent and helpless people.

Unusual Fertility in Women.

The record instance of human fecundity is that reported by Beer in 1808, in the case of a Viennese who, in the course of eleven labors, gave birth to thirty-two children. Similar, though not as pronounced examples of fertility have been so frequently observed as no longer to excite comment. Fr. von Neugebauer, writing in the *Zentralblatt für Gynäkologie*, July 19, 1913, believes that multiple pregnancy is much more common than the statistics seem to indicate. She alludes to the theory advanced by King of Melbourne, that all mammals have as many offspring as they have nipples, provided that they live under favorable conditions. It would seem to follow that woman with two breasts would normally have twins. As regards multiple births there appears to be operative a numerical law known as the "lex Hellin": twins occur once in eighty labors; triplets once in eighty times eighty labors; quadruplets once in eighty times eighty times eighty labors, and so on. Fr. v. Neugebauer maintains that twin pregnancies are much more common than generally recognized. Many twin pregnancies are overlooked in practice. Upon the birth of a child there may pass unnoticed a rudimentary or blighted twin *in utero*. If every placenta were carefully inspected one would frequently discover a fetus papyraceus, a fetus amorphus, an acormus, etc., or there may be present a rudimentary second egg sac with a rudimentary fetus. As an instance of unusual fecundity occurring in her own practice, the author reports the case of a woman forty years old who, married for twenty years, gave birth normally to five children, and was then infected with syphilis by her spouse during her sixth pregnancy. She aborted, and did likewise in her seventh, eighth, and ninth pregnancies. Following a course of antisyphilitic treatment she carried out her tenth pregnancy to term and gave birth to a living child. The eleventh, twelfth, thirteenth, and fourteenth pregnancies terminated in an abortion. Following another course of inunctions she gave birth to a living child, but the succeeding five pregnancies ended in abortions. Active antisyphilitic treatment was again instituted, and the twenty-first and twenty-second pregnancies terminated in the birth of living children. A number of abortions had occurred, in addition to those above mentioned, but were not observed by the medical attendant. The twenty-third pregnancy resulted in extrauterine gestation and a dead eight-month fetus was removed from the tube. The summary of this patient's reproductive history is as follows: Twenty-two uterine pregnancies, including nine living children of whom eight were nursed, and thirteen abortions; and one extrauterine pregnancy.

Some Results of Historical Research.

Throughout the entire globe there seems to be a concerted attempt at obtaining historical data which must come up to a certain standard of trustworthiness. Naturally in uncivilized countries the work is done by Europeans; but even in the old culture countries documentary and other proofs are revolutionizing our hackneyed concepts of disease in earlier times. Much good work has been done lately through the Section for the History of Medicine and Science of the Society of German Naturalists and Physicians (*Muenchener medizinische Wochenschrift*, October 21), which met last September. Hübotter presented an original Chinese anatomy which could be traced back in part to 3,000 years before Christ. Naturally this work had received many additions like all prehistoric works on science. Despite the distance in time and space a close correspondence with the Greeks and Galen is often apparent, as if their doctrines came originally from China. Neuberger shows that "Hannibal's vinegar" is a myth, because there were no rocks in his pathway over the Alps which were solvent to acids. Houorka showed that women practitioners (not midwives) flourished in old Rome. Ebstein traces the acetic acid test of urine for albumin back to Dekker, in 1674. The urine was also boiled. These tests lay fallow for one and a half centuries and then appeared in various shapes at different hands. "Sweet urine" was recognized by the taste in Hindustan before the Christian era. Water was purified for armies by Arnold de Villanova and others by filtration, the addition of a little vitriol, etc. Fischer traced antisepsis back to Plencicz of Vienna in 1705. The latter had practised medicine in Vienna for over 50 years, and seems to have had the correct ideas as to specific germs, their multiplication, etc. He distinguished between virulent germs and saprophytes and understood autoinfection. Plencicz's work passed absolutely unnoticed by his contemporaries. According to Sudhoff, the city of Basle in 1350 recognized eight infectious diseases. The same list is to be found elsewhere: it includes plague, leprosy, malignant pustule, scabies, trachoma, erysipelas, epilepsy (!) and lung diseases (phthisis?).

News of the Week.

City Death Rate.—For the week ending November 29, the death rate in New York was 12.51 per thousand, representing a total of 1,288 deaths, as compared with a rate of 12.62 and a total of 1,251 deaths for the corresponding week of 1912. The increase in the number of deaths was not proportionately as great as the increase in population. The death rate for the first forty-eight weeks of 1913 was 13.77 per thousand, as against 14.08 for the same part of last year.

Camden Hospital.—In honor of Dr. Simon Baruch of New York, his son, Bernard M. Baruch, has presented to the city of Camden, S. C., Dr. Baruch's birthplace, a hospital building with a capacity of thirty beds. The maintenance of the hospital is provided for by an endowment fund of $80,000 which was a gift from a resident of Camden, and the furnishings have been largely the gifts of Northern men interested in the town. At the dedication exercises on December 1, Dr. Baruch made an address and on behalf of his son presented the deed for the land and the keys of the building to the citizens of Camden. Both white and colored patients will be received, but the two services will be kept entirely separate.

Dental College Dedicated.—The new building of the College of Dental and Oral Surgery on East Thirty-fifth street, New York, was formally dedicated on December 3, exercises being held at the College. Among the speakers were Dr. John H. Finley, State Commissioner of Education, Borough President McAneny, and Dr. John Winters Brannan, representing the Board of Directors of Bellevue and Allied Hospitals.

New Montefiore Home.—On November 30, the

new buildings of the Montefiore Home for Chronic Invalids at Gun Hill Road and 210th street, New York, were opened for inspection and formally dedicated, the occasion being also the twenty-ninth annual meeting of the directors of the home. The plant consists of nine buildings: an administration building, a service building, a synagogue, a dormitory, four pavilions, and the Medical Director's home. They are built in colonial style of reinforced concrete, with tapestry brick and white limestone trimmings. All are of fireproof construction. The site comprises eight acres of land, surrounded by a 60-foot parkway. The annual report of the president, Mr. Jacob Schiff, made at the time of the meeting, states that during the past year 1,083 patients were treated at the Home and at the Country Sanitarium, Bedford Hills, of whom 472 were under treatment at the end of the year. All but 43 of these were free patients. The number of those discharged during the year was 490, classed as improved, 245; cured or well, 5; apparently cured or disease arrested, 121; unimproved, 119.

Washington Heights Hospital.—A campaign to raise $150,000 for a new building for the Washington Heights Hospital, New York, was begun on December 3. Volunteer workers to the number of 400 have been enrolled as collectors, and it is planned that they shall visit every house in that section of the city between December 8 and 18. By the latter date it is expected that the entire amount will have been raised.

Hospital Needs.—The Hospital Saturday and Sunday Association of New York in a recent report states that the cost of running the forty-seven hospitals in the association during the last year was $4,932,309.45, an increase of $382,441.79 over the preceding year. The income from operation during that time was $2,160,957.09, and from endowment $1,023,158.94, leaving $1,749,193.42 to be secured from voluntary gifts. The income of the forty-seven hospitals last year was $18,706.62 less in payments from patients, $25,657.03 less from the city, and $21,890.98 less from endowment. In spite of this decrease, however, the hospitals gave 134,272 days of hospital service, making a total of 2,084,442 days of treatment, of which 1,291,442 days, or 62 per cent., were entirely free.

Personals.—Dr. Paul Haertl of Germany, who came to this country for the purpose of making an inspection of Saratoga Springs and of giving suggestions for the development of the town, sailed for home last week.

Dr. Carl Herschmann also sailed for home last week after having made a study of American athletic training methods, for which purpose he was sent here by the Austrian Government.

Dr. John W. Brannan has removed to No. 48 West 51st Street.

Dr. A. J. Ranney, for twelve years superintendent of Lakeside Hospital, Cleveland, has recently resigned his office because of ill health, and Dr. A. R. Warner, assistant superintendent, has been named as acting head of the institution and will probably be named permanently at the meeting of the directors of the hospital on January 1.

The trustees of the Wesson Memorial Hospital of Springfield, Mass., have placed in the hospital a bronze tablet in memory of Dr. J. H. Carmichael, the first surgeon-in-chief of the institution.

New Paterson Hospital.—Ex-Mayor Nathan Barnert of Paterson, N. J., who has maintained the Barnert Hospital in that city for some years, has offered to give a new building to take the place of the present institution. He has transferred to the city an entire block consisting of sixteen lots, and, if his offer is accepted, will erect thereon in memory of his wife a hospital at an estimated cost of $250,000.

Charitable Bequests.—One thousand dollars for the support of a bed was bequeathed to the French Hospital, New York, by the will of Mrs. J. H. Bacigalupo, who died on November 26.

By the will of the late William Scholle of this city, the Montefiore Home receives a bequest of $4,500, and the Mount Sinai Hospital one of $2,500.

By the will of the late Henry Untermeyer of New York, the sum of $2,500 is bequeathed to the Mount Sinai Hospital Training School for Nurses, the income to be used as a prize to be awarded at the commencement exercises of the school to the student who shall have the best record for kindness and proficiency in the practical duties of bedside nursing during the preceding year.

Measles in Alaska.—A dispatch from Alaska states that measles is epidemic on the islands of Kodiak and Afognak, and that up to November 27 over 100 deaths had occurred in the infected region. Most of the sufferers are natives. The revenue cutter Tahoma was sent from Seattle on November 13 with physicians and medical supplies for the relief of the islanders.

School Inspection in Newark.—The Board of Education of Newark, N. J., has recently reorganized the system of medical inspection in the public schools and has dropped thirty physicians who have been acting as inspectors, leaving a staff of only eight. The staff of nurses is to be increased. The change goes into effect on January 1.

Medical Society Elections.—Southern Medical Association: Annual meeting at Lexington, Ky., on November 19 and 20. Officers elected: *President,* Stuart McGuire, Richmond, Va.; *First Vice-President,* J. W. Jervey, Greenville, S. C.: *Second Vice-President,* F. H. Clarke, Lexington, Ky.; *Secretary and Treasurer,* Seale Harris, Mobile, Ala. Dr. Harris was also re-elected editor of the *Southern Medical Journal.*

Southeastern Iowa Medical Association: Annual meeting at Burlington, Ia., on November 20. Officers elected: *President,* Dr. C. R. Armentrout, Keokuk; *First Vice-President,* Dr. J. S. Gaumer, Fairfield; *Second Vice-President,* Dr. J. N. Patterson, Burlington; *Secretary-Treasurer,* Dr. E. F. La Force, Burlington; *Board of Censors,* Dr. W. A. Sternberg, Mt. Pleasant; Dr. C. S. James, Centerville, and Dr. J. F. Herrick, Ottumwa.

El Paso-Big Springs (Tex.) Medical Association: Annual meeting at Abilene on November 18. Officers elected: *President,* Dr. Granville T. Hall, Big Spring; *Vice-President,* Dr. Samuel R. Cates, Abilene; *Secretary,* Dr. W. R. Smith, Colorado.

Interurban Academy of Medicine: The annual meeting, attended by members from Superior, Wis., and Duluth, Minn., was held at Superior on November 19, when the following officers were elected: *President,* Dr. Charles Delbitt Conkey, Superior; *Vice-President,* Dr. Charles F. McComb, Duluth; *Secretary-Treasurer,* Dr. Andres G. Hoyde, Superior; *Censor,* Dr. Homer Collins, Duluth.

Black Hills District (S. D.) Medical Society: Annual meeting at Deadwood on November 17. Officers elected: *President,* Dr. Felix E. Ashcroft, Deadwood; *Vice-President,* Dr. Thomas W.

Moffit, Deadwood; *Treasurer*, Dr. Frederick W. Minty, Rapid City; *Censor*, Dr. Carlyle Hare, Spearfish.

Eleventh District (Ga.) Medical Association: Annual meeting at Valdosta on November 18. Officers elected: *President*, Dr. Charles W. Roberts, Douglas; *Vice-President*, Dr. James M. Smith, Valdosta; *Secretary*, Dr. John W. Simmons, Brunswick.

Trinity County (Tex.) Medical Society: Annual meeting at Trinity on November 20. Officers elected: *President*, Dr. Charles Horace Bradley, Groveton; *Vice-President*, Dr. George R. Barnes, Trinity; *Secretary-Treasurer*, Dr. William Harris Pope, Trinity.

Tristate Medical Association: Annual meeting at Memphis, Tenn., on November 13. Officers elected: *President*, Dr. John Darrington, Yazoo City, Miss.; *Vice-Presidents*, Dr. William D. McCalip, Yazoo City, Dr. Edward C. McDaniel, Tyronza, Ark., and Dr. H. B. Everett, Binghampton, Tenn; *Secretary*, Dr. James L. Andrews, Memphis, Tenn.; *Treasurer*, Dr. James A. Vaughan, Memphis.

The Association of Southern Medical Women, an auxiliary to the Southern Medical Association, organized at Lexington, Ky., on November 18, with the election of the following officers: *President*, Dr. Lillian H. South, Bowling Green, Ky.; *Secretary-Treasurer*, Dr. L. Rosa H. Gantt, Spartanburg, S. C. The association will hold annual meetings in conjunction with the Southern Medical Association.

St. Charles County (Mo.) Medical Society: Annual meeting at St. Charles on November 12. Officers elected: *President*, Dr. Joseph M. Jenkins, St. Peters; *Vice-President*, Dr. Henry N. Corley, St. Paul; *Secretary-Treasurer*, Dr. Thomas Lee Hardin, St. Charles.

Obituary Notes.—Dr. John Howe Clark, Rear Admiral United States Navy, retired, died at his home in Amherst, N. H., from paralysis, on November 30, aged 76 years. Dr. Clark was graduated from the Harvard Medical School, Boston, in 1862, and thereafter served as a surgeon in the United States Navy during the Civil War. From 1883 to 1886 he was Fleet Surgeon of the Pacific Squadron, and from 1893 until his retirement in 1899 was Medical Director and President of the Naval Examining Board at Washington, with the rank of Rear Admiral. .

Dr. John Guerrant Trevilian of Richmond, Va., a graduate of the Medical College of Virginia, Richmond, in 1861, for many years chief surgeon to the Richmond City Home, and a member of the American Medical Association, the Medical Society of Virginia, the Church Hill District Medical Society, and the Richmond Academy of Medicine and Surgery, died at his home after a long illness on November 24, aged 73 years.

Dr. Charles DeWitt Rawson, Jr., of Otley, Ia., a graduate of the Drake University College of Medicine, Des Moines, in 1905, died at his home on November 19, at the age of 31 years, from injuries received in an automobile accident several days before.

Dr. William Kendall Newcomb of Champaign, Ill., a graduate of Rush Medical College, Chicago, in 1882, and a member of the American Medical Association and the Illinois State and Champaign County Medical Societies, died at his home on November 25, aged 56 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ANNUAL MEETING OF R. C. S.—FEMININITY AND INTERNAL SECRETIONS—LEPROSY—ADDITIONS TO HUNTERIAN MUSEUM—SCARLATINA—INSURANCE ITEMS—OBITUARY.

London, November 21, 1913.

The annual meeting of the Royal College of Surgeons was held yesterday, and some few members attended to make their usual demand for representation on the council. Mr. Makins, vice-president, took the chair, in the absence of the president, who is in the United States. The report showed a satisfactory state of the finances, in spite of a great depreciation of securities held by the college. Mr. Sidney Lawrence, honorary secretary of the Society of Members, wanted to know why the council did not address them by the courtesy title of doctor. The chairman said if any member expressed a desire to be so addressed they would comply with his wish. The resolution embodying the members' demand for votes was then brought forward and carried by the few assembled for the purpose. The mover said the question had been agitated for nearly thirty years, and ought to be settled in democratic fashion. He and his supporters seem to think the blessed word democratic is synonymous with right. But what are called the rights in this case are settled by the charter of the college, and one gentleman said he had been studying that document and found to his indignation that the members were impotent as regards the government of the college and what was wanted was a reform of the charter.

The truth seems to be that although called members they are in fact only licentiates and form no part of the body corporate. Their right is to practise surgery. This they obtain from the college, which grants it under the royal charter. It is granted on passing an examination. For this they pay a fee—the price of the license. That is the only money they pay, and it is disingenuous to talk as they constantly do of contributing more of the income of the college. An urgent whip failed to secure much of a meeting, for when a resolution about the regulations was about to be put a count-out closed the proceedings, only twenty-nine persons being present and thirty being necessary to form a quorum.

The special discussion arranged for the Gynecological Section(R. S. M.), this session on the "Relation of the Internal Secretions to the Female Characteristics and Functions in Health and Disease," was duly opened on the 6th inst. by Dr. Blair Bell in an elaborate paper which had been thoughtfully put in type in advance, and was distributed to the audience as it will appear in the "Proceedings" of the society. Looking at the question from a broad standpoint, Dr. Bell regarded femininity as entirely dependent on the internal secretions. Moreover, to these same secretions he attributed the production of the female characteristics, both primary and secondary; by them, also, directly and through the general metabolism, the changes at puberty were initiated. The internal secretions were then concerned in the maintenance of the characteristics and functions they had produced. These secretions act collectively as well as individually. The removal of one organ producing

them brings about changes in the others and also in the general metabolism. The pathology of many obscure conditions connected with sex characteristics and development is explained by these considerations. So, too, may be traced the influence of the internal secretions on the psychology of women, on menstruation, and the metabolism of pregnancy. Irregular primary and secondary development of the organs and functions were then considered and afterwards derangements of the fully established female characteristics and functions. The results of partial and complete removal of different ductless glands from animals were shown in a series of tables and microphotographs.

The second paper was contributed by Miss L. McKroy, M.D., who had been invited to continue the debate. Her paper will also appear in the "Proceedings." She dwelt on the importance of collaboration between laboratory and clinical workers and thought more exact comparisons were required of the variations between different species of animals and mankind. In her view the secretions modified sex development, but not secondary characteristics which probably were due to cell development at a very early period of embryonic life. Clinical records were needed as to the effect of oophorectomy at different periods and as to when hysterectomy combined with it. The clinical aspects of ovarian transplantation and the influence of ovarian secretion on metabolism and the other internal organs of secretion and these in turn on those of menstruation were considered. The treatment of disorders of this function at puberty, and at the early menopause were specially mentioned, and the use of glandular extracts said to give encouraging results. A number of invited speakers took part in the discussion.

Dr. H. Bayon has been giving some demonstrations on leprosy. On Wednesday he gave a lantern lecture and yesterday afternoon discussed the subject at the Tropical Medical Society. He declared infection only occurred in about 2 per cent. of persons living under the same roof, and it is not known how contagion takes place. About 2 per cent. of cases improved when left untreated, but in selected cases 5 out of 10 might be gotten to improve, so that good was being done. The bacillus of leprosy was so slightly toxic that it was necessary to concentrate the extract in order to treat the disease by injections. The toxins of the bacilli were soluble in water. The method was not of value for diagnosis as early cases did not react. Dr. Bayon showed on the screen early cases in which the symptoms had disappeared, but said it would not do to talk about cure until 5 to 10 years had passed. The treatment by the soluble toxins was quite useless in advanced cases, but he thought the outlook at present was more than it had ever been. Different rules and regulations had been made respecting lepers in various countries, but in India, the Sudan and other parts arrangements were not yet completed. In Basutoland, 25 years ago, only about 300 lepers were living; the government declined to interfere, and now there were 800, and the cost of dealing with them would run up to about £50,000. In South Africa about one-half the lepers were segregated. In the Philippines the Americans had reduced the number by 90 per cent., and the sooner we followed their example the less would be the cost. Segregation with the cooperation of the patients is the ideal plan.

Dr. P. Abraham spoke of the proposal to establish a leper institute in London, and argued that it should be for all diseases of the skin. Dr. Sandwith hoped that a potent drug would be discovered for leprosy such as salvarsan proved in other cases, and he was glad that Dr. Bayon could speak well of intramuscular injections of chaulmugra oil. There was once much leprosy in England and segregation should be resorted to in case it should return.

A party of members of the Catford Natural History Society, led by their president, Dr. Percy Ames, paid a visit to the Royal College of Surgeons, where they were received by the conservator of the Hunterian Museum, Prof. A. Keith, who pointed out some of the most interesting and recent additions. Among these were some casts of skulls which showed the boldness of surgeons in the Neolithic period—say 4,000 or 5,000 years ago. In one of them half the roof of one side of the cranium had been cut away by some sharp instrument—probably of flint. The edges of the wound had evidently completed the process of healing, so it was quite certain the patient had survived this formidable treatment. Prof. Keith said that trephining was often done by French surgeons of that period, but only rarely by the English, for so far he had met with only one specimen, although it was known that Cornish miners trephined until comparatively recent times. The museum had of late acquired a number of skulls of native people, showing that they had been trephined by natives. Dr. W. E. Redman had presented a native practitioner's outfit and examples of his work. Mr. Donald Atkinson, who explored an ancient burial place in England, found a skeleton with weapons showing he had lived and probably fought at the early time of the Saxon invasion. He was an old man and the bones deformed by rheumatic disease. Dr. Keith pointed out how the skull was deformed by earth pressure, which always destroyed its symmetry, though it was possible by exact methods to restore the original shape with some approach to accuracy. Another skeleton was of a boy of about 16, found by Mr. Moir, with fragments of a vase, which Mr. Reginald Smith considered to belong to the neolithic or beginning of the Bronze period. This afforded an opportunity of studying the physique of an English lad who had been dead 5,000 years or more, and which Prof. Keith found did not differ in any way from modern boys of his age.

The Hospitals Committee of the Asylums Board reported on Saturday that during the autumn it had been at times impossible to admit immediately every case of scarlatina, on account of deficiency in the supply of the nursing staff. The officers of health were notified of this and asked to furnish lists of the most urgent cases. A large number of institutional nurses had been engaged, and the P. M. O. requested to report on the terms and conditions of employment of the staffs at the Board's hospitals for infectious diseases and state any views he may have as to making the service more attractive. In reply to a question the chairman of the committee was glad to state that no longer was any case waiting for admission, and he thought they were now able to deal with any case applying. The only difficulty had really been a lack of nurses for a time.

Mr. Kingsley Wood, who is on the Insurance Advisory Committee, speaking at an Approved Society on Saturday corrected some misleading accounts that had been circulated about the surplus fund. It now amounted, he said, to £1.40,000, because 400,-

000 persons had not chosen their panel doctor. It was not only a London matter, and there must be an unallotted surplus of above a million. The London committee had been advised by eminent counsel that they could not divide among panel doctors their accumulated sum. He thought it would have to come before the law courts. Possibly some might be distributed among panel doctors. It is difficult to see any equitable reason for such a course. He suggested establishing a great nursing scheme for London, for which no provision had been made, and which would alleviate much suffering, especially among women of the industrial classes.

Contemporaneously with the foregoing, a meeting of the Medical Guild was being held in the Edinburgh College of Physicians at which a resolution was adopted to carry on an uncompromising opposition to the methods of administration of the act. It was said that it had been compelled by circumstances to join the panel, but felt it a hateful system, which deprived them of their rights as citizens. One member called it blackmail, and said had it been charitable the profession would have supported it. Another said Mr. Lloyd George appealed to cupidity —the lowest sentiment. Above 100 practitioners, I hear, were present and unanimous.

On the same day there was a conference of West of England and S. Wales Provident Societies, which resolved that the present system was cumbersome and costly, and demanded a State medical service.

Last week the *Lancet* came out in new type—new, but old, for the larger size now adopted, or readopted, is almost precisely that in which the first number was printed in 1823. I congratulate the proprietors, for the journal is improved in appearance and much easier to read—almost as easy as the MEDICAL RECORD.

Dr. R. L. Bowles, J.P., consulting physician to the Folkestone Hospital and the St. Andrews Convalescent Home, died on the 15th of November, aged 79. He took M.D. at St. Andrews and was made F.R.C.P. in 1882. He contributed freely to the journals and societies on a variety of subjects.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

PATHOGENIC CYCLE OF THE CHOLERA BACILLUS—UNEXPLAINED CASES OF CHOLERA—APPARENT CASE OF LEPROSY—ABSENCE OF PLAGUE CASES—CHANGES IN THE BUREAU OF HEALTH—PERSONAL.

MANILA, October 31, 1913.

MUCH additional evidence is coming to light to support the hypothesis that the organism of cholera undergoes a definite cycle during certain stages of which it becomes virulent and probably at other stages it is nonpathogenic. During the past two years cholera has not occurred in the Philippines in recognizable form and faithful investigation fails to trace the infection to having been introduced from a foreign country. Stool examinations are made of all steerage passengers and during the past year no cases of cholera or cholera vibrio carriers have been found at the quarantine inspection which is conducted of all foreign vessels by the United States Public Health Service. It is held that there is no good reason why cholera should not be constantly present in endemic form in the Philippines as well as in India or other countries. The climate and the habits of the people are much the same. Among the Manila cases up to October 20, 66 contact groups or a total of 960 persons were examined and among these 40 showed some type of vibrio and 29, or 3 per cent, harbored the true cholera vibrio. In order to make a further test of this matter, a group of 25 persons was chosen in a slum block in which no cholera had yet occurred, and in one of these groups a cholera vibrio carrier was found. For test purposes a stool examination has been begun of the inmates of the San Lazaro Insane Hospital in Manila and the first person examined has proved to be, according to the Bureau of Science, a true cholera vibrio carrier. On the other hand, 220 prisoners confined at Bilibid Prison were examined for cholera vibrios with negative results.

From the foregoing it appears possible that cholera organisms in some form may be constantly present in some human intestines and when the stage of their cycle is reached during which they are pathogenic for another individual, and if the conditions for their transfer to a susceptible individual are favorable, an outbreak of cholera may be started. After the first cases of cholera, the spread of the disease perhaps depends on contact infections, and the thoroughness with which the disposal of human excrement is carried out probably largely determines whether a cholera becomes epidemic or is promptly eradicated. In a place like Manila, the proper disposal of all human excrement has not yet been accomplished. Many of the poorer sections of the city are only tidal flats. The residents are too poor to provide themselves with a sewer connection and the public closets are often so far removed that pollution of the ground surfaces under and near the houses in these sections undoubtedly takes place. As children play around such premises and flies, roaches, and other insects possibly may transmit infection from such ground surfaces to the food of the people, it will be understood how readily the cholera may spread when it makes its appearance in a section of this kind. There also seems to be a close relationship between vaults and privies and cholera. At 57 houses from which cholera cases were taken 10, or only 17 per cent., were found to have a water closet system for the disposal of human excrement and in almost all of these instances a vault or privy was in the immediate vicinity.

Many cases of cholera continue to occur in which the origin of the infection cannot be traced. For instance, on October 15 there appeared a case of cholera in a child nine years of age in the town of Novaliches, which is located in an isolated region about ten miles from Manila. Upon inquiry it was learned that the only foods which were introduced into the household that came into the town from the outside were rice and fish and that both of these were cooked before being eaten. On account of the fact that cholera occurred in no other house in Novaliches, it would seem safe to infer that at least no general food infection could have taken place. Water was obtained from the town well.

Another case of cholera occurred on the steamship *Muncaster Castle* in one of the members of the Indian crew. This vessel arrived in Manila six days out from Singapore on October 14 and anchored in the bay until October 18. None of the crew went ashore. Stevedores, however, from shore went aboard for the purpose of discharging cargo during this period. On October 18 one of the Indian members of the crew became suddenly ill and at San Lazaro Hospital the diagnosis of cholera

was confirmed. In this case no food or water for the crew was taken aboard at Manila. The food used was ship's stores which were secured at Singapore and had been on board for more than two weeks at the time that the Indian became ill. It is assumed that in this instance a cholera carrier among the stevedores must have carried the infection on board, perhaps to a toilet, and that the Indian became infected in that manner.

A girl who was admitted to the San Lazaro Hospital on January 5, 1911, and was clinically and microscopically diagnosed upon admission as a leper, was released on October 30, 1913, on probation, after having been negative for leprosy for a period of two years. This patient received the chaulmoogra oil by the hypodermic method under the same circumstances as did the two previous lepers who were reported as having been discharged, apparently cured, during June.

With the exception of the case of human plague which occurred in Manila on September 19 and the rat infections, the last of which took place on September 11, no plague of any kind has been present in Manila since June, 1913, from which it would appear that the measures which were taken to destroy the plague infection have been successful.

Since the advent of the Democratic administration in the Philippine Islands, which began on October 6, 1913, a number of projects have been presented to the Legislature for changing existing sanitary laws under which the Bureau of Health is at the present time administered. For instance, it is proposed to appoint a Council of Hygiene to consist of seven members. This Council is to have absolute control of all medical and sanitary matters in the Islands. Instead of having matters under one head, as at present, it is proposed to make the Director of Health the executive officer of the Council, thus virtually returning to the old form of board administration which was abandoned in 1905. It is also proposed to transfer the Philippine General Hospital, which is now a division of the Bureau of Health, to the University of the Philippines. It is understood that instructions have also been given that in future no American medical men are to be appointed. All vacancies are to be filled by Filipinos. The abolishment of the Bureau of Science as a separate entity is also proposed and hereafter it is to form a division of the University of the Philippines. In addition to the foregoing, instructions have been issued that owing to the low state of the Insular Treasury, reductions in the amounts heretofore allowed for maintaining the Bureau of Health must be made. Just to what point these reductions are to go has not yet been definitely determined.

Dr. S. C. Gurney of the Constabulary, Dr. B. C. Crowell of the College of Medicine and Surgery, and Mr. E. L. Walker of the Bureau of Science have gone to Saigon as delegates of the Philippine Government to attend the Third Biennial Meeting of the Far Eastern Association of Tropical Medicine. Dr. Butler went as the representative of the U. S. Navy. The Congress will hold sessions from November 8 to November 15.

THE HEALTH OFFICER IN THE PHILIPPINES.

To the Editor of The Medical Record:

Sir:—Not long since you published an editorial relating to the alleged demand by Mr. Francis Burton Harrison, the new Governor-General of the Philippines, for the resignation of Dr. Victor G. Heiser, the Director of Health.

I was so distressed by this report that I wrote to President Wilson an earnest letter in reference to it. I have just received from Brigadier-General McIntyre, Chief of the Bureau of Insular Affairs of the War Department, a letter, of which I enclose for you a copy, by which you will see that this report was entirely incorrect.

Inasmuch as your editorial gave great prominence to this matter, it would be only just to Mr. Harrison and the President that equal prominence should be given to the correction of this unintentional mistake.

W. W. Keen.

Philadelphia, December 5.

WAR DEPARTMENT,
Bureau of Insular Affairs,
Washington.

December 1, 1913.

Dr. W. W. Keen,
1729 Chestnut Street,
Philadelphia, Pa.

My dear Dr. Keen:—Your letter of November 21st to the President with reference to the newspaper report that Mr. Francis Burton Harrison had demanded the resignation of several Chiefs of Bureaus in the Philippine Islands, among them being that of Dr. Victor G. Heiser, the Director of Health, was, after acknowledgment, sent to this Department.

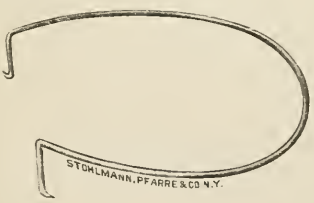
While we had no information which would lead us to believe that the newspaper report was accurate, we made the matter the subject of inquiry and we are advised in a cablegram from the Governor-General that he had not and did not contemplate the removal of Dr. Victor G. Heiser; that his invaluable experience and rare professional qualifications were fully appreciated. This view of Dr. Heiser's service conforms fully to the view which the War Department takes. Very sincerely,

Frank McIntyre,
Brigadier General, U. S. Army,
Chief of Bureau.

A PERINEORRHAPHY RETRACTOR.

To the Editor of the Medical Record:

Sir:—Dr. A. Reich, in a recent number of the Medical Record described and illustrated a self-holding spring retractor which he has designed for use in perineorrhaphy and other gynecological operations. The instrument in its essentials so nearly duplicates one which I presented to the profession over ten years ago that I am constrained to request an opportunity in your columns to claim priority.



The instrument which I devised has been continuously on sale by Tiemann & Co. and although they at first insisted upon using spring steel in its manufacture, they later consented to make it of phosphor bronze or, as I much prefer, of German silver wire. This preference is based upon the fact that the latter metal possesses sufficient flexibility to make any amount of desired retraction and at the same time

is capable of being weakened or strengthened at will by the operator to suit the needs of any case. My instrument is as useful in a perineorrhaphy as in an incised wound. The shape of this sharp self-holding retractor obviates the necessity of a guard near the point, which was doubtless added in Dr. Reich's instrument in order to prevent the points from piercing the tissues too deeply. I also devised a form of blunt retractor on the same general principle. A large-sized retractor of this type may be used in the vagina in place of the usual bivalve speculum.

The second illustration in Dr. Reich's article shows the wire bent at its middle into a spiral spring. I found by experiment that such a spiral bend neither strengthens nor in any way improves the instrument. It only complicates matters and was hence omitted in my retractor.

The original instrument was presented before the surgical section of the Academy of Medicine on February 9th, 1903, and the article describing it was published in the *Journal of the American Medical Association* in April of that year. In that paper attention was called to the fact that the principal field of utility of the retractor is in general emergency operations or those in the doctor's office work where the desired number of assistants are not available. Even where the usual number of assistants are at hand the use of this instrument may permit them to help the operator in other ways.

In ordinary surgical work it is easily applied and quickly shifted and by reason of its shape will lie flat upon the surface of the body, out of the way and stay where it is put. Where the field of operation is large it is convenient to use two of the retractors with their openings facing each other. Three sizes with their diameters respectively two, three, and four inches, with wires of calibers to correspond, make a useful working assortment. Time has proved the worth of this form of retractor in other hands than my own.

WILLIAM S. THOMAS, M.D.

7. The Effect of Nitrogenous Waste Products in the Blood in Chronic Interstitial Nephritis. M. Seymour.
8. The Terminology of Medicine in Relation to Its Original Sources. S. Delano.

1. Clinical Value of the Wassermann Reaction.—A. Post states that the Wassermann reaction is of use for two different purposes: first, for diagnosis, and second, as a measure of the effect of treatment. As a measure of treatment, it is taken before treatment is begun, at intervals during treatment, and after treatment has been omitted for a length of time. When found positive before treatment and negative after treatment, it shows that treatment has had an effect on the disease. Sometimes there is a gradual reduction in the strength of the reaction in successive tests. It may be reported +++ before treatment, ++ after treatment has been begun, + a little later and negative a little later still. When the reaction is thus extinguished, there is always room for hope that the disease is absolutely cured. Unfortunately, the reaction is known to return to positive in some cases. The reaction may be rendered negative by treatment when the disease is not cured, exactly as other symptoms may be made to disappear.

4. Transfusion by Means of Glass Cylinders.—A. R. Kimpton describes this method which he has devised in conjunction with J. H. Brown. It consists in the use of glass tubes having a capacity of 150 or 250 c.c. These are corked at one end, below which there is a side tube. The other end tapers to form a cannula. The tubes are sterilized and coated on the inside with a mixture of stearin, paraffin, and vaseline, in the proportions of 1, 2, and 2. The technique of using these tubes is as follows: A tourniquet is placed on the donor's arm tight enough to give venous congestion and still allow arterial blood to flow in. With novocaine a vein just below the elbow is exposed cleanly, through an incision about one and one-half inches long. This vein is tied off proximally and a ligature placed around it distally, but *not* tied. This ligature is raised by an assistant, thus acting as a clamp. The vein is now transfixed by a cataract knife and a slit made. A similar vein of the recipient's arm (without a tourniquet) is prepared in a like manner, except it is tied distally. The cannula of a tube is now inserted into the vein of the donor and held upright until filled by venous pressure. This usually takes not over two to three minutes for a 250 c.c. tube. If not filling well, this usually means that the tourniquet is too tight. While filling, the donor is instructed to open and shut his hand. This perhaps hastens the inflow. Being filled, the tube is withdrawn and held on its side with the side piece uppermost to prevent the blood from running out. The cannula is now inserted into the vein of the recipient and held in an upright position. An actual cautery bulb pump is attached to the side tube and by a little pressure the tube is emptied, the cannula being withdrawn while still a little blood is left in it. Several tubes may be filled and emptied at one operation.

1. The Treatment of Ataxia.—W. J. M. A. Maloney begins the treatment of ataxics who are not bed or chair ridden by utilizing simple mechanical aids to minimize ataxia when walking. A high shoe or boot, specially strengthened with leather on the outer side of the ankle, increases the support at the ankle and prevents the foot turning in. The heel is low, wedge shaped, the base of the wedge being on the ground, and is continued along the outer side of the shoe. A welt as broad as the patient will permit (usually about one-quarter inch projects) surrounds the sole. A steel plate is (in the beginning in severe cases) placed in the sole to prevent bending. The shoe should be as light as is consistent with maintaining its shape. When the shoe is on the ground it rests with its whole bearing surface. The patient gets support from every part of this broadened surface simultaneously. The occasional sudden "giving" at the knees and ankles has a very demoralizing effect upon ataxics. The patient is made to lie down, blindfolded. He is enjoined to dismiss all thoughts of extraneous affairs, to allow his mind to tranquilize, and to attend strictly to what he is told. The room is maintained as quiet as possible to avoid dis-

tracting him. He is then ordered to relax the muscles first of his face, then of his neck, then of his trunk, and then of his limbs. Each order is repeated and restated, first alone, and then linked with the preceding order. The whole process is conducted slowly and with suitable pauses. From these relaxation exercises, practised blindfolded, three results are attained: First, ineffective, often useless, and sometimes completely disconcerting muscular contractions which have been acquired in attempts to balance, are got rid of so that the coordinating exercises can be begun on an unconstrained musculature and not superimposed upon existing habit contractions. Secondly, active relaxation confers a great training in attending to muscular sense impressions. Thirdly, the patient becomes less fearful and more receptive because, in so far as fear is maintained by its motor expressions in his attitude, it is diminished. Next movements are begun. Passive flexion and extensions of the ankle are first practised. Then the knee and the hip of the same limb are similarly exercised. The trunk muscles are coordinated by relaxation and movement. The head and neck muscles are similarly treated. Creeping movements are then taught. Finally walking is taught. Relaxation should be as zealously practised as are movements.

2. **Diagnosis of Arteriosclerosis.**—L. F. Bishop points out a distinction between arteriosclerosis, which he characterizes as a degenerative disease of the body in which the heart and blood-vessels take the most prominent part; and endarteritis, which is essentially a disease of the blood-vessels. These conditions are frequently confounded with each other. The author believes that the general disease is due to sensitization of the cells to particular proteins either of food or of bacterial origin, the continuous action of which leads to progressive damage to the cells. The therapeutic test is a valuable aid in diagnosis. If an individual, with a blood pressure in the neighborhood of 200 mm. Hg., precordial pain on exertion, albumin and casts in a urine of low specific gravity, profound depression of spirits, high hemoglobin and some numbness of one-half of the body or slight aphasia, who is put upon a low protein diet, subjected to a phlebotomy, compelled to exercise, deprived of his salines, and given suitable treatment of the intestines, does not make a comparative recovery, the author is inclined to believe that he is suffering primarily from endarteritis, disease of the kidneys, or other localized organic disease. But if such a subject does make a comparative recovery, in that his blood pressure falls to his *optimum* pressure, he recovers from his depression and cardiac pain, and he is able to resume his normal occupation, the author believes that he is suffering from a degenerative disease of the whole body, of metabolic origin and, under suitable supervision, no account need be taken in the diagnosis of the bugbear of progressive sclerosis.

3. **Medical Treatment of Surgical Cases.**—J. H. Jopson believes that in practically all surgical cases there are certain fixed indications for medical treatment, less in some and greater in others, and that while such indications can be reduced in number, they cannot be done away with entirely. In some instances they are acute, and in others complicated and demanding great therapeutic knowledge and skill to successfully cope with them; moreover, that their proper treatment is modified to some extent by the surgical conditions present, and by operative as well as nonoperative surgical methods of treatment. In a thorough organization of hospital staffs which provides for cooperation of physician and surgeon in the line of treatment at all times, there are opportunities for improvement which only such association affords. Something more than a haphazard cooperation at critical times is needed to insure success in all cases, and in all plans for hospital reorganization and reform some provision must be made in this direction. If the physician on duty, with his assistants, could pay weekly or semi-weekly visits to the surgical wards in company with the surgical staff, and go over the medical treatment of cases with the surgeon, there would be afforded the opportunity for the medical man to familiarize himself with the needs of surgical patients, and for the physician and surgeon together to foster methods of preoperative and post-operative treatment that not only would add greatly to the comfort of the patient, but would in time greatly increase our therapeutic knowledge and open new fields of medical research.

1. **Experimental Production of Gastric Ulcer.**—E. C. Rosenow notes that the intravenous injection of streptococci of the proper grade of virulence may be followed by ulcer of stomach and duodenum. The ulceration is due to a localized infection and secondary digestion. The ulcers are usually single and deep with marked tendency to hemorrhage and perforation, and resemble the human gastric ulcer in many respects. When we take into consideration this close resemblance, that injection of streptococci which have grown in tonsils produce the lesions, and that the virulence of the germs when the affinity for the stomach is greatest is of such character that a general infection does not occur, it appears altogether reasonable to suppose that in man gastric ulcer may be caused by streptococci also. The supposed relation between infected tonsils or gums and gastric ulcer may be due not to the swallowing of bacteria, but to the entrance into the blood of streptococci of the proper kind of virulence to produce a local infection in the wall of the stomach. Many other observations might be cited such as associated infections of the gall-bladder and appendix, which suggest that gastric ulcer may be due to streptococci.

6. **Polyposis Gastrica.**—J. S. Myer reports a case of multiple adenoma of the gastric mucosa diagnosed during life and operated on. The operation was followed by death twelve hours later, permitting a thorough autopsy and examination which revealed little besides the stomach conditions. The diagnosis was made from the presence of a small polyp obtained by lavage and a large one in the feces. The author thinks it possible that much help could be obtained in future cases by roentgenoscopy and that achylia with unusual mucus production should be considered suspicious, and in severe gastric hemorrhage in a patient with achylia gastrica, with normal or increased motility, polyposis is more that probable. Invagination of the pylorus by a polyp could hardy be mistaken for any other condition after one has experienced the peculiar palpatory findings met with in polyposis gastrica.

9. **Hospital Costs.**—T. Howell discusses the problem of hospital costs and the causes of their variations. These costs include only the operating expenses, and as com-

puted by hospitals are only about 60 per cent. of the true cost. The hospital with an operating cost of $1 a day and the other of $3 represent the two extremes. The first represents the so-called city hospital operated in connection with almshouses and restricted by small appropriations. The other represents a restricted class of wealthy hospitals where economy is not so essential. Neither of these represents the average and they are not discussed here. Taking representative hospitals, city and private, we have costs from $1.25 to $2 per diem per patient, while another class, mostly private ones, have costs from $2 to $2.75. These are the two typical classes, and their equipment and buildings are very similar or identical. The initial cost of the $2.50 a day hospital is probably somewhat greater than that of the other. The actual factors affecting hospital costs are first, location; second, amount of scientific work done; third, number of employees and salaries paid; fourth, medical school connection; fifth, proportion of private room to ward patients. The hospital in the large city where standards are high will cost more to maintain than one in a small city for the same reasons that the cost of a family varies likewise. Hospitals located in the South, other things being equal, should have lower costs than those in the North, the question of fuel accounting for this one thing. The author believes that it will be found that the payrolls are the most influential factor in determining the average cost per patient. In the low-cost institutions the proportion of employees to patients is about two to three, and this is reversed in the high-cost hospitals. Municipal hospitals outside of the large cities are apt to be controlled by an economical city government which keeps their cost down. Another factor is that certain city officials and their clerks do the work for them that private hospitals must pay for. Hospitals which do high-lass, scientific and educational work are bound to be more expensive than those which do merely routine clinical work, and they are likely to have a more exacting and important class of cases. He has no statistics of American hospitals connected with medical schools, but in London such are more expensive. The larger the proportion of private room to ward patients the larger will be the average cost per patient. Contrary to the general belief, larger institutions have higher per capita costs than small ones, owing to the broader lines on which they work and their more varied activities. The author does not believe that it will be possible to standardize hospital costs on account of the varying conditions that exist. Each institution, according to its own peculiar conditions and the demands made on it, is a law unto itself.

6. A Case of Tumor of the Pituitary Body. A. L. Taylor.

2. Some Requirements for Modern Clinical Teaching.—Sir Dyce Duckworth does not accept the pronouncement that modern medicine is gradually becoming a branch of experimental science. Medicine is an art guided increasingly by the disclosures of scientific researches. The physiologist's standpoint is not that of the physician. The former is not a bedside artist and has little knowledge of the inward human elements in the ailing individual. A rational empiricism is a fine part of the art of medicine. The doctrine of the diatheses should be taught. Human beings are not so many ninepins turned off from a lathe out of a block of wood. In the arthritic habit or diathesis, we find a specific readiness for infection by the peccant bacteriological elements which induce rheumatic fever in the earlier decades of life. Later on we find in this class a marked tendency to the perverse metabolisms which engender gout and the protean phases of that specific malady. The strumous habit of body, with its two varieties of refined and coarse physiognomies, presents us with a soil which is the most favorable of all for the cultivation of the bacilli of tuberculosis, and for most of the vicious microbes we have knowledge of. A close study of these two distinct habits of body indicates that there is a remarkable antagonism between them. The arthritic diathesis provides the worst possible soil for the tubercle bacillus, which can hardly lodge or develop in it. The scrofulous soil is little friendly to rheumatic infection, and rarely disposed to the morbid metabolisms issuing in gout. The inherent vitality of the patient is a great element to be reckoned with. Disregard of this factor probably accounts for more gloomy prognoses than are justifiable, the vital resistance of the patient not having been appreciated. The author does not perceive any special advantages in clinical teachers being debarred from private practice. He also admires the methods pursued in the Parisian school, for there we find the art of medicine bound up with the best scientific side of it. The great clinicians there have the benefit of the fuller experience of private practice and consulting work, and they certainly devote themselves assiduously to their duties in the wards. A clinical teacher has great responsibilities. Before all things he must be human and sympathetic, never forgetting that he is dealing with patients who have souls as well as bodies, and not with mere "cases." He has to illustrate and teach good manners as well as medicine. He must believe in his art, for a sceptic in therapeutics can teach nothing. He should not pursue many novelties, for novelty-hunters have not been well instructed in the principles of medicine in their early career. To these requirements the author would add, lastly, a large measure of tact and common sense, no small amount of geniality and humility, and a due degree of such dignity as rightly belongs to men charged with serious duties to their country and their fellow creatures.

3. Neurasthenia and Its Treatment.—J. S. Risien Russell states that the cases of neurasthenia fall conveniently into one of three main groups: cerebral, spinal, and cerebrospinal, and that the first group may be further conveniently subdivided in view of the fact that in some of the patients the symptoms are physical, whereas in others they are purely psychical, although in many both physical and psychical symptoms obtain. The headache, vertigo, and other purely physical symptoms that belong to one variety of the cerebral type, and the phobias, obsessions, and other mental symptoms that belong to the other; the feeling of physical exhaustion, pains in the back, weakness of the legs, and other similar symptoms belong to the spinal type; and in the cases that constitute the cerebrospinal type cerebral and spinal symptoms obtain in the same individual. In the large majority of cases there is no other method of treatment that offers the same chances of success as the so-called "rest cure," provided it is conducted in a home given up to treatment of the kind. Personality plays so important a part in the treatment of neurasthenia that it is highly necessary to secure people who, while sympathetic, have nevertheless sufficient force of character to inspire confidence in the patient. In some cases of neurasthenia suggestion is a valuable adjunct in the treatment. Massage and the application of faradic electricity form part of the usual routine in the ordinary rest cure, but there are patients who are not helped by massage, as it proves too irritating to them, aggravating all of their symptoms and increasing their insomnia when this happens to be a symptom. Massage should be employed only in these patients if an adequate amount of rest can be secured during the course of treatment, as other-

wise it is calculated to do harm in the majority of cases. Of hydropathic methods the pack and warm baths find a place, especially in the treatment of insomnia; while the needle bath and spinal douche, which are useful in many cases of neurasthenia, are especially so in the sexual and in the spinal forms of the affection. Arsenic is one of the most useful tonics that can be employed in the treatment of these patients. The glycerophosphates, lecithin, and allied substances, and in some cases iron, all find a place among the useful remedies in neurasthenia.

5. The Primary Cause of Rheumatoid Arthritis.—H. W. Crowe brings further evidence in support of his belief that rheumatoid arthritis is caused by an organism which he has isolated from the urine in a large proportion of patients suffering from this disease. This germ is identical with the *Micrococcus epidermidis* described by Welch, and is given the name *Micrococcus deformans.*

3. "Standard" Opaque Meal for Radiographic Examinations. A. C. Jordan.
4. Some Acute Abdominal Cases. G. F. Aldous.

1. Treatment of Syphilis in the Early Stages.—T. W. Gibbard and L. W. Harrison lay down the following rules for this treatment: Commence treatment in the early primary stage whenever possible. Destroy the primary sore whenever possible and insist on the patient receiving not less than three salvarsan and ten mercurial injections in the manner described. On no account neglect subsequent observation, and prescribe a definite course which is just as strenuous as in the first instance if the patient shows the least sign, clinical or Wassermann, that his disease has not been eradicated. Be cautious about pronouncing a patient cured in any case, but certainly do so till he has continued free from all signs, clinical or Wassermann, for at least a year after suspension of treatment in primary cases, and two years in secondary cases. The price of salvarsan and the amount of special work which such a scheme entails make it inapplicable under present conditions to patients in poor circumstances, but it is hardly necessary to say that the control of syphilis in its earlier stages affects the lives and happiness of a sufficiently large percentage of the population, present and future, to make it of national importance.

4. The Acute Abdomen.—G. F. Aldous draws the following distinction between the acute abdomen and those cases presenting acute abdominal symptoms: In the former there is general peritonitis, due to some cause such as rupture of the stomach or intestine either by disease or trauma, rupture of abscess, etc. In the latter there is no general peritonitis, and the acute symptoms are caused by some form of internal strangulation of gut, cyst with twisted pedicle, ectopic gestation, intussusception, etc. In either group of cases the word "acute" means no delay. The difficulty of diagnosis is usually great and is often made more difficult by delay and by the administration of some form of opiate.

Berliner klinische Wochenschrift.

November 17, 1913

Certain Research Into the Physiology of Digestion and Metabolism.—Zuntz discusses the fermentations of human food in the cecum and colon. The values are given in part from the gases set free, which do not escape by the rectum but enter the blood directly and escape from the lungs. These volatile gases are inflammable. Studies of digestion in animals which digest cellulose show in regard to carbohydrates that 99.7 gms. could be digested, but since 40 gm. escape per rectum, about 60 gm. are actually digested in overfeeding with carbohydrates. There is also a definite relationship between carbohydrates ingested and carbonic acid set free. The determination of amount of gas set free from nutriment is 10 per cent. by weight of the amount of solids fermented in an hour. These values are checked up by the results of other methods. The entire subject, involving as it does the application of new standards to digestion and utilization of food in the entire animal kingdom, is not yet in shape for a familiar presentation.

Therapy of Diabetic Coma.—Blum gives the management of this condition in an article which first considers the essence of the latter. Since opinions as to the latter vary, much the same want of harmony is found under treatment. Only in the negative sense do we find a consensus of opinion. Circulatory stimulants have been condemned, as well as diuretics. The indication for alkalies in some form is duly recognized. The author believes in exhibition *per os*, as in the form of effervescent citrate of magnesia. The rule for giving alkalies is simple—they should be pushed until the urine gives the alkaline reaction. By some sodium is pushed almost *ad libitum*. However, there is no indication for the constant exhibition of alkalies. The author would not even push sodium until the urine is temporarily alkaline because when this reaction appears the appetite usually vanishes and quite severe digestive disturbances occur. The author is warmly in favor of purgation and colonic lavage, despite the fact that these measures often show no direct improvement.

Diathermy for Leprosy.—Leprosy seemed from the very onset a disease well adapted to diathermic currents. Unna, Jr., has given the matter a careful study. The results were not what might have been imagined, *i.e.*, a bactericidal activity against the exciters of the disease with resulting subsidence of the latter. On the other hand, the author may lay claim to the use of diathermy as an accessory antileprotic, which softens up the nervous structures and makes them accessible to oil treatment. During this anesthesia it is possible to extirpate radically many leprous tissues, superficial and deep.

Alimentary Fatty Heart.—This article by Professor Wegelin, which will be continued, opens as follows: This condition is equivalent to the fatty infiltration of the normal heart. Some authors attach no clinical significance to this phenomenon. The heart, fatty or not, can go ahead up to the point of death without functional insufficiency. Nevertheless no one regards such a heart as normal, although the fetal heart regularly passes through this cycle. Deposit of fat in the myocardium is a physiological phenomenon.

Münchener medizinische Wochenschrift.

November 11, 1913

Must the Prognosis of Cardiac and Vascular Diseases Remain on the Dead Point?—Grassmann states that the vast increase today in this class of diseases requires a much more intensive study of the subject. Greater pains must be taken to obtain publicity. The significance of diseases of the organs of the circulation for the morbidity and mortality has not yet been sufficiently emphasized. But improvement in the prognosis of these diseases is no longer an individual medical subject for it now implies a social obligation. Early diagnosis is impossible without repeated examination. But early treatment is possible when the diagnosis has been made. At least there may be effected a change in occupation, which allows the full application of treatment. The old empirical treatment must be reinforced by all rational methods, which is possible only when these resources are centralized.

Abderhalden's Dialysis Procedure in Scarlatina.—This reaction seems destined to throw much light on auto-intoxication of all kinds, and in general the relations which subsist between the organs. However, it is not entirely intelligible how one organ can be connected with a great variety of affections which possess nothing in common. Scarlet fever we naturally associate with the lymphnodes, which are believed to contain its specific virus. Hence gland substance was prepared from many sources, and the blood serum dialysed against them. The results were as follows: From the fifth to the thirty-second day of the fever the presence of the defensive ferments was demonstrable by Abderhalden's process, if lymphnode tissue was used. These ferments are specific only towards lymphnodes *per se*, not to those altered by scarlet virus.

Freudian Interpretation of Dreams.—Bleuler apparantly keeps close tabs on his own dreams in respect to Freudian interpretations and also naturally on the dreams of others. He also contrasts dreams with the hallucinations of the insane. The Freudian method is extremely complicated, and a dream is the result of the interaction of many experiences, recent and ancient. Given a dream in which a number of objects figure—shapes, colors, actions, etc., it should be possible to discover the precise source of these from previous experiences. The jumbling, the absurdity, all lend themselves to a rational explanation. Certain features characterize dreams and hallucinations alike, for example, conflagration. In the impulsive state known as pyromania, an impulse to burn may be first presented in a dream state! This has been proved in the case of young children who set small fires after dreams. It is true, however, that another conception appears which makes the act of fire not one of wanton destruction, but conservative in character. A boy for example has a vision of fire, a waking impulse to burn something, yet all the while he has a lucid reason for his conduct, or as the author puts it "an eminently practical motive." The author expresses his belief that for the disentanglement of the dream conditions, Freudian analysis alone is effective. As in ordinary phychoanalysis the sexual element, the self repression, etc., are all important. The relationship to schizophrenia, the dementia precox of others to dream states is too close for coincidence.

Deutsche medizinische Wochenschrift.

November 13, 1913

Prevention of the Dangers of Transfusion.—Ottenberg and Kalisky referring to modern transfusion as inaugurated by Crile in 1905 sum up their paper as follows: Accidents which result from hemolysis or agglutination may be prevented entirely by a preliminary test. This the authors have demonstrated in 125 patients in the Mt. Sinai Hospital during the past five years. The relationship between hemolysis in vivo and in vitro is a very close one, and hemolysis in vitro doubtless implies intravascular hemolysis. Agglutination is not an absolute contra-indication to transfusion, but non-agglutinative donors should be chosen when possible. Phagocytosis of the red blood cells by the leucocytes is doubtless the result of interagglutination of the two bloods. It happened twice to the authors that the blood of the patient agglutinated that of the donor. In 35 cases of agglutinative transfusion this phenomenon did not occur. Of the negative cases two developed a high degree of urticaria and one a high temperature after transfusion. In cases in which the serum of the donor was agglutinative to the cells of the patient there was no phagocytosis in the blood. In selection of donors in respect to agglutination, it is of greater importance to avoid agglutination of the cells of the donor by the serum of the patient than to do the contrary. Febrile reaction, urticaria or other eruption occur in about 10 per cent. of transfusion without regard to hemolysis or agglutination and no results follow transfusion of the fibrin ferment and disintegration of blood plates.

Retrograde Incarceration of the Intestine.—Merkens says of this condition that it presupposes the existence of at least two intestinal loops in the hernial sac. It occurs as a rule because the mesentery of the connecting sling must pass twice through the constricting ring. In rare cases the cause is a pull on the mesentery, kinking of the same, or rotation of the sling upon its axis. In diagnosis the demonstration of Wahl's symptom with simultaneous existence of an incarcerated hernia is of great importance. Although a correct diagnosis can very seldom be made, whenever we operate on a large incarcerated hernia, especially on the right side, we must always keep in mind the possibility of this complication. If we overlook retrograde incarceration we may see gangrene develop within a few hours.

Abortive Treatment of Syphilis.—Lier states that in every case of primary syphilis, as well with negative as with more or less positive Wassermann, a combined salvarsan Hg. cure should be instituted, this preceding the excision or radical destruction of the sclerosis. Treatment should be continued unremittingly until the WaR becomes negative and all clinical manifestations have disappeared. Buschke's hostility toward the radical treatment of primary syphilis, based as it is upon theoretical considerations, should carry no weight in the face of our positive results. Repeated observations of the cerebrospinal fluid of one's cases complete the status of terminal finds and remove the scruples of sceptics.

Acute Lichen Planus Treated by Lumbar Puncture.—G. Pernet reports the case of a woman, aged 52, who presented herself at the West London Hospital on June 24 with an acute lichen planus which had been present three weeks. It was spreading very quickly and the pruritus and irritation were extreme. She was admitted and lumbar puncture was performed the next morning, 7½ c.c. of cerebrospinal fluid being withdrawn. From that time the pruritus began to yield, and by 4 o'clock the same day it had practically ceased. No other treatment was given. The condition was now involuting. The cerebrospinal fluid did not show lymphocytosis, but, as is usual, it reduced Febling. Two years before the author had had a similar acute case in a male patient. The result of lumbar puncture was good. In this case the cerebrospinal fluid did not reduce Fehling's solution. In a case in which the puncture was done and the patient allowed to go home very severe headache ensued and lasted five or six days; it was far better to have the patient under observation. The sooner the puncture was done for acute lichen planus the better the result *qua* pruritus. Ravaut, of Paris, had worked at this subject for three years, and his published writings should be consulted for further details.—*Proceedings of the Royal Society of Medicine.*

Symmetrical Swellings on Arytenoids.—H. Tilley reports the case of a male, aged 30, who complained that his throat got dry after using his voice for a few minutes. There were no other symptoms. On the anterior and median aspect of each arytenoid and above the level of the vocal process a small, pale, raised prominence could be seen. These came into contact on phonation, but did not interfere with the free movement of the arytenoids and the voice was not affected. The patient had syphilis and had been treated for the disease, but without any effect on the above appearances, which might have been of the nature of pachydermia. Possibly the symptoms had nothing to do with the laryngeal appearances.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

Under What Circumstances Are Syphilitics to Be Accepted as Insurance Risks?—Lenzmann asks permission of the reader to unfold his private convictions upon a subject which is especially important and just now highly practical for insurance companies. The author cites three points for discussion. 1. The risk of one syphilitically infected is far greater than that of a healthy subject. 2. In no department of medical science has there been made such fundamental progress, during the past few years, as in the domain of lues research. These advances have an eminently practical value for life insurance. 3. Thus far life insurance companies have not utilized these advances for the improvement of their risks. The author's conclusions regarding the improvement of syphilitic risks are as follows: A subject suffering from florid syphilis should be advised to undergo radical treatment until a negative Wassermann reaction is reached. He may then be accepted and remain for three years (in more advanced cases two years) under control.

Should an applicant confess syphilis—not of florid type—he is to be studied with the Wassermann. Should this be negative the risk may be unconditionally accepted, provided a "cure" has preceded the reaction. Such a period of treatment is variable. If infected six years ago the period of treatment should be three years at least; if four years ago, two years, etc. If the term of treatment falls short of these limitations the deficit should be made up before the subject is accepted. The author advises more supervision, not further treatment, unless new symptoms appear, or the Wassermann is positive. Treatment is then pursued until it becomes negative. In applicants for insurance who are suspected of having been infected at some time with syphilis, the Wassermann must be used, even in ignorance by the suspect of a syphilitic infection. If the reaction is positive we must postpone the case for one or two years—in accordance with the suspected date of infection—the applicant being closely controlled. Any insured who withdraws from control is excluded from further insurance, besides being liable to certain costs.

The author confesses that his views are not accepted with open arms, and that many scruples have been raised against them. These vary much in character. Not a few claim that with the great increase in our knowledge of syphilis and its treatment the original hazard has so diminished that syphilis *per se* does not add to the ordinary risk. The author retorts that this conception takes no account of postponed affections of the nervous centers and blood-vessels; it must be borne in mind that these very structures are naturally predisposed to disease with the advance of civilization.—*Blätter für Vertrauensärzte der Lebensversicherung,* Nos. 4 and 5, 1913.

Notes on Life Assurance in Egypt.—The spread of European institutions and the establishment of local assurance offices in Egypt offering terms as favorable as those in Europe have greatly increased the popularity of life assurance in that country. Dr. Harold B. Day, M. R. C. P., divides the proposers into four main classes: (1) The Western European—British, French, or German. Since the two latter generally insure in an office of their own nationality, this class is composed almost exclusively of British residents. (2) The natives of Southern Europe, including Italians, Maltese, Greeks, and other inhabitants of Southeastern Europe. Many of these are of mixed origin and born out of the country of their nationality. (3) The Eastern races, chiefly Syrians and Armenians. (4) The native Egyptian. The first class is composed of men, born and bred in Western Europe, who have come to reside in Egypt. Many of these are Englishmen in the Egyptian Government Service, who are under middle age and have been required to pass as first-class lives before appointment. The men in private business are not so carefully selected, but their financial circumstances are usually favorable enough to permit of marriage and frequent change of climate, making them good risks. The second class, composed of foreigners of mixed nationality, make up the greater number of proposers. Such persons are readily acclimated, but are less careful of their health than the average Englishman. The members of this class are mostly hard-working business men, of sedentary habits and as their means and method of living vary considerably, each case must be judged on its own merits. Useful information is often conveyed by the general nature of their surroundings. The next class, comprising the Oriental type, such as the Syrian, may be classed as intermediate between the foregoing and the native Egyptian. Histories are hard to obtain and the services of an interpreter are often necessary. The last class is formed of the native Egyptian, and while the smallest, it is increasing in the proportion of those seeking life assurance. The difficulty of accepting these lives in the past has been considerable and most offices will not offer whole-life policies. At the outset, the proposer may be ignorant of his real age, or may be unable to offer any proof of it. This difficulty may be solved by offering insurance for a limited term. Family history, even when obtained, is often unreliable. Alcoholic intemperance is rare among all classes of Egyptians—Christians as well as Moslems. As a set-off, however, sexual excess and immoderate cigarette smoking are common, although not so prevalent as formerly. Provided then, that the medical interrogation and examination have been satisfactory, the question arises: Are the prospects of longevity the same for the native Egyptian as for the average European? It may be conceded that the innate vitality of the average man is the same whatever his race or social position may be. Since circumstances prejudicial to health make their influence felt most acutely during early life, a high rate of infant mortality is the best indicator of defective hygiene. Judged by this standard, all Eastern countries, including Egypt, fall much below the British standard. Ignorance and superstition not only levy a heavy toll on infant life, but are prejudicial to the health and longevity of adults. Illness is so often mismanaged that effective treatment is difficult. A great change is already apparent in the habits and health of the upper classes of the native population, due to the spread of European ideas. Education and sanitation are rapidly extending their influence from the pupil to the home. We may take the infant mortality in the proposer's family as a useful index of individual health. A proposer in good health, whose children are successfully reared, may be accepted for a whole life on European terms. On the other hand, a man of Eastern race, whose life does not conform to the European standard of hygiene is best offered a fixed term.—Life Assurance Medical Officers Association, May, 1913.

Book Reviews.

The Practitioner's Visiting List for 1914. Price $1.25. Philadelphia and New York: Lea & Febiger.

The new edition of this visiting list maintains the high standard which it has achieved as a handsomely bound book for the recording of professional calls and other data. In addition to the ruled blank pages there is a section of text containing a scheme of dentition, tables of weights and measures, and comparative scales; instructions for examining the urine, table of doses, incompatibles, poisons and antidotes, etc.

Ueber Cystitis. Von Privatdozent Dr. R. Hottinger. Zurich. Price, 1 mark. Halle a. S.: Carl Marhold, 1913.

This is a concise and complete review of cystitis. Cystoscopic appearances of the various types of the disease form the bulk of the monograph. Orthodox treatment is advised.

Etudes sur le Séro-Diagnostic et le Traitement de la Syphilis. Strategie et Tactique. Par le Dr. Leredde. Paris: A. Maloine, 1913.

The author studies variations of Wassermann's reaction in syphilis, the different methods of diagnosis based on use of fresh serum, the effects of salvarsan and neosalvarsan, and their efficiency in the cure of tabes. He cites fifty-four cases of syphilis observed personally and concludes that grave cases are not those of syphilis with evident stigmata, but the veiled cases; that treatment must be adapted to individual needs and should be stopped only when any serum reaction shall have disappeared permanently. The author insists on the necessity of verifying practical cures by examination of the blood serum as in examination of the urine to determine the cure of albuminuria or diabetes.

Geschichte der Ohrenheilkunde, 2ter Band, 1850-1911. By Prof. Adam Politzer, Emeritus Professor of Otology University of Vienna; Emeritus Royal Privy Counsellor of the University Otological Clinic in Vienna. Price 24 marks. Stuttgart: Ferdinand Ente. 1913.

The second and last volume of the History of Otology by Politzer follows the first by about one a half years. It embraces a most scientific and comprehensive lapse of time beginning in 1851 with a description of the anatomy and physiology of the labyrinth under the initial hand of Marchese Corti. Corti devoted himself with persevering enthusiasm in Hyrtle's School of Anatomy in the Vienna University, chiefly to the labyrinth and vestibule of the internal ear, and was the first to give fundamental knowledge as to the course and anatomical endings of the thousands of filaments of the acoustic nerve. The so-called "organ of Corti" refers distinctly to the inner and outer rods, lamina, spiralis membranacea, the membrana basilaris, tectoria, etc. There were over 10,000 filamentary nerve-endings traced in Waldeyer's work in Stricker's laboratory later. Corti's four works were published in 1851 under the chapter "Recherches sur l'organe de l'ouie des mammifères." He was followed within ten years by such successful workers as Voltolini, Schultze, Reissner, Böttcher, Deiters, Kölliker, Henson, Rüdinger, Pritchard, and so many others as to give the probable source of the present day basis of anatomy. Politzer and Rüdinger gave artistic interest and incentive by their well-known lithographs, and plastic moulds to the anatomy of the middle and inner ears. This reference to the work of 1850 to 1870 is made in lengthy detail because our knowledge of the functional anatomy of the labyrinth, vestibule, and semicircular canals is one of the unremitting and devoted labors of these workers. Chapters most condensed and instructive follow in rapid succession on the description of the eighth nerve, physiology of the vestibule, cochlea, and semicircular canals. The basic sources of to-day's surgical work on the labyrinth and vestibule date from the laboratory work of these men. Helmholtz, in 1856, and later König developed the scientific value of musical tones and gave an astounding impetus to experimentation in this line of research. In so limited a presentment of this great review of otology by the celebrated Politzer, now in his seventy-fourth year, one can only mention the chief surgical diseases and measures, which were brought out in and since 1860: catheterism of the Eustachian tube, auditory tests, intracranial otitic complications, sinus phlebitis, cochlear and labyrinthine diseases of a degenerative type, neuroses, etc. The last 260 pages are devoted to the development of otology in individual countries from 1850 to 1911. The first nation is England, where, as is well known, Joseph Toynbee, William Wilde, and James Hinton were the pioneers. North America—or the United States—has 35 pages at the hands of Blake of Boston. The first clinic was the New York Eye and Ear Infirmary, founded by Dr. Edward Delafield in 1820. In Philadelphia the Institution for Diseases of the Eye and Ear followed in 1822; in Boston the Massachusetts Charitable Eye and Ear Infirmary, etc., etc. A list of otological journals and of college chairs of otology, with their incumbents, and an all too brief personal sketch of workers in otology in the United States follows. The earliest otologists were Roosa, Agnew, Knapp, Noyes, Pomeroy, Sexton, and Buck, to be followed by a long list of men of the present in New York, Brooklyn, Boston, etc.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc. Edited by Henry W. Cattell, A.M., M.D. Volume III. Twenty-third Series, 1913. Price, $2.00. Philadelphia and London: J. B. Lippincott Company.

This volume of the well-known quarterly contains twenty-one articles on diagnosis, treatment, medicine, surgery, legal medicine, and electrotherapeutics. The best of these articles is probably that of Craig on the prophylaxis and treatment of malarial infections. It is marked by thoroughness and restraint and is an excellent one in many ways. Ashford's paper on uncinariasis and Bainbridge's on electrotherapeutics in the treatment of cancer are also to be recommended. This volume measures well up to the standard set by the series.

A Practical Treatise on the Causes, Symptoms, and Treatment of Sexual Impotence and other Disorders in Men and Women. By William J. Robinson, M.D., Chief of the Department of Genitourinary Diseases and Dermatology, Bronx Hospital and Dispensary; Editor *The American Journal of Urology, Venereal and Sexual Diseases;* Editor and Founder of *The Critic and Guide;* Author of "Sexual Problems of Today"; "Never Told Tales"; "Practical Eugenics," etc. President of the American Society of Medical Sociology; President of the Northern Medical Society; Ex-President of the Berlin Anglo-American Medical Society; Fellow of the New York Acadamy of Medicine; Member of American Medical Editors' Association, American Medical Association, New York State Medical Society, Medical Society of the County of New York, American Urological Association, Harlem Medical Association, Society for Moral and Sanitary Prophylaxis, etc., etc. Price $3. New York: Critic and Guide Co., 1913.

Sexual impotence is one of the most important maladies which confront physicians in general, and urologists in particular. The paucity of writings on this topic leads one to zealously investigate such as are presented. In this book Dr. Robinson has produced a unique mixture of good, bad, and indifferent. It is divided into nine sections with the following headings, which fairly well indicate their contents: Masturbation, Pollutions and Spermatorrhea, Sexual Impotence in the Male, Sexual Neurasthenia, Sterility, Sexual Disorders in Women, Priapism, Miscellaneous topics, and Prescriptions. The first of these sections is especially full and detailed. Herein, the author expresses the opinion that locomotor ataxia may occasionally be caused by excessive masturbation. The treatment in general is that advocated by other writers. However, it may be assumed that the two or three patients who underwent the "little rather brutal procedure" of applying "rapidly a red hot wire to the child's genitals" seemed to possess vigorous and pugnacious fathers. In the third section appears the following statement: "I am fairly convinced that continual sexual abstinence from any sexual gratification may result in partial or complete, temporary or permanent impotence." Without prejudice to this statement, it must be remembered that it is diametrically opposed to the holdings of some of the greatest authorities in our profession; authorities that are accepted without question. Overmuch space is given to case reports. If an equal amount of time and labor had been given to the pathology of the lesions and detailed descriptions of technique, the work would have greater scientific value. The therapeusis is in general good, the chapter on prescriptions containing many good formulæ and combinations. It is questionable, however, whether or not these ready-made prescriptions will ever aid any physician to think for himself. In the section on miscellaneous topics the author gives full sway to his philosophy, propounds many vital questions, and provides pabulum for every student of sexology. The literary style occasionally approaches the academic, but as a rule the prefatory promise is kept, to use language that is personal, clear, straightforward, conversational.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-ninth Annual Meeting, Held at New Orleans, La. October 23, 24, and 25, 1913.

THE PRESIDENT, DR. ALBERT E. STERNE, INDIANAPOLIS, INDIANA, IN THE CHAIR.

(*Concluded from page* 1009.)

Some New Points in Round-Ligament Surgery.—Dr. CHANNING W. BARRETT of Chicago showed slides demonstrating points in different round ligament operations and the importance of several points connected therewith. First, that the infrequency of adhesions of the sigmoid, cecum, appendix, omentum, bladder or small bowel, as well as other intraabdominal complications, were of such frequency as to render any round ligament shortening not only incomplete but oftentimes hazardous. Slides also demonstrated that the retroperitoneal grasping of the round ligament produced an immediate potential hernia, which was avoided by puncturing the peritoneum at the internal ring, a method of combined shortening from the abdominal incision on one side and through a hernial incision on the other for cases with inguinal hernia. Through this inguinal hernial incision the author had corrected a femoral hernia at its proper end. A method of reaching the round ligaments at the internal ring by means of a skin puncture, after intraabdominal conditions had been corrected and the ligaments secured through a medium incision was also shown; likewise a method of reaching them through a transverse skin incision, the ends of which brought one near the internal ring. The distinctive features of all these procedures corresponded to the method proposed ten years ago and was still used in the vast majority of cases, namely, that they picked up the round ligament in the abdomen where it was easy to find and had it running normally to the internal ring with normal relations in the abdomen. This operation, as far as known, had given no mortality, no interference with pregnancy, no failure to hold the uterus in position after pregnancy, and less than one-tenth of one per cent. known of returns at any time. Such results warranted the further use of this operation.

Consideration of Results in the Treatment of Hip Disease.—Dr. JOHN RIDLON of Chicago said the mechanical treatment of hip disease aimed to do for longer or shorter periods in most cases three things, namely, to immobilize the joint, to remove the weight of the patient from the joint in standing and walking, and to exert traction on the limb. A hip might be immobilized by a plaster of Paris spica as efficiently and as comfortable as in any way. The patient's weight could be removed from the joint by putting him in bed; this more efficiently than any other way. Traction could be exerted by the use of weight and pulley, either with adhesive plasters applied to the limb after the manner of Buck or of Taylor. The author showed pictures of braces and numerous lantern slides of hip disease cases showing the condition before treatment and the results after treatment. The cases reported illustrated a fact which all observing orthopedic surgeons knew, namely, that some cases would attain very good results without any treatment whatsoever; some attain very bad results under the most prolonged and best of treatments; but the orthopedic surgeon also knew that by treatment he lessened pain, shortened the duration of the disease, prevented a great deal of the deformity that would otherwise occur, and saved life.

Classification of the Gastrointestinal Diseases of Infancy.—Dr. ISAAC A. ABT of Chicago said the digestive disturbances through constitutional anomalies depended on some inherited defect in the structure of tissues and organs. Thus the far-famed exudative diathesis did not depend upon the feeding but upon a congenital vice. In such infants eczema, lymphatic enlargements, bronchitis and bronchial asthma, and eosinophilia manifested themselves to a greater or less extent despite the quantity or quality of food. As to the classification of Finkelstein, he divided the subject as follows: (1) Weight disturbances characterized by a diminished tolerance for milk, especially milk fat. The infant did not thrive. The weight was stationary as a rule. The bowel movements were hard, dry and formed. (2) Dyspepsia was a more severe disease manifestation than the foregoing. It was characterized by a diminished tolerance not only for fat, but also for carbohydrates. Such children did not gain in weight even if the diet was increased, constituting the so-called paradox action. (3) Decomposition; a condition characterized by marked loss in weight, low temperature, and slow pulse. The loss in weight continued even when considerable food was administered. The child was easily infected, or infection took place readily. A marked intolerance for fat and carbohydrates was present. These infants were subject to secondary infectious processes, as furuncles, abscesses, etc. (4) The next clinical group was alimentary intoxication, characterized by fever, disturbances of consciousness, albuminuria, rapid superficial breathing, great intolerance for food, particularly for sugar and other whey constituents. In considering the disturbances produced by breast milk, Finkelstein referred to underfeeding as well as the dyspepsia produced by overfeeding. Disturbances of nutrition on account of congenital perversions of the constitution received attention For instance, he discussed the neuropathic constitution, the exudative diathesis and errors in development as factors influencing digestion and nutrition. He also considered the effect in quantitative changes in food which referred to overfeeding and underfeeding. Passing to the next qualitative changes, he paid particular attention to the injuries produced by starch. Infants suffered infection because food tolerance had been lowered by the disturbances of nutrition, the lowered resistance which resulted in consequence making infection possible. Parenteral infections were more frequent than genuine gastrointestinal infection. Knowledge of the gastroenteritis of infants, so far as bacteriological facts were concerned, was only slightly developed, and consequently present views were subject to considerable changes in the future. In order to interpret cases at the bedside, teach and describe this disease group, a working hypothesis based upon some classified arrangement was an absolute necessity. Uniformity was much to be desired, and this much-desired end could only be reached when unanimity was born of knowledge.

The Feeding of the Sick Infant.—Dr. FRANK C. NEFF of Kansas City, Missouri, stated that one should regard constipation as an evidence usually of an intestinal indigestion. The constipated new-born baby fed entirely on the breast was with difficulty relieved through the diet. Correction of the mother's diet, digestion, and mode of living might be tried, but often met with little effect upon the child. He had never attempted to administer fruit juices to infants less than three months old, but older infants would often tolerate from teaspoonful to tablespoonful quantities of orange, grape, pineapple, or prune juice with good results. Supplemental feedings of cow's milk with the addition of a malted gruel, such as the so-called malt soup, showed a beneficial effect upon the gray, dry, soapy stools. The effect of malt sugar was laxative, and of more benefit than any of the laxative drugs. Following a disturbance in balance which was not corrected there was a decided intestinal disturbance with numerous watery, mucous stools, vomiting, and an elevated temperature. Fats, sugars, and flours must here be reduced, and in severe cases also the whey contents of the food. Breast milk was preferable to any artificial feeding. Next comes Finkelstein's albumin milk. Finally, skim or buttermilk in case the other foods were not obtainable. These should be given in small quantities at first. The feeding of infants suffering from systemic poisoning resulting from improperly digested and assimilated food and also from infections must provide for elimination through the kidneys and stool. The feeding of infants with pylorospasm had as yet shown little advance. Lapage advised regulating the feeding, using easily digested food that left no residue and had the greatest chance of passing the pylorus. It was advisable to give small amounts, even as little as a teaspoonful, frequently, until the child improved and the vomiting ceased. Sometimes a change of food alone would lead to temporary improvement. Feeding through a tube without much dilution of the food was advisable, after washing the stomach. Nutritive enemata were of doubtful value.

Pyloric Stenosis in Infancy: An Analysis of Twenty Cases Personally Operated Upon.—Dr. H. M. RICHTER of Chicago reported twenty cases. Of these eighteen were of the type described as hypertrophic pyloric stenosis; two were of the type known as spasmodic. In all of the eighteen a definite, firm olive-shaped tumor was demonstrated at operation; in seventeen of the eighteen it was palpated and recognized through the abdominal wall before the operation. In one case in which it was not palpable before operation, the clinical findings were so clear that the diagnosis was made without reserve. The tumor consisted of a firm olive-shaped body, roughly one-half to three-quarters of an inch in length. It was covered by smooth, glistening peritoneum that had the ap-

pearance of being stretched over the mass. There was no external evidence of inflammatory reaction; no attempt at fixation. The mass was as freely movable as a mass at the pylorus so commonly was when found in the adult, and this mobility was recognized clinically and was probably the cause of the frequency with which clinicians had failed to demonstrate it. The tumor had the firmness of cartilage; it was not soft or pliable in any case; there was no case in which its consistency made the finding questionable; no case in which a graduation could be made out between the tumor mass and the adjacent stomach and duodenum; it was sharply defined. In two cases in which a pyloroplasty was done, and in one case that came to autopsy, a section of the pylorus showed the mucosa to be relatively redundant, so that it bulged out of the incision when relieved of the compression by the tumor. The histological picture had been perfectly worked out by others; in one case of his series that came to autopsy the finding agrees with the universal report, viz.: a simple hyperplasia of the circular muscle fibers, with no change in any structure of the pylorus. The stomach, when it had not been emptied before opening the abdomen by the passage of a tube, was always found distended to a marked degree of tension; the duodenum was always empty and collapsed. It was perfectly evident that the tumor formed a complete obstruction of the canal. In the earlier cases where the operation was continued without emptying the stomach with a tube, the various manipulations never forced the air in the stomach through the tumor into the bowel. The bowel remained collapsed and ribbonlike up to the moment of removing the clamps, when it would balloon out, and the advancing column of air could easily be followed as far as the jejunum was exposed. No hydrostatic test could more clearly prove the existence of a complete block, though the degree of tension was not determined. In none of the eighteen cases was there any accompanying congenital malformation, though in one a particularly short mesocolon made it impossible to do a retrocolic gastrojejunostomy. Other obsersvers had reported accompanying congenital malformations. In presenting this series of twenty cases, which was the largest heretofore published in America, he wished to bring out the facts, first, that the mortality had been reduced below that claimed by any method of nonsurgical treatment, and second, and of equal importance, that the ultimate condition of the patient was that of a normal individual.

Some Points in the Treatment of Acute Ileocolitis.—Dr. J. Ross Snyder of Birmingham, Alabama, in discussing the treatment of acute colitis in the child insisted that to be rational the treatment must be individual. There were, however, certain principles of treatment applicable to all cases. With the onset of the disease, it was imperative that the intestinal tract be cleaned out. His personal preferences for this purpose was castor oil by mouth and normal saline solution for irrigation of the bowels. If there was troublesome or persistent vomiting, the stomach should be washed, the washing to be followed by the administration of broken doses of calomel until one-half to one grain was given, and still later followed by oil. Although the initial purgation and irrigation were essential, he protested against the practice of giving a daily dose of oil and of continuing frequent irrigations. This practice was not only useless, but it was absolutely contraindicated in that it destroyed all possibility of rest to the inflamed and ulcerated bowel. If toxemia of grave nature accompanied the onset, a hypodermocylsis of salt solution should be given without delay. Given early in the attack, salt solution was often an excellent and sometimes necessary measure, but he was convinced that after the heart had been weakened by the ravages of this disease, the subcutaneous injections of salt solution was not only futile but that it was capable of producing disastrous results by overcrowding the heart. By stopping all food, by clearing out the intestinal tract and, if necessary, by the use of salt solution subcutaneously, the toxema in the majority of colitis cases promptly subsided and the disease became a purely local one, demanding for restoration to normal nothing so much as rest. If peristalsis continued, irritable and excited, the author used opium more and more freely. This drug has been subjected to so much abuse, so much had been written about its dangers when used in the particular condition under discussion that for a number of years he fought shy of it. To-day, without its use in acute colitis, the disease was often unnnecessarily prolonged and its dangers were frequently augmented. There was no truth in the statement that children suffering from colitis did not bear opiates well. They bore them a great deal better than they did the wear and tear and the strain accompanying the irritable peristalsis. Once the intestinal tract had been relieved of toxic decomposing and irritating food residue, opiates should be called into quick service and they should be given in amount sufficient for the purpose intended. Rest was not only to be assured by withholding further purgation, by withholding food, and by the use of opiates, but the environments of the child should be made peaceful and quiet. Many of these children were of such age as to be susceptible to the depressing influence of anxious faces, tears, and morbid and thoughtless remarks, which were too often seen and heard over the sick bed. The child with colitis should be kept in bed in the recumbent position.

The Treatment of Goiter.—Dr. John H. Johnson of Coffeyville, Kansas, said the treatment of goiter should depend on each individual case. Operative measure should never be looked upon as routine, but whatever method of treatment was used the patient should be kept under constant observation to note the benefit derived from that treatment. Complete rest, physical, mental and emotional, was essential in all methods of treatment for periods of weeks, if possible. A sanitarium environment, where the patient was away from the home surroundings, giving a change of scene at an altitude of 2,000 to 4,000 feet, was by far the most effectual measure in the majority of cases. The seashore was never good in these cases. Kocher says that, "an altitude from 3,000 to 5,000 feet, with a mild hydrotherapy in the form of cold sponging and baths, regulations of the diet to reduce the proportion of albumin or fats, and a rest cure, interrupted by a regular systematic increase of muscular exercises against resistance, with phosphorus, arsenic or iron internally, makes the best internal treatment." The removal of constipation should be seen to. This treatment alone had immediatcly and markedly aided in diminishing goiter. Two bases were reported by Dr. Cantieri, of Milano, Italy, which had been successfully treated with the thyroidectomized milk of goats. The recovery had been continuous, and permanent in one since 1908. In the second case he combined the thyroidectomized milk with electric treatments applied locally to the gland which resulted in a cure.

Essentials of Modern Artificial Feeding of Infants.—Dr. Robert A. Strong of New Orleans said the commonly used sugars in infant feeding were lactose or milk sugar, maltose or malt sugar, and saccharose or cane sugar. Malt sugar, on account of being very expensive, was used in combination with dextrin. Maltose was more rapidly converted and absorbed, hence was less liable to cause fermentation. Maltose was the most desirable, yet the literature showed that the opinion was not unanimous on the use of any particular sugar. In Germany malt sugar preparations were used almost exclusively in milk modification. The present status of starches was about the same as it had been for the past five years. The addition of cereals was still desirable, but not before the fourth or fifth month. The routine use of lime water continued with many, while others contended that its use was unnecessary in normal infants. He had adhered to the routine practice of using it with the belief that the excess of alkali might meet the demand of the infant organism in an impending and obscure acidosis, and besides, its use had never been demonstrated to be harmful. He had used albumin milk in cases of decomposition in his services at the Charity Hospital, and the results had been sufficient to warrant his belief in its efficiency as a temporary measure. As to the methods of feeding, he had been using whole milk mixtures almost exclusively for the past four years, and had been teaching it for the past three years, and he was firmly convinced that it was the logical procedure in the average case.

The Relation of Sinus Diseases to General Systemic Infections.—Dr. Richard J. Tivnen of Chicago said that both clinical experience and analogous infections had clearly demonstrated that infection could be, and was, transmitted from the accessory sinuses to neighboring and distant structures. The frequency of sinus infection, as reported by different observers, varied from 22 to 43 per cent. Sinus infections were not uncommon in association with influenza, croupous pneumonia, diphtheria, erysipelas, scarlet fever, measles, small-pox, tuberculosis, typhoid fever, and cerebro-spinal meningitis. A number of these cases had often associated with them many other infections, such as joint infections, etc. Possibly, the susceptibility of the sinuses to these diseases and these later joint complications might have a closer relationship than was usually assumed. Instances of infections of neighboring organs, as the eye, orbit, and brain, due primarily to sinus infections, were numerous. After referring to the association of erysipilis with sinus infection he concluded that the primary infection of this disease was, in many instances, to be found in the accessory sinuses. Reference

was also made to gastric disturbances common to accessory sinus infections, such as nausea, vomiting, and loss of appetite, these disturbances being probably inaugurated by the constant swallowing of the purulent secretion with reabsorption of ptomaines. Referring to the joint infections as secondary in connection with a primary sinus infection, such an association was exceedingly probable. While the sinuses had not been so specifically associated with joint infections as had other structures of the upper respiratory tract, in his opinion a systematic and consistent investigation of sinus involvements would not infrequently establish a casual relationship between diseases of these cavities and joint infections. His conclusions were that the nasal accessory sinuses did not occupy the position of prominence as factors in systemic infections to which they were entitled; and while he disclaimed any desire to assign to these cavities unmerited prominence as etiological factors, he nevertheless emphasized his belief that in all obscure general systemic infections a thorough investigation of the nasal accessory sinuses and their appendages should be carried out as a routine measure.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. D'Orsay Hecht, Chicago; *First Vice-President*, Dr. W. W. Butterworth, New Orleans; *Second Vice-President*, Dr. Willard J. Stone, Toledo, Ohio; *Secretary*, Dr. Henry Enos Tuley, Louisville, Kentucky (reelected); *Treasurer*, Dr. Samuel C. Stanton, Chicago, Illinois (reelected).

Cincinnati, Ohio, was selected as the place for holding the next meeting.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held November 7, 1913.

Dr. L. W. Hotchkiss in the Chair.

Diverticulitis of the Sigmoid.—Dr. Anthony Hart Harrigan presented a patient, 65 years of age. The family and previous histories were negative. She had had four full term pregnancies. The menopause occurred 25 years ago. She had had an umbilical hernia for eighteen years. She was always constipated. The day before admission to the hospital she returned from Europe. She had been very seasick during the entire journey. She had no pain. At 4 o'clock in the afternoon of August 8, 1913, the day of her arrival, she had severe pains in the lower abdomen; they were severe, persistent, and did not radiate from the suprapubic region. She had no chills, fever, sweats, or headache. She was admitted to the Fordham Hospital August 9, 1913. Examination showed a markedly distended abdomen; also a small reducible hernia at the umbilicus. There was no redness, swelling, or tenderness of this hernia. There was rigidity of both recti muscles, more marked in the lower quadrants. There was tenderness in the lower right quadrant but no mass was felt. The rectal and vaginal examinations were negative. The temperature was 103° F., pulse 98. The leucocytes numbered 17,000 and there were 85 per cent. polymorphonuclears. It was thought that the patient was suffering from a spreading peritonitis due either to an affection of the appendix or gall bladder. On opening the abdomen the small intestine covered with plastic lymph presented. The condition of the appendix was found to be negative, as was the condition of the gall bladder. The hand in the peritoneal cavity felt a hernia consisting solely of omentum. In the pelvis a mass was felt lying above the right broad ligament. It was about the size of a baseball, round, movable, and the surface was nodular. This mass was easily delivered and consisted of a loop of intestine; it was identified as the large intestine by the presence of a longitudinal band. The convex surface presented at least 25 small elevations ranging from 1/3 to ½ inch in diameter and from 1/3 to ¼ inch in height. The surfaces of these elevations were covered with the normal peritoneal coat of the intestine. At one point a small elevation showed a minute opening through which intestinal contents could be easily expressed. The appendices epiploicæ were swollen, inflamed, and the mesentery was markedly inflamed. The body was identified as the sigmoid by a study of its position and relations. The perforation was closed with interrupted sutures of linen. The loop was returned to the pelvis and a long cigarette drain inserted. There was a slow convalescence with considerable suppuration. The patient was discharged on October 12, 1913, with complete closure of the wound.

Resection of the Cecum, Ascending Colon, and the Terminal Portion of the Ileum, Pericolic Membrane.—Dr. Anthony Hart Harrigan presented a woman, 31 years old, who was admitted to the hospital August 7, 1913. Her family and previous histories were negative. Her present illness began at 2 A.M. with severe cutting pain in the right side of the abdomen. At 7 A.M. the pain shifted to the left side. Vomiting began at 3 A.M. and persisted. A physician was called in and he gave her an enema which was unsuccessful. After the administration of morphine she was brought to the hospital in an ambulance. No history could be obtained from her because she was under the influence of morphine. A mass was seen and felt in the right iliac region; this was dull on percussion. There was rigidity of both recti muscles. The temperature was 99.4° F. and the pulse 80. An exploratory operation was performed at 10 A.M. under ether narcosis. On opening the abdomen a cystic mass was found occupying the right iliac region and upper part of the pelvis. The first impression was that they had to deal with an ovarian cyst with a twisted pedicle. Further investigation, however, when the mass was delivered, showed that it consisted of the cecum, ascending colon, and terminal ileum intimately bound together and rotated in its longitudinal axis. In other words a partial volvulus. On closer examination it was found that the ascending colon was covered or enclosed by a membrane which passed downward over the cecum, covering or enclosing the appendix. This membrane also passed downward and inward over the terminal ileum. The latter was acutely angulated into four or five kinks. An attempt was made to straighten out the ileum by dissecting the binding adhesions. This was soon given up because of fear of wounding the intestine. It was then decided to short circuit in order to relieve the intestinal obstruction. The ileum immediately above the site of kinking was divided. The peripheral end was closed with four layers of sutures, one of catgut and three of linen. A lateral anastomosis was made at the beginning of the transverse colon with the aid of clamps. The ileum was easily brought to the colon with no tension or dragging. The anastomosis was antiperistaltic. The distended end of the divided ileum was closed and sutured to the peritoneum. The incision was closed in layer fashion up to the point of the attachment of the distal end of the ileum. A smooth convalescence followed. The bowels moved spontaneously. The sutures were removed on the eighth day. A second operation was performed on August 21. The distal end of the ileum was liberated from the parietal peritoneum. Separation of recent adhesions was done and the patient was discharged on September 22 and referred to a convalescent hospital. An exact pathological diagnosis was not made at the primary operation. Three conditions were suspected in this case, tuberculosis of the cecum, pericolic membrane and Mechel's diverticulum disturbance. The specimen presented showed no evidence of tuberculosis, carcinoma, or Mechel's diverticulum. The diagnosis of pericolic membrane was made from the study of the gross specimen. The question arose whether in addition to the pericolic membrane they had to deal with an intensified type of Lane's kink.

Dr. Edwin Beer said that in the literature of the last ten years there had been no new developments along the line of diagnosis of diverticulitis. Recently at the Mayos' clinic in Rochester it was shown that they had been able to see something with the aid of bismuth. Dr. Beer thought that the case presented was a good one to try out with the x-ray and made the suggestion that this be tried.

Dr. Harrigan said that he would suggest this to Dr. Stewart and report upon this at a later meeting.

Adenocarcinoma of the Ileum.—Dr. Edward W. Peterson presented a patient, 51 years of age, who was admitted to the hospital July 24, 1913, with symptoms of intestinal obstruction. Her family history was negative. Her personal history was that a small tumor had been removed from the parotid region about five years ago. She had always been more or less delicate. She possibly had malaria eighteen years ago and had been very anemic during the past five years. During the past six weeks she had lost fifteen pounds in weight. During the past two years she had suffered with a feeling of distress and fulness in the gastric region. This seemed to have no relation to meals, posture, or to any special time. She had belching of gas; this became very frequent, but there was no vomiting and no constipation. During the past six weeks she complained of severe pain which came on suddenly and then would be absent for several days. The patient was very thin and emaciated. The abdomen was distended and there was a visible peristalsis. Operation was advised and a resection of the intestine performed as well as an appendectomy. A lateral anastomosis was done with the result that the patient now was in good condition, had a good appetite, her bowels were acting well. The specimen removed was an adenocarcinoma of the ileum.

Splenectomy for Stab Wound of the Spleen.—Dr. Joseph Pierre Huguet presented this patient and specimen. The accident happened September 29, 1913. The injury was one and a half inches above the last rib on the left side and he was in considerable shock. The pulse was 120. The hole was large enough to admit a finger and blood clots came from it. On opening the abdomen the peritoneal cavity was found to be filled with blood clots. He finally was able to deliver the spleen which he found to be fairly adherent and came up with difficulty. Dr. Huguet showed the specimen removed. The opening in the spleen caused by the stab he tried to sew, but the sutures came out and the only resource left was to do a splenectomy, which was done. The patient after the operation never had a temperature over 100.5° F. or a pulse over 100. Dr. George Ben Johnson had collected 178 cases of splenectomies and 150 of them were traumatic. Of the 150, seven were stab wounds and six gunshot wounds. In the case of the patient just reported the blood count showed 4,100,000, hemoglobin 85 per cent., and the white cells numbered 14,000.

Some Points on Technique of Skin Grafting with Use of Aluminum Leaf.—Dr. F. M. Foote said that hitherto skin grafting had been an uncertain procedure. He used the aluminum leaf which was stiffer than the silver leaf. When it was sterilized it did not go to pieces. The top of the granulations were merely shaved and the grafts applied and they took in 100 per cent. of the cases. He presented two patients which showed perfect results.

Dr. Walter M. Brickner could not see what particular advantage the aluminum or the silver grafts had over the rubber tissue.

Dr. Foote replied that with the use of the rubber tissue there was produced more or less moisture and this necessitated a frequent changing of the dressings. The aluminum leaf dressing was absolutely dry; many of the skin grafts did not require changing for one or two weeks; when removed the parts underneath would be found to be dry. He emphasized the fact that the grafts should never be soaked in saline solution before being applied. The entire surface was covered.

Esophagoplasty after Intrathoracic Resection of the Esophagus for Carcinoma.—Dr. Willy Meyer presented this communication which he illustrated with lantern slides. He said that if the tumor in the esophagus was to be extirpated the whole operation, including the making of the gastric fistula, should be planned with a view to reconstruction of the esophagus. A tube should be made which would enable the patient to swallow his food and pass it down into the stomach. Patients with malignant esophageal stricture complained of their inability to swallow and their principal desire was to have the ability to swallow restored to them. Dr. Meyer asked why not, then, if on thoracotomy a case was found to be inoperable, divide the esophagus proximal to the tumor and invert the distal end. Then transpose the oral stump under the skin of the neck and chest and if not long enough unite it with the opening of the Jianu tube. If it proved too short a connecting rubber tube would reestablish swallowing of liquid and semiliquid food. If this should prove unsatisfactory a skin plasty would have to be made to bridge the defect and thus complete the extra thoracic esophagoplasty.

The Pathogenesis and Treatment of Hernia of the Linea Alba.—Dr. Alexis V. Moschcowitz read this paper. He said that all herniæ that occurred in the midline of the abdomen, with the exception of those that occurred at the umbilicus, were grouped collectively under the name "hernia of the linea alba." Whey were more frequent above the umbilicus than below. Longitudinal bulgings of the linea alba were occasionally called herniæ, but they were not herniæ in the true sense of the word, because there was no defect in the transversealis fascia. Because of their greater frequency above the umbilicus, these herniæ had also been called epigastric herniæ. They varied greatly in size, but the greater majority of them were very small. After considering the surgical anatomy of the linea alba which enabled him to explain certain peculiarities of an epigastric hernia, especially a hole in the transversalis fascia through which a vessel passed to the surface, he described the following simple surgical procedure. A small vertical incision was made over the center of the so-called hernia. The skin and subcutaneous fat were divided and retracted, thereby exposing a lump of fat. Search was then made for the blood vessel and it was usually found upon the left side of the protrusion; this vessel was ligated. The fat was teased apart; the shreds of fat were ligated to obviate a secondary hemorrhage. The ligatures were placed close to the bottom of the hole in the transversalis fascia. The stumps were then pushed back into the hole, and the latter closed with one or two stitches. The sutures which closed up the hole grasped all of the component parts of the linea alba at that particular point, namely, linea alba plus transversalis fascia. Strangulation was exceptionally rare in epigastric herniæ, but that it could occur was proven by the case reported by Dr. Hotchkiss in *Annals of Surgery*, LIV, p. 78.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Alabama State Board of Medical Examiners.

July 8, 9, 10, and 11, 1913.

(*Continued from page 1012.*)

ETIOLOGY, PATHOLOGY, SYMPTOMATOLOGY, AND DIAGNOSIS.

1. Give the etiology of mucous colitis.
2. Give the etiology of scurvy.
3. Give the pathology of endocarditis.
4. Give the pathology of abscess of liver.
5. Give the symptomatology of erysipelas.
6. Give the symptomatology of heat-stroke.
7. Give the diagnostic symptoms of pellagra.
8. Name one variety of pernicious malarial fever and give its diagnosis.
9. Give the diagnosis of diabetes mellitus.
10. Give the differential diagnosis between appendicitis and ovaritis.

PHYSICAL DIAGNOSIS.

1. Name points for observation in the inspection of the thorax.
2. Name points for observation in the inspection of the abdomen.
3. Give the varieties or kinds of respiratory (breath) sounds and the explanation of each (adventitious sounds not asked for, such as râles, for example).
4. Give the varieties or kinds of voice sounds and the explanation of each.
5. Give the physical signs of bronchial asthma and their explanation.
6. Give the differential physical signs between a thoroughly compensating cardiac hypertrophy caused by mitral stenosis and one caused by aortic insufficiency, and the reasons for same.
7. Give the physical signs of pericarditis with considerable effusion and their explanation.
8. Give the physical signs of arteriosclerosis.
9. Give the method for the physical examination of the spleen.
10. Give the physical signs of a bladder distended with fluid.

(Optional, to be answered or not, as the applicant prefers): Make a diagnosis in the following hypothetical case: Right side—Absent movement; bulging intercostal spaces; absent fremitus lower three-fourths, increased upper fourth; flatness lower one-third; tympany middle and part of upper third, dullness remaining upper third; absent respiratory and vocal sound lower third; amphoric breathing and egophony middle and part of upper third; bronchial breathing and bronchophony remaining upper third; succussion positive. Left side—Exaggerated movement and respiratory sound and apex of heart to left of mammary line.

OBSTETRICS.

1. What changes take place in the circulatory apparatus of the fetus after birth?
2. What conditions may be mistaken for pregnancy?
3. How would you diagnose the death of the fetus *in utero?*
4. What are the results of retroflexion of the gravid uterus with incarceration?
5. What are the premonitory symptoms of eclampsia?
6. What precaution should be taken in the management of face presentations?
7. What precautions should be taken against septic infection during labor and in the puerperal state?
8. Describe the internal method of performing podalic version and what are the dangers to the fetus?
9. (a) Give the diagnostic points of value in breech presentation prior to rupture of the membranes. (b) Name and describe positions of breech presentation.
10. Describe briefly the operation of cesarean section.

GYNECOLOGY.

1. Give the etiology of metrorrhagia.
2. Give the effects of öophorectomy.
3. Give the names of the two most important muscles of female perineum.
4. What is meant by fibrosis of the uterus?
5. Describe the endometrium.
6. Name the conditions that cause sterility in the female.
7. What pathological conditions are caused by posterior displacement of the uterus?
8. Classify tumors of the uterus.
9. Describe one operation for procidentia uteri.
10. Give the contraindications for curettage.

ANSWERS.

ETIOLOGY, PATHOLOGY, SYMPTOMATOLOGY, AND DIAGNOSIS.

1. *Etiology of mucous colitis:* Dysentery, diseases of the liver or heart, tuberculosis, nephritis, exhausting diseases, and indigestion.

2. *Etiology of scurvy:* Improper diet, the absence of fresh vegetables with the salts normally contained in them.

3. *"Acute simple endocarditis* may be prenatal as well as postnatal. In the former class of cases, the right side of the heart is usually involved, while in those instances observed after birth, the disease is most often limited to the left side. While the disease may attack the entire lining membrane of the heart it is especially marked at the valvular portions of the endocardium. The earliest change is that of hyperemia of the membrane rendering it red and swollen. As the inflammatory exudate is thrown out the surface of the valves become roughened and warty excrescences are formed. These verrucose formations are to be found on the auricular surface of the mitral valve and on the ventricular surface of the aortic valve at the line of contact of their leaflets, usually from 1 to 2 mm. from their free margin. These vegetations are produced by a proliferation of the cells of the adventitia and of the external connective tissue; fibrin from the blood is deposited on the formations, thus serving to increase their size. The excrescences are friable and may be easily detached or broken off and carried in the blood stream as emboli, to various parts of the body, particularly the left side of the brain, the kidneys, and the spleen. If retained in position, fibrous tissue is eventually formed; the valves become thickened and contracted, producing chronic endocarditis. The leaflets may then become the seats of various infiltrations." (Hughes' *Practice of Medicine.*)

4. *Pathology of abscess of the liver.* "The liver is enlarged, swollen, and opaque, and presents the ordinary evidences of parenchymatous degeneration or cloudy swelling. In addition, in the cases of so-called multiple pyemic abscesses it exhibits a number of variously sized abscesses —usually small, but often coalescing to form larger, sometimes many-chambered cavities, with purulent contents. The so-called single, tropical, or amebic abscess of the liver is described by Manson as consisting at first of one or more grayish, ill-defined, anemic, circular patches, half to one inch or thereabouts in diameter, in which the lobular structure of the liver cannot be made out. A drop or two of reddish, gummy pus may be expressed from the necrotic patches. Later the center of these patches liquefies, and distinct but ragged abscess cavities are formed. An abscess thus commenced extends partly by molecular breaking down; partly by more massive necrosis of portions of its wall; partly by the formation of additional foci of softening in the neighborhood and subsequent breaking down of the intervening septa. These may involve almost if not an entire lobe, usually the right. The pus is usually thick, viscid, chocolate-colored and streaked with blood, and often contains large pieces of necrotic liver tissue. *Entameba dysenteriæ* may be found in more than one-half of the cases (in some of the other cases in the wall of the abscess). The ordinary pyogenic organisms are rarely encountered. A large abscess may consist of a suppurating hydatid cyst." (Kelly's *Practice of Medicine.*)

5. *Symptoms of erysipelas:* Sudden onset; high temperature; a sharply defined red patch on the skin which spreads in all directions, the edges being raised and hard; variable constitutional disturbance.

6. *Symptoms of heat-stroke:* Dizziness, feeling of oppression, nausea, headache, vomiting, high temperature, sometimes diarrhea, relaxation of muscles, loss of consciousness and convulsions. It generally occurs during exposure to the rays of the sun.

7. *Diagnostic symptoms of pellagra:* Anemia, gastric pain, diarrhea, salivation, mental and physical depression; an erythema that is bilateral and occurs on the exposed parts of the body; muscular spasms, neuromuscular pains, vertigo, headache, paralysis, melancholia, spinal tenderness.

8. *Pernicious estivoautumnal malarial fever* is diagnosed by finding the specific protozoon in the blood of the patient. This form is caused by the *plasmodium præcox.*

9. *Diabetes mellitus* is diagnosed by the large quantity of urine, with sugar in it, great thirst, enormous appetite, muscular weakness, emaciation, and the acetone odor of the breath.

10. In *appendicitis* the pain is of sudden onset and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle, and tenderness at McBurney's point; there are usually fever, nausea, vomiting, and constipation.

In *inflammation of the right ovary* the pain is not localized, but may be bilateral, and spreads to the vagina and rectum; there is no tenderness at McBurney's point; it is usually worse, just before the menstrual period, which sometimes affords relief; on vaginal examination the ovary is found to be tender.

PHYSICAL DIAGNOSIS.

1. *In inspection of the thorax,* one should note: The size, shape, and symmetry of the chest; the movements during respiration; the rhythm, force, and frequency of the heartbeat; the position of the apex; any pulsations or enlargements; beading of the ribs; the color of the skin, and any eruptions.

2. *In inspection of the abdomen,* one should note: The general nutrition, size, shape, movements, pulsations, retractions; color of skin, and eruptions; the presence of white or colored lines; enlarged superficial blood-vessels; peristaltic movements; distention, or new growths; and general retraction.

3. *The respiratory sounds.* "The respiratory murmur may be modified in intensity, rhythm, and quality. The modifications of *intensity* are puerile, exaggerated, or feeble respirations. The modifications of *rhythm* are asthmatic, emphysematous, and cogged-wheel or jerky respirations. The modifications of *quality* are bronchial, cavernous, and amphoric breathing. *Bronchial breathing* occurs in lobar pneumonia, phthisis, compensatory emphysema, tumor, syphilis, and infarct. Both inspiration and expiration are harsh and have a high-pitched (tubular) character. *Cavernous breathing* is low-pitched and blowing in character and is heard over cavities. *Amphoric breathing* is similar to the sound produced by blowing gently over the mouth of an empty jar. It is present in phthisical cavities, pneumothorax with patulous opening, and localized consolidation near a large bronchus." (*Pocket Cyclopedia.*)

4. *The voice sounds. "Vocal resonance* is increased over the apex of the right lung in health and in phthisical and pneumonic consolidations. It is diminished in thick chest-walls, pleural effusions, emphysema, and pulmonary edema. *Bronchophony,* or exaggerated vocal fremitus, occurs in phthisis. *Pectoriloquy,* the complete transmission of the whispered words to the ear, is heard over phthisical cavities and in pneumothorax when the lung is patulous. *Ægophony,* in which the voice has a nasal, trembling sound, is heard at the upper border of dullness in pleural effusions." (*Pocket Cyclopedia.*)

5. *Bronchial asthma.* "Physical examination during the attack reveals a distended chest, as the lungs are overfull of air which cannot be expired. Moreover, as the thorax is thus in the inspiratory position, its movements, in spite of the violent respiratory efforts, are extremely limited, and the diaphragm is lowered and almost immobile. The respirations are normal or decreased in frequency; inspiration is short and quick; the expiration is prolonged and wheezy because of the difficulty in expelling the previously inspired air through the narrowed tubes—an expiratory dyspnea. Percussion is normal or hyperresonant. On auscultation a multitude of sonorous and sibilant râles are heard, during both inspiration and expiration. Toward the close of the attack, and during its course if bronchitis coexists, moist râles of various sizes are perceived." (Butler's *Diagnostics of Internal Medicine.*)

6. In *initial stenosis* there will be observed a presystolic thrill; the hypertrophy will be right sided; the left side of the heart will be of normal size; the second pulmonic sound may be accentuated.

In *aortic insufficiency* the murmur is diastolic; the left ventricle is hypertrophied; the arteries will be found throbbing; and the characteristic Corrigan pulse is present.

7. *Pericarditis with effusion.* "The physical signs are: Marked increase of the cardiac dullness; displacement of the apex beat; muffling of the heart sounds; displacement of other organs (if effusion be great). The shape of

the dullness is characteristic. It is conical, the apex of the cone being truncated and situated at the level of the second rib, owing to the close attachment of the pericardium to the great vessels at this point. The apex beat is generally pushed upward and to the left. It lies, when it is palpable at all, distinctly within the left border of cardiac dullness, not, as in enlargement due to valvular disease, in close relationship to it. The marked distention of the pericardial sac surrounds the heart with fluid, and causes a dullness extending much beyond the limits of the organ itself. The amount of bulging and displacement of organs will, of course, vary with the amount of fluid present. As resolution takes place the friction returns, and may be very coarse in character. Muffling of the heart sounds is not always present, and is not entirely due to the presence of fluid, for the fetal heart is quite distinctly heard through an amount of fluid greater than is usually present in pericarditis. The muffling is therefore due mainly to weakness of the cardiac muscle from accompanying myocarditis, although where the quantity of fluid is very great, in serous and chronic pericarditis, this may in part account for it." (Wheeler and Jack's *Handbook of Medicine.)*

8. *Physical signs of arteriosclerosis.* The arteries are tortuous and feel like a pipe-stem; the apex beat of the heart is powerful and may be displaced to the left; cardiac dullness is increased downward and to the left, owing to hypertrophy of the left ventricle; the first sound of the heart is apt to be loud and booming, and the second sound accentuated.

9. *Examination of spleen.* "A greatly enlarged spleen and more rarely one scarcely more than palpable may be seen to move with the respiration; furthermore, in any case of splenomegaly a marked prominence of at least the left upper quadrant is produced. Auscultation may reveal friction sounds in the presence of perisplenitis, or the organ may be anchored by adhesion, but it is ordinarily freely and directly movable with respiration, and palpation is the only method yielding important results. The position of the patient should be right lateral if minor enlargements are to be noted, as in typhoid fever or other acute infections, and the right hand should make pressure posteriorly while the left makes palpation. Abdominal distention defeats palpation save in great enlargement, and the normal spleen is not palpable. If greatly enlarged the dorsal position is to be preferred and the condition can hardly be overlooked, unless with a tense wall the careless or hurried examiner fails to get below the actual border or to distingnish between muscular resistance and the splenic mass." (Greene's *Medical Diagnosis.)*

10. In the case of a bladder distended with fluid there will be a tumor in the hypogastric region, dullness on percussion over the tumor, and the introduction of a catheter will cause the tumor to disappear.

Optional. Right-sided pleurisy with effusion.

OBSTETRICS.

1. *Changes that take place in the circulatory apparatus at birth:* The hypogastric arteries dwindle and become impervious; the Eustachian valve atrophies; the foramen ovale closes; the ductus arteriosus and ductus venosus become obliterated; the umbilical vein becomes obliterated and is afterward known as the round ligament of the liver.

2. *Conditions that may be mistaken for pregnancy:* Amenorrhea, ascites, fibroids, ovarian tumors and cysts, obesity, tympanites, subinvolution of the uterus, and pseudocyesis.

3. *Symptoms of death of fetus in utero:* Cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements are absent, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time, crepitus of its cranial bones may be elicited.

4. *Retroflexion of the gravid uterus, with incarceration, may result in:* Constipation, irritability of the bladder, retention of urine, cystitis, pyelonephritis, rupture of bladder, sloughing of the uterus, peritonitis, exhaustion, and shock.

5. *Premonitory symptoms of eclampsia* are: Dizziness, disturbances of vision, flashes of light before the eyes, vertigo, headache, diminished secretion of urine with lessened output of urea and some albumin, and pain in the epigastric region.

6. If the chin is presenting anteriorly, expectant treatment may suffice; but care must be taken to observe that the chin does not rotate backward. Spontaneous version may occur, and the presentation becomes a vertex one. Failing this, or as a means of favoring this, postural treatment, such as Walcher's position, has been recommended. If, in spite of this, engagement has not occurred, cephalic version is indicated, care being taken not to rupture the membranes. If this is not successful, podalic version should be tried. If, after all these manipulations the child is still alive and the head is engaged, symphyseotomy is indicated; if the child is dead, craniotomy should be performed.

7. The aseptic management of normal labor aims to *prevent* infection. The prophylaxis consists in thorough disinfection of the *patient*, the *physician*, and the *instruments* and *appliances* employed. The simplest method is as follows: "The *patient*, at the beginning of labor, takes a tepid bath and is well scrubbed all over with soap and water. Then an enema of soap and water to empty the bowel; after the action of which the external genitals, thighs, buttocks, and abdomen are carefully washed with a 1:2000 bichloride solution, special attention being given to overlook no fold or fissure of the surface. The vaginal douche, of 2 per cent. creolin solution, or the weak solution of bichloride of mercury formerly used before labor, has been abandoned, unless there be some already existing infection, when it may be used. The normal vaginal mucus is itself germicidal in some degree, as well as a useful lubricant, and should therefore be allowed to remain undisturbed. Moreover, washing out the vagina exposes the woman to some danger of infection from an unclean syringe. The *physician*, before making any examination or doing any operation, removes his coat, bares the arms to above the elbows, when the hands and arms are thoroughly scrubbed with soap, water, and a stiff nail-brush. Scrape the under surface of the nail-ends and the fissures surrounding the nails with some pointed instrument, not sharp enough to scratch, and having washed off all soap in some clean water, immerse the hands and leave the arms in a 1:2000 bichloride solution, and continue this last washing for ten minutes." (King's *Obstetrics.)*

Nothing should come in contact with the genitals of the patient that is not sterile; and examinations should be as few as possible.

8. "*Internal version* is done by passing one hand into the uterus, seizing and bringing down one or both feet. The cervix must be sufficietly dilated to allow the hand to pass. It should be done as soon as possible after the membranes have ruptured. If there is only slight retraction of the uterus it may be done, by an expert operator, by deeply anesthetizing the patient, but one who has not had much experience of the operation should not attempt it. If the uterus is firmly retracted it should never be attempted. The patient may lie on her left side, or preferably on her back. The right hand may be used in all cases, but in some the left one does better. It depends on which way the child is lying. Use the hand which will most easily reach the front of the child. Thus, if its back is toward the mother's right side, use your right hand, and if the back is toward her left, the left hand; but if you are not accustomed to working with your left hand always use the right. The hands and arms should be thoroughly sterilized, and well washed in lysol solution. Pass the hand in a cone shape to dilate the cervix, if it is not sufficiently dilated already, and pass the hand on to the front of the child, rupturing the membranes, if they are unruptured. As much of the liquor amnii as possible should be retained in the uterus by damming it back with the wrist. If a contraction comes on, spread your hand flat on the front of the child and wait until the uterus relaxes. If you do not do this the pressure upon your closed hand will almost paralyze it, and may cause rupture of the uterine wall. Catch one or both feet, making sure it is a foot and not a hand. As soon as you get a foot, pull the leg down steadily into the vagina, if the uterus is quiescent, but if a contraction comes on, wait, spreading your hand out as before. The child's body usually rotates quite easily, unless the uterus is retracted round it. If version is attempted when the uterus is retracted, as in a transverse case, care must be taken to unhitch the shoulder from under Bandl's ring, if it is caught, but only an expert should undertake such a risky operation, and it should only be undertaken if there is a chance of saving the child's life. The final part of the deliverv is carried out in exactly the same way as when the breech presents." (Jardine's *Delayed and Complicated Labor.*)

The *dangers to the fetus*, are: Injury from the traction, asphyxia, and death.

9. In *breech presentation* the back of the fetus may be palpated to one side of the mother's abdomen, the head is found at the fundus of the uterus, and auscultation gives the heart sounds above the umbilicus. The breech is

either above the brim of the pelvis, or else it fills up the pelvis so that pelvic palpation is impossible.

The *positions of breech presentation*, are:—Left sacro-anterior, right sacro-anterior, right sacro-posterior, and left sacro-posterior.

10. *Cesarean Section.* "Fluid extract of ergot, ɱxx, is injected into the thigh muscles just as the anesthesia is begun. The operator assures himself that there is no loop of intestine between the uterus and abdominal wall, beneath the field of incision. Should a coil of intestine be found there, it is pushed above the fundus. An assistant holds the uterus in central position. The skin incision extends one-third above and two-thirds below the level of the umbilicus. It is best made through the right rectus muscle. The external layer of the rectus sheath is divided, the muscular bundles separated with handle of scalpel and the fingers, and the deep layer of the sheath and the peritoneum divided after lifting them with tissue forceps. Bleeding vessels are controlled by gauze sponge pressure, or held by catch-forceps before opening the peritoneum. A short longitudinal median incision is made in the uterine wall beginning at the fundus, avoiding the membranes if still unbroken. This is extended downward with fingers, scissors, or scalpel to a total length of about six inches. The hand is thrust through the membranes and the child is extracted by the head or the feet, whichever is most accessible. In case of anterior implantation of the placenta, usually the hand may best be passed directly through it. The cord is clamped at two points with catch-forceps, cut between them, and the child is passed to an assistant. The uterus slips out of the abdomen as the child is extracted, and the intestines are kept back with hot sterilized towels placed over the upper part of the incision. The coverings help also to protect the peritoneum from soiling. The uterus is wrapped in hot moist cloths. As a rule, it is better not to wholly eventrate the uterus. The placenta, if not spontaneously separated, may be peeled off by grasping it with one hand like a sponge. If the cervix is not sufficiently open for drainage, a large rubber tube or gauze strip is passed down through it and withdrawn from below. Irrigating or mopping the uterine cavity is unnecessary. Asepsis is promoted by leaving it as nearly as possible untouched. The peritoneum is sponged dry with the least possible friction or handling. The uterine wound is closed with deep No. 2 chromated catgut sutures at intervals of about 1/3 inch. They are given a wide sweep laterally through the muscular wall, falling short of the decidua. The peritoneal coat of the uterus is closed with a No. 1 continuous plain catgut suture, forming a welt over the deep suture line. The hemorrhage is inconsiderable and usually ceases with the introduction of the first sutures—a hypodermic of ergotole should be given before beginning the operation, and one of ergotole and pituitrin on the delivery of the child. Retraction of the uterus is ensured by manipulating it, if necessary, through a hot towel, or by faradism. When there has been much blood lost, a quart or two of warm sterilized 0.9 per cent. salt solution may be left in the peritoneum. The parietal peritoneum is closed with a plain running No. 0 catgut suture. Interrupted silkworm-gut sutures are then passed at intervals of about ¾ inch; through all but the peritoneum, from within outward. The fascia is brought together with interrupted No. 2 plain catgut sutures, or with a continuous suture. The silkworm-gut sutures are now tied. The abdomen is cleansed, and the wound covered with a dressing of several thicknesses of dry sterile cheesecloth; over this is placed a thick compress of sterile absorbent cotton. The dressings are secured with strips of zinc oxide adhesive plaster, and held in place by a Scultetus binder." (Polak's *Obstetrics.*)

GYNECOLOGY.

1. CAUSES OF MENORRHAGIA. *Constitutional:* Purpura, scorbutus, hemophilia, hepatic cirrhosis, over indulgence in food and alcoholic drinks. *Local and Vascular:* Uterine congestion and displacement, endometritis, subinvolution, fibroids, and other tumors.

2. *Effects of Oophorectomy:*—"The operation, if thoroughly performed, is followed generally by atrophy and consequent arrest of function in the uterus, and the precipitation of the menopause. The artificial production of this critical period gives rise to phenomena quite similar to those which characterize the natural menopause, except in most cases menstruation is arrested permanently at once. The popular impression that the operation unsexes the woman in a mental sense or renders her masculine is a mistake. The effect of the operation upon sexual desire is variable, but probably no more so than that of the natural menopause. The question of insanity as a result of the operation has been raised; it probably occurs no more frequently than after other operations of equal gravity, probably not oftener than with the natural meonopause." (Dudley's *Gynecology.*)

3. *Two important muscles of the perineum:*—The transversus perinei and the levator ani.

4. *Fibrosis of the uterus.*—"This is a morbid condition of the uterus which presents the following characters: The patients are usually multiparæ between thirty-five and forty-five years of age, but the condition is also met with in younger women, and in nulliparæ. They complain of menorrhagia which lasts from fourteen to eighteen days. At times the bleeding is so profuse as to place life in danger. The uterus is enlarged, and the cervix is hard to the touch. When the cervical canal is dilated the tissue of the cervix tears rather than stretches; the endometrium is quite smooth, but the walls of the uterus are hard and resisting, and the curette makes a harsh grating sound in passing over it, and brings very little tissue away. The structural changes are very striking; the uterus is larger than usual, and its walls are thick and tough. On section the arteries stand out prominently, exposing their thickened walls. On microscopic examination the muscle tissue of the uterus is seen to be replaced by an abnormal growth of fibrous tissue. The walls of the uterine arteries are very thick, and the lumina of the vessels much narrowed and sometimes obliterated. The glands of the endometrium are markedly atrophied, so that the mucosa presents a much thinner layer than the normal. The changes in the tissues of the uterus are analogous to the curious fibrotic changes which occur in the walls of the cardiac ventricles as a sequel of syphilis. In the uterus the changes are probably a remote consequence of septic endometritis." (Sutton and Giles' *Diseases of Women).*

5. "The *mucous membrane of the uterus* is thick, and consists of a lining of ciliated epithelium, supported on a vascular and very cellular fibrous tissue. Long tubular glands extend down into the muscular coat invading its deep layer. In the cervix the glands are shorter, but more branched, and are lined by columnar mucus-secreting cells. Near the os uteri the epithelium becomes columnar, and passes at the orifice into the stratified squamous type. During menstruation the mucous membrane becomes congested, the surface becomes partially disintegrated, and an escape of blood takes place from the surface." *(Aids to Histology).*

6. The *most common causes of sterility in woman* are: Gonorrhea, absence or errors in development of any part of the genital tract, malformations of genitals, fistulæ, lacerations, obesity, alcoholism, pelvic inflammations, dyspareunia, inflammations of uterus, tubes, or ovaries, elongated cervix. The cause may not be in the woman, but in the man.

7. *Posterior displacements of the uterus may cause:* Menstrual irregularities (such as amenorrhea, dysmenorrhea, or uterine hemorrhages), abortion, leucorrhea, sterility, constipation or pain on defecation, neurasthenia, hysteria, and various reflex symptoms. The ovaries and tubes may be displaced or pressed upon; the uterus may be compressed, or dilated.

8. *Tumors of the uterus may be classified as follows:*

I. *Malignant:* Carcinoma, sarcoma, deciduoma malignum, endothelioma.

II. *Benign:* Fibromyoma, adenomyoma, polypi.

9. *Operation for procidentia uteri.* "An incision two or three inches in length is made immediately above the symphysis, and the fundus uteri is drawn forward by a volsellum. Three silkworm gut stitches are inserted through the abdominal parietes and peritoneum, and also through the body of the uterus just posterior to its axis. The stitches should include about ¾ inch of the uterine wall in their grasp, and go about ⅛ inch deep. On drawing them tight, the uterus is fixed forward against the abdominal wall and contracts adhesions. In some cases it may be desirable to scarify the uterine wall before tying the stitches, so as the better to determine adhesions. As a general rule the adhesions stretch somewhat, and hence allow a certain degree of play, but without the likelihood of a return of the displacement." (Rose and Carless' *Surgery.*)

10. *The contraindications to curettage* are: The possibility of pregnancy and malignant tumors.

(To be concluded.)

Hydatid Cysts of the Liver.—D. G. Greenfield reports the case of a male, aged 10 years, in whom when he was aged 3 years his mother noticed a lump on the right side of the abdomen. In the course of two years three hydatid cysts were drained. A year ago he had slight hemoptysis.—*Proceedings of the Royal Society of Medicine.*

Therapeutic Hints.

A Rule for the Administration of Unusual Fractional Doses of a Drug.—Dr. M. S. Aaronson of New York writes that he has devised a rule whereby one may readily administer any fractional dose of a drug, starting out with one of the standard tablets of known strength. Thus if one has a tablet of morphine containing ¼ of a grain, and if it is desired to administer 1/60 of a grain of this drug, the procedure is as follows: Take 60 minims of water and in this dissolve the tablet. Eight minims of this solution contains the required dose. This rule is applicable in the administration of any fractional dose, whether or not the denominator of the fraction is a multiple of the denominator of the fraction represented in the tablet as supplied by the manufacturer.

A Diuretic Mixture in Cardiac Edema.—Fürbringer and Kohlschütter recommend the following:

℞ Infusion of digitalis, 150 grams.
Tincture of strophanthus, 3 grams.
Citrated caffeine, 2 grams.
Solution of potassium acetate (40 per cent.), 50 grams.

The dose is one tablespoonful every two hours.

Ortner combines the infusion of digitalis with a double salt of caffeine. He frequently uses theocin or its preparations in conjunction with the infusion of digitalis.

The Treatment of Pruritus Vulvæ.—Gusserow recommends the use of the following ointment:

℞ Cocaine hydrochloride, 0.15 gram,
Menthol, 1 gram,
Salol,
Olive oil, āā, 2 grams.
Lanoline, add 40 grams.

Fritsch prescribes the following mixture for internal use:

℞ Potassium bromide,
Sodium bromide,
Ammonium bromide,
Chloral hydrate, āā, 5 grams.
Morphine hydrochloride, 0.05 gram.
Atropine sulphate, 0.005 gram,
Distilled water ad 200 c.c.

M. et Sig: One to two tablespoonfuls to be taken at night.

An Emetic for Children.—The following mixture, known as "linctus emeticus," is well adapted for use in children:

℞ Tartar emetic, 0.06 gram.
Powdered ipecac root, 1.2 gram.
Distilled water, 30 grams.
Oxymel of squill (B. P.),
Simple syrup, āā 15 grams.

Of this mixture there should be given from one teaspoonful to one tablespoonful every 15 minutes until the effect is produced.

Pituitary Extract in the Treatment of Constipation.—B. A. Houssay and J. Beruti report favorable results following the hypodermic administration of pituitary extract as a means of stimulating intestinal peristalsis. The injection of 2 cubic centimeters often produces an evacuation at the end of one or two hours. If 3 cubic centimeters be used, then defecation results in from six minutes to one hour. It is pointed out that the doses that stimulate peristalsis are higher than those that excite uterine contraction.—*La Presse Médicale.*

CLINICS, DEPARTMENT OF PUBLIC CHARITIES

CALENDAR, DECEMBER, 1913

MONDAYS			
City Hospital	Ophthalmology	Dr. Strouse	2:00 P.M.
	Surgery	Dr. Dawbarn	2:00 P.M.
	Dermatology and Syphilis	Dr. Gottheil	3:00 P.M.
Cumberland St. Hospital	Laryngology and Rhinology	Dr. Stewart	4:00 P.M.
	Surgery	Dr. Walmsey	3:00 P.M.
	Surgery, Oral	Dr. Shea	4:30 P.M.
TUESDAYS			
Neurological Hospital	Neurology	Dr. Byrne	9:00 A.M.
Randall's Island Hospital	Orthopedics	Dr. Ogilvy	10:00 A.M.
	Ophthalmology	Dr. Mulcahy	2:30 P.M.
Cumberland St. Hospital	Gynecology	Dr. Burnham	1:00 P.M.
	Surgery	Dr. Iler	3:00 P.M.
Kings Co. Hospital	Genitourinary Surgery	Dr. Morton	2:00 P.M.
Coney Island Hospital	Surgery	Drs. Fiske and Bogart, Murphy and Lack	10:30 A.M.
	Medicine	Drs. Hall, Nash, Hegeman and Byington	3:30 P.M.
WEDNESDAYS			
City Hospital	Surgery	Dr. Dawbarn	2:00 P.M.
	Obstetrics	Dr. Dorman	2:30 P.M.
Neurological Hospital	Neurology	Dr. Maloney	10:00 A.M.
Cumberland St. Hospital	Ophthalmology and Otology	Dr. Schenck	4:00 P.M.
Kings Co. Hospital	Orthopedics	Dr. Truslow	10:00 A.M.
	Dermatology	Dr. Winfield	1:00 P.M.
	Gastroenterology	Dr. Lincoln	2:00 P.M.
	Orthopedics	Dr. Napier	4:00 P.M.
Coney Island Hospital	Pediatrics	Drs. Beck, McQuillan, Pendleton and Van Wart	3:00 P.M.
THURSDAYS			
City Hospital	Medicine	Dr. Evans	9:00 A.M.
	Gynecology	Dr. Child	2:00 P.M.
Metropolitan Hospital 4th	Dermatology	Dr. Dearborn	2:30 P.M.
4th; 11th; 18th;	Genitourinary Surgery	Dr. Carleton	2:30 P.M.
11th	Laryngology	Dr. Foster	2:30 P.M.
18th	Medicine	Drs. Klots and Seward	2:30 P.M.
18th	Obstetrics	Dr. Storer	2:30 P.M.
4th; 18th	Ophthalmology and Otology	Dr. Boyle	2:30 P.M.
18th	Pediatrics	Dr. Wallin	2:30 P.M.
4th; 11th; 18th	Surgery	Drs. Ostrom and Harrington	2:30 P.M.
Cumberland St. Hospital	Gynecolgy	Dr. Burnham	1:30 P.M.
	Surgery	Dr. Walmsey	3:00 P.M.
Kings Co. Hospital	Obstetrics	Dr. Judd	10:00 A.M.
Coney Island Hospital	Gynecology	Drs. McEvitt, Mills, Mayne and Rankin	1:30 P.M.
	Rhinology and Laryngology	Dr. Tucker	1:30 P.M.
	Surgery	Drs. Fiske, Bogart, Murphy and Lack	3:00 P.M.
FRIDAYS			
City Hospitol	Surgery	Dr. Dawbarn	2:00 P.M.
	Laryngology and Otology	Dr. Dougherty	2:30 P.M.
	Dermatology and Syphilis	Dr. Gottheil	3:00 P.M.
Neurological Hospital	Neurology	Dr. Abrahamson	9:00 P.M.
Cumberland St. Hospital	Surgery	Dr. Iler	3:00 P.M.
	Surgery, Oral	Dr. Shea	4:30 P.M.
SATURDAYS			
City Hospital	Genitourinary Surgery	Dr. Fuller	1:00 P.M.
	Pathology	Dr. Larkin	2:00 P.M.
Kings Co. Hospital	Pediatrics	Dr. Parrish	3:30 P.M.

All registered physicians, resident and visiting, and medical students, are cordially invited to attend these clinics.

Cards of admission, valid until October 1st, 1914, may be obtained at the Academy of Medicine, 17 West 43d St., Manhattan, and at the Medical Society of the County of Kings, 1313 Bedford Ave., Brooklyn, as well as from the secretaries of the several medical colleges.

Case of Paralysis of Both Internal Recti with Slight Ptosis.—E. H. Harries-Jones reports the case of a child aged 5 years in whom there was almost complete paralysis of the third nerve on both sides; the eyes were divergent, with widely dilated pupils which did not react to light or accommodation. Ptosis was only partial. The eyeballs did not move upward, downward, or inward. The optic disks were pale on their temporal sides, but the vessels were normal, and there was no sign of there having been any optic neuritis. The history of the case was peculiar, the mother stating that the child went to school last January (six months ago) "quite right," but returned in the afternoon with the eyes in the present condition. There have been no further symptoms—no headache, giddiness, or sickness.—*Proceedings of the Royal Society of Medicine.*

AORTITIS SYPHILITICA.

By I. W. HELD, M.D.,

NEW YORK,

ATTENDING PHYSICIAN AND RADIOLOGIST, HAR MORIAH HOSPITAL.

THE history of luetic affections of the aorta is of comparatively recent date, although brief references are made by Lancisi, Morgagni, and Scarpa to the relation of syphilis to the arteries.

With the exact pathological studies of Virchow begins the knowledge of syphilis of the internal organs, and it was Heubner,[1] at that time a pupil of Virchow, who made an exact histological study of the cerebral arteries in syphilis. Heubner is rightfully credited with having laid the foundation of the study of syphilis of the small blood-vessels.

The study of syphilis of the large blood-vessels begins with the English military surgeon, Welch,[2] who described the statistics of aneurysms in the English army, and called attention to the important fact that 66 per cent. of them are of syphilitic origin. Other observers soon reported even higher percentages of aneurysms as the result of syphilis.

The first one to call attention to the fact that the syphilitic changes of the aorta differ from those that are the result of arteriosclerosis was Döhle,[3] a pupil of Heller. The pathological institute in Kiel took up the work of Döhle with more exactness, and in their report fully confirmed his assertions. It is surprising that Virchow was such a strong opponent of the Kiel school. The interest of Chiar and Benda[4] was awakened in the year 1903, and after working independently on the subject of syphilis of the aorta they, too, fully coincided with the views of Döhle.

While the exact pathogenesis as to syphilis of the aorta is not settled yet, there is no longer any doubt that there is an independent affection of the aorta due to syphilis, and the findings have been confirmed by such pathologists as E. Libman, Coplick, Stengel, Adami, Osler, von Hansemann, Pick, Oesterreich, and Benda.

Numerous are the names given to this affection. The best names are supplied by Heller,[5] who calls it mesarteritis luetica, or von Behring,[6] who labels it aortitis syphilitica, both names being fully descriptive of the conditions.

Morbid Anatomy.—In typical cases a most characteristic picture is found. We find either diffuse areas or spots of fold-like elevations of a hard consistency. Between the elevations contractions as the result of fibrous tissue formation are found, forming distinct depressions. The latter are so deep that in some places they appear like grooves. Superficially the intima does not appear to have undergone any changes. The areas of calcification and fatty changes, characteristic of arteriosclerosis, are missing here. Another characteristic feature is that syphilitic changes have a tendency to spread to the aortic valve, and also to the other ostii. This is important clinically, as will be shown later. The further thinning out of the above described depressions leads to the formation of aneurysms. The abdominal aorta is, according to some, never affected.

Microscopical changes are confined to the media. Everywhere round cell infiltration, granular tissue formation, and formation of blood-vessels are found.

Some areas in the media are necrotic. The adventitia shows inflammatory changes. The intima may be free from changes altogether, or only secondary thickening is seen. In cases where arteriosclerosis and syphilitic aortitis coexist, the intima shows atheromatous and calcareous changes. In such cases the post-mortem diagnosis becomes difficult, and we have to-day a great aid in the post-mortem Wassermann examination of the blood. I was much impressed in L. Pick's pathological laboratory by the aid which this method affords in diagnoses.

Etiology and Pathogenesis.—Since anatomical studies have called our attention to the frequency of syphilitic infection of the aorta, we recognize the disease much more frequently clinically. A few statistics will serve to demonstrate the frequency of the disease under discussion in its relation to syphilis. Stadler,[7] in 156 cases of syphilis, found in 82 per cent. syphilis of the aorta. Eugen Fränkel,[8] in 102 cases of syphilis, found in 53 syphilis of the aorta. Bach and Wiesner[9] found syphilitic changes in the aorta and pulmonary artery in 67.4 per cent. In this country Libman, Longcope, and Coplick likewise frequently found the aorta to be the seat of syphilitic infection.

Ages, according to most observers, are between thirty and fifty. Romberg[10] rightly remarks that when there is evidence of aortic or coronary disease in middle life, suspect syphilis. According to Stadler, the time between the primary infection and aortic disease was in 200 cases hard for him to determine, for the majority deny infection, and some are ignorant as to whether they ever were infected. In most cases, however, it can be said with safety that the average time between the primary infection and involvement of the aorta is from fifteen to twenty years. In six cases that I had occasion to observe clinically, three denied primary infection, one showed symptoms twenty-six years after the infection, one thirty-two years after, and one as early as five years after the primary infection. A similar case found in literature, having occurred five years after infection, is cited by Stadler. The case came to autopsy. A few cases with clinical manifestations between five and seven years after the primary lesion are cited in literature.

The relation between tabes dosalis, dementia para-

lytica, and syphilitic aortitis, has lately been shown to exist by a number of prominent observers. Stadler in his 248 cases found 6.2 per cent.; Stinzing[11] found 3.8 per cent.; Rogge and Müller[12] found 10 per cent; von Strümpel[13] even observed a greater number. Of late the clinical observations of Goldscheider[14] and others show very frequently the relation of tabes dosalis to syphilitic aortitis. It is of the utmost importance to examine cases of tabes for diseases of the aorta, and vice versa.

Symptomatology.—The clinical manifestations of syphilis of the aorta differ, depending upon what part of the aorta is affected, the extent of the infection, as to whether the aortic valves and other ostii are involved, the condition of the coronary arteries, the myocardium, and, as very pertinently pointed out by Huchard,[15] the condition of the kidneys. There are doubtless many cases, and I had occasion to see some in L. Pick's series of cases, where distinct syphilitic signs of infection of the aorta are found in patients who had shown no symptoms at all during life.

The symptoms, however, when present differ. In cases where the aortic valve and coronary vessels are involved there exists a distinct symptom complex. To illustrate, I shall take the liberty of citing one of our observations at the Har Moriah Hospital:

A—z, male, forty-six years old; married and father of six healthy children; his wife never aborted. He is a business man and of good habits. At first he denied specific infection; his blood, however, having given a strongly positive Wassermann reaction, and also positive complement fixation test for gonorrhea, he confessed to having had both diseases twenty-eight years ago. He stated that he had very few secondary symptoms, and therefore was treated very incompletely for syphilis. He remained well, however, until two years ago. His first symptoms began with a burning sensation under the sternum, later giving rise to pain. These pains began to radiate to the left shoulder, later to both shoulders, being somewhat aggravated by exercise. Still later he began to develop marked and troublesome pulsations in many of his arteries, particularly the temporal, brachial, and carotid arteries. He was especially troubled at night; he might be comfortable all day, and even when doing light work, but during the nights he would be awakened by a sudden fright, tightness under the sternum, finally giving rise to pain leading to both shoulders and down the arms, associated with dyspnea, and relieved on the coughing up of bloody expectoration. He complained frequently of a sensation as if his heart had stopped beating.

Physical Examination.—Visible pulsations of the temporal, cartoid, brachial, and femoral vessels suggest to us aortic insufficiency. The facies, however, so characteristic of aortic insufficiency, viz., bright eyes, dilated pupils, the wide palpebral slits, and pale bluish sclera, are not present in our case. His face was suffused, his lips cyanotic, and his cheeks were reddish. His blood-pressure showed maximal 150, minimal 60 mm. merc. The pulse on palpation showed sudden up stroke, and sudden fall (pulsus celer et altus) or the Corrigan water hammer pulse. Both pulses were equal and 80 per minute. The apex beat was in the sixth interspace 1 c.cm. outside of the left mammillary line. Percussion showed increased dullness over the aorta, both to the left and to the right, and the heart likewise enlarged. On palpation there was no thrill. On ausculation we heard a diastolic murmur over the third interspace, more to the left of the sternum; the murmur was blowing in character and transmitted in all directions, but not beyond the precordium. Besides this there was heard a systolic murmur over the aorta, a symptom due to roughening and dilatation of the aorta. The first sound at the apex was indistinct, the pulmonic second sound likewise indistinct. Over the carotid a diastolic murmur was heard; over the large vessels, especially the femoral, the pistol shot sound was distinctly heard, and by strong pressure with the stethescope we got the Duroziez sign, viz., a diastolic to and fro murmur of the vessels.

Head's zone over the precordium was very characteristic in that case, and Dr. E. Libman, who kindly examined the case with us, demonstrated most conclusively the sign to which Mackenzie called attention, viz., that the red line caused by the pin becomes mottled, in contradistinction to the healthy side, where the line is only red.

In this physical examination, although in so many respects resembling aortic insufficiency, our attention was called to the syphilitic origin of infection by the following indications: First, the absence of any other causative factor, like acute articular rheumatism, acute infectious disease, excessive bodily work; second, the beginning of the disease with pain under the sternum, gradualy progressing to the stage of angina pectoris at a comparatively early age; third, the attacks of pain being worse at night. The night pain seems to me to be of some importance, as it was present in most of our cases. And last, but not least, we recalled the advice of Fr. Kraus, E. Libman, and others, that wherever there is an aortic disease, suspect syphilis. In this man, of course, our diagnosis was strengthened by the positive Wassermann reaction, and by the typical fluoroscopic and radiographic findings of the dilated aorta, particularly the descending portion. His heart, also, while enlarged, was not the size of the characteristic cor bovinum of the non-specific aortic insufficiency. (Most important differentiating point.) Examinations of the blood, urine, and nervous status were completely negative.

Symptoms when the Lesion is Confined to the Arch of the Aorta.—On account of local pressure, probably due to aortic plexus neuralgia, as already taught by the late E. G. Janeway, or better still, according to Longcope,[16] due to inflammation of the root of the aorta, symptoms occur early in the disease. A case referred to us by Dr. M. Schneck is so characteristic of the symptom complex under discussion, that I shall describe it here fully:

J. S., age 27; married; a massively built laboring man, who had always enjoyed good health. About two years ago he began to notice pain under the sternum, which grew worse under physical or mental exertion. Later he had severe attacks of pain during the night, radiating to back and both shoulders, with shortness of breath during the attacks. Characteristic of the attacks was the fact that he experienced no anxiety, so characteristic of angina pectoris; and let it be mentioned right now that this is a very important feature in differentiating such attacks from angina pectoris vera.

Pulses equal, high tension, regular, and not compressible. Blood pressure: maximal 200, minimal 170. Over the neck no visible pulsations. Apex beat in the fifth interspace left mammillary line, the right border in the midsternal line. There was visible pulsation over the apex and in the epigastrium. Over the aorta dullness was very marked, two fingers beyond the left border of the sternum, and three fingers beyond the right. On palpation there was no thrill. On auscultation over the aorta a harsh, loud systolic murmur was heard, not transmitted. The x-ray examination showed the heart moderately enlarged, with the aorta considerably dilated, characteristically resting like a ball over the heart. The typical Head's zone over the aorta was present. The patient denied specific infection; however, blood was taken for a Wassermann examination, and was found to be strongly positive. Then he confessed to having been infected five years before.

In this case our attention was at once directed to syphilis by the extremely high blood-pressure at such an early age, and by the attacks simulating

angina pectoris but not being of the character of a true angina pectoris, viz., the absence of extreme anxiety, pallor, and perspiration. The murmur could not be mistaken for the characteristic murmur in aortic stenosis because of the absence of transmission and of the thrill; also absence of harsh, loud murmur.

Another type of cases is of those that have gone to the stage of aneurysm formation. While it is not in the domain of this paper to discuss aneurysm fully, I must give a short description of a case treated by us in the Har Moriah Hospital:

M. W., age 56; married; four healthy children. Very obstinately denied any specific infection. He was well until two years ago, when his first complaint was brassy cough and hoarseness. Later a pain under the sternum began to annoy him, characterized by its nagging and boring features. Later the pain showed a tendency to shoot up to the left side of the neck and frequently he had pains over the entire left side of the head, with a feeling of numbness over that same side. Dyspnea was rather mild, unless he coughed excessively. He, too, spoke of his pains being worse at night.

His face was slightly suffused, veins more dilated over the left side of the head, neck, and chest. Pulsation over the right carotid, right temporal vessel very marked, the left carotid and left temporal hardly palpable. Palpation over the axillary vessels and the elbows likewise showed that it was more marked on the right than on the left. Palpation over the radial vessels gave the same result. Blood pressure: right, 160 maximal, 120 minimal; left, 110 maximal, 80 minimal. The pupils were unequal, the left being contracted. A larynx examination by Dr. E. Libman, and confirmed by Dr. Meyerhoff, showed the left vocal cord paralyzed, due to pressure on the left recurrent laryngeal nerve. Palpation over the precordium disclosed a very feeble impulse, no visible pulsation over the aorta, no tracheal tugging, and no heaving systolic or diastolic shock. Percussion over the aorta showed marked dullness more to the left, where it extended about three and a half fingers. The heart on percussion showed no appreciable enlargement. Auscultation disclosed over the apex a feeble first sound, accompanied by a short systolic murmur, second sound snapping. Over the entire region of the sternum, corresponding to the pulmonic and aortic area, a short distant systolic murmur was heard.

Because of the absence of a specific history, and of the characteristic tugging, systolic and diastolic shock, expansive pulsation, and loud murmur, we at first thought of a mediastinal tumor. The *x*-ray examination showed a marked shadow over the aorta, corresponding to the arch, also a shadow extending more to the left than to the right. Turning the patient in the lateral position, the area between the spine and the aorta was seen to be obstructed by the shadow, which, according to Gradel, von Bergman, and Levy-Dorn, is a marked characteristic of aneurysm of the descending portion of the aorta.

A Wassermann was returned strongly positive, and the patient then quietly confessed to having been infected thirty-four years before. The absence of visible and palpable pulsations of the aorta in this case may be explained by the fibrous tissue formation and marked calcareous deposits that are present at times in aneurysms.

Cases where the ascending portion of the aorta alone is diseased may show no symptoms whatsoever during life, and only a post-mortem discloses the condition. The other cases were so similar to those described above that I do not deem it necessary to describe them in detail.

Knowing through the pathological studies of the above-mentioned authors that so many cases are seen at autopsy who died of intercurrent diseases, but still showed such marked pathological changes in the aorta, pathologists at times regard with suspicion the diagnostic skill of the internist. Where does the fault lie? The circumstances mentioned below may throw some light on the subject:

1. Early in the disease when signs are still lacking, although symptoms may be present, the condition is most apt to be confounded with neurasthenia (a most unfortunately frequent occurrence).

2. Patients usually consult one physician after another, giving no one a chance to establish a proper diagnosis.

3. Notwithstanding the fact that modern methods can aid us in an early diagnosis, the usual denial of the patient as to any infection and the responsibility of a busy physician prevent the latter from employing those methods, and hence the diagnosis is incomplete.

4. Many patients are of the hypoesthetic type, so that the early aches and pains do not bring them to the physician.

5. The recently established fact that many cases of tabes dorsalis and dementia paralytica also have syphilitic aortitis, as seen on the post-mortem table, is not generally appreciated.

I shall therefore endeavor to describe the symptoms and signs of the earliest and most atypical cases. At first we should most carefully study the history of the patient. Stadler[7] describes incipient cases as follows: "Early in middle life the patient begins to tire easily; he notices first that he cannot carry out any extra responsibilities, then, that he accomplishes even his ordinary undertakings with great effort. He has aches in different parts of the body, perspires readily, and develops a capricious gastrointestinal tract. Sooner or later, however, his pains show a pronounced tendency to confine themselves to the chest, chiefly over the sternum and the left side of the chest. He feels tender areas over the left side of the chest. There is palpitation and dyspnea on slight exertion, properly termed by Huchard *dyspnea d'effort*. Pain begins to disturb his night rest, and the patient is a hypochondriac.

Another characteristic symptom is the psychical state of the patient. Headaches, loss of memory, disturbing dreams, and sometimes even hallucinations, have been described by Hertz,[17] and while the last-named symptoms may also be present in aortic insufficiency, they only occur in the latter during the stage of decompensation, while in syphilitic aortitis they are already present, even when there are no physical signs. Is it any wonder that a diagnosis of neurasthenia is made? But just such cases tax the physician's skill most.

In our physical examination not only ordinary methods should be employed, but the most refined laboratory methods should be resorted to. Blood-pressure should be repeatedly taken, and the exact size of the heart should be studied fluoroscopically and orthodiagraphically. If the first sound at the apex becomes indistinct, and the second aortic ringing, accompanied by a systolic murmur of the aorta, we have a clue that there is a disease in the aorta; and this occurring early in middle life should at once awaken our suspicion of specific affection of the aorta.

In the absence of definite physical signs, it is worth while to utilize the method of Albert Abrams.[18] He makes the patient extend the head forcibly in order to bring the aorta nearer, whereby with a light Krönig-Goldscheider percussion, the enlargement of the aorta can be more easily distinguished. If he does not succeed in the manner described he percusses quickly, with the patient in full expiration, which, he maintains, likewise facilitates the bringing out of the sound, as the lung resonance does not interfere at this stage. He also found that he could influence the vagus in causing dilatation and contraction of the aorta. The former is accomplished by percussing on the lower four dorsal vertebræ, and the latter by percussing over

the seventh cervical vertebræ, thereby causing what he calls aortic reflex. Percussion over the verterbræ should not extend over twenty seconds. Normally transversely over the manubrium dullness extends between 2 cm. and 3 cm. to the right of the midsternum, and 1½ cm. to 2½ cm. to the left of the midsternum. The only exception to the rule is in splanchnoptosis, where the aorta is likewise stretched, and that can be seen fluoroscopically in the dropping heart (bathycardia). Over the descending portion of the aorta there is a distinct bulging which can be modified when the patient is made to press his abdomen up with his own hands.

We should also carefully inspect such patients and take note of large veins over the region of manubrium, and whether veins over both sides of the chest are equally enlarged, a most important sign of interthoracic disturbance.

Palpable pulsation in the jugular fossa, if we are not dealing with emaciated people, is of significance.

Some authors call attention to the subclavian artery being found 1 cm. to 2 cm. higher, corresponding to the side of the aorta diseased. On account of the elongation and dilatation of the aorta, the extreme motility of the heart is considered a sign of disease of the aorta. Von Hoffmann[19] takes exception to this view, and cautions against acting on this sign, as it is so common in nuerasthenics, and people who have lost a great deal of weight. However, it seems to me that if other symptoms, or other early signs are present, the freely moveable heart should also aid us by awakening suspicion. It is also essential that we should practice palpatory percussion, by means of which a marked resistance under the sternum may be noticed. Of course we must exclude bronchial glands, suprasternal struma, and persistent thymus. Curschmann[20] calls attention to the fact that in disease of the aorta the heart sounds are heard distinctly over areas where otherwise they cannot be heard, or if at all only lightly, as over the right supraspinus process when the descending portion of the aorta is diseased. Romberg[10] and Hirschfelder[21] speak of the heart sound being transmitted to the left and lower inner side of the scapula when the descending aorta is diseased.

A careful study of the nervous status should be made. Should even suspicious signs of tabes dorsalis or dementia paralytica exist, and the blood examination for Wassermann prove negative, the cerebrospinal fluid should be examined for a Wassermann reaction. In cases where the Wassermann is absent the luetin test, as first pointed out by Noguchi[22] should be utilized in doubtful cases. The luetin test is of late being given credit by Kaliski.[23]

The aid of the *x*-ray is so important and has assisted us so much in our cases that I think it advisable to enter into some detail in this regard. The first thing to be noticed fluoroscopically where the aorta is the seat of the disease is the dense shadow over the aorta. If such is seen, even when there is no appreciable widening, we have reason to suspect pathological changes in the aorta. As the disease progresses we notice an increase in the width of the aorta and, what is very important, its irregularity. The heart may at that time show absolutely no enlargement, but, according to Groedel,[5] the heart has a typical horizontal position. A. Abrams of San Francisco, and Levy-Dorn in Berlin, lay great stress on the orthodiagraphic study of the aorta; Groedel believes that fluoroscopic and radiographic studies alone are sufficient.

With the patient in the ventrodorsal position, we can see the arch of the aorta if dilated, as well as the descending portion. In order to study the different parts of the aorta, it is advisable to change the position of the patient while fluoroscoping him. Placing him in a lateral position, viz., left side to the screen and right side to the tube, we can judge whether ascending portion, descending portion, or the entire aorta is the seat of the disease. In advanced cases of dilatation of the aorta it is not easy to ascertain whether we are dealing with aneurysm or dilatation, and even pathologists at the post-mortem table differ in their judgments as to such aortas. Oesterreich, for instance, calls all dilatations cylindrical aneurysms, while other pathologists of equal standing consider them dilatations. However, with the patient in the lateral position the fluoroscopic examination will clear up the diagnosis.

In aneurysms the clear field between the spine and the aorta is obstructed. In the majority of aneursyms we also notice expansile pulsation, although the absence of pulsation should not make us exclude the existence of aneurysm. In the case described above there was no pulsation, probably because of the thickening of the aorta by fibrous tissue formation and calcareous deposits.

Prognosis.—Restitutio ad integrum is entirely out of the question. Life, however, if the disease is recognized early and properly treated, may be prolonged for many years. In the series of Stadler's cases 23 died suddenly, 26 as the result of slowly progressing myocarditis, 3 as the result of pulmonary embolism, and 3 of apoplexy. Huchard considers uremia as the most frequent cause of death, and emphasizes the need of the most critical examination of the kidneys in all cases of syphilis of the aorta.

Treatment.—Although Ehrlich himself cautioned against the use of salvarsan in cardiac and vascular diseases, Grassmann[25] was the first to try salvarsan in luetic aortitis. He advised that only small doses should be used, and given twice weekly, 0.2 to 0.3 until four doses are administered.

We should also try to prevent reaction which, according to Wechselmann, is best accomplished by using water doubly distilled, and sterilized. As a further word of caution, I would state that while it has been customary of late to inject salvarsan intravenously in the office, letting the patient walk home, in cardiac and vascular diseases the patient should stay in the hospital at least from 24 to 36 hours; and where there is aneurysm, or marked myocardial involvement, he should be kept in the hospital two weeks, through the usual course of treatment.

We should not forget the words of P. Ehrlich, that rest is a great factor after the use of salvarsan, whenever the heart is diseased. Some of the cases of sudden death that were reported to Ehrlich after the use of salvarsan were really due to the fact that the patient had done unusual physical work soon after the injection.

At the end of the course of salvarsan treatment the mercury salycilate in doses of 0.02-0.03 intermuscularly should be given once or twice weekly, or inunctions of the blue ointment in doses of 4.0, thoroughly rubbed in every night until thirty inunctions are used. Saturated solution of potassium iodide, 15 drops three times daily, should also be given. A form of mercury that has of late been recommended by Hirsch[26] is the oxycyanide of mercury in .01 solution, and acoin 0.4 to 15.0 of sterile water, one-half c.c. of each intramuscularly. This form of mercury, according to the above named au-

thor, is painless, readily absorbed, and is particularly indicated when tabes dorsalis complicates the disease.

Where the pain is marked and not relieved by this specific treatment, codeine may be used, or according to I. Adler,[27] dionin, in doses of 0.015 to 0.03 once or twice daily. As in the beginning insomnia is a great factor, a hypnotic like veronal 0.6, in the form of a suppository or in a cup of hot milk, is to be given.

A mild and non-depressing hypnotic that I applied and found useful is adalin in a dose of 0.5 half an hour before retiring. Another drug that is dependable, especially when the blood pressure is high, is diuretin, 0.5 t.i.d. If the pressure is not high, it is usually combined, according to A. Fränkel,[28] with caffeine citrate 0.06.

Where the kidneys are involved, it should be our aim to determine by our functional tests the form of kidney affection, and arrange treatment accordingly. If, according to Huchard, it is true that the uremic type—the vascular type—predominates, the indications are toward a great restriction of nitrogenous food substances.

Work, if allowed at all, should be moderate. Habits should be extremely regulated, smoking either entirely prohibited or restricted, and liquors absolutely prohibited. Diet is to be regulated according to the complications. If arteriosclerosis and myocardial changes complicate the condition, liquids should be restricted and none at all taken with meals. The diet should be more the lactovegetable form, with buttermilk at least daily, and only white meats, with fish substituted once or twice a week. All forms of food should be avoided that tend to cause fermentation; also sparkling mineral waters, so as not to press up against the diaphragm and increase the intrathoracic difficulties. The bowels should be kept freely open, so as to prevent any straining. If the patient can afford a yearly visit to a spa like Hot Springs, or a European spa where carbondioxide baths are given under competent supervision, this is very valuable. Baths should be allowed only lukewarm, temperature between 98° and 100°.

Results of Treatment.—Judging from the cases reported, notably those of Longcope (*l.c.*) and Oberndorfer,[29] the treatment is only of temporary value. The former, who observed his cases for a long time, noticed that while salvarsan gave great relief after five or six days, the first four or five doses made the patients very much worse, which he attributed to a Herxheimer reaction. After that patients began to improve, particularly the anginal symptoms disappeared, and only reappeared in the course of several weeks. Oberendorfer, who had studied 99 autopsies of aortic syphilis, whose histories during life he followed closely, arrived at the conclusion that while the symptoms had disappeared in many, and were alleviated in some, the pathological condition remains stationary.

Judging by the six cases I had occasion to observe, the case with aneurysm has been comfortable for the last nine months; the physical signs, however, remain stationary. Of the cases that presented the coronary and aortic valve involvement one responded to treatment immediately, but now, four weeks after the salvarsan injection, although he is getting the mercury and potassium iodide, he needs hypnotics, anodynes, and complete rest in order to alleviate the symptoms, so that his improvement was only of a very transient nature. The other case has been more fortunate. He has had no symptoms, when not exerting himself, for the last three months. He also has restful nights, but exertion causes him sub-sternal distress. In general, however, he claims to be very much improved. The other three cases were milder than the ones described, and while not very incipient cases, because they already had marked physical signs and distinct fluoroscopic findings, they feel considerably improved, and are even doing light work. The results of the Wassermann reaction were only possible for us to study in four cases. In two it became negative, in one it remained strongly positive, and one from 4 pluses, reduced to 2 pluses.

THE CARCINOMA QUESTION AS IT PERTAINS TO THE UTERUS.

By CHANNING W. BARRETT, M.D.,

CHICAGO.

PROFESSOR OF GYNECOLOGY, UNIVERSITY OF ILLINOIS MEDICAL SCHOOL; GYNECOLOGIST TO CHICAGO POLYCLINIC SCHOOL AND HOSPITAL; GYNECOLOGIST TO HENROTIN MEMORIAL HOSPITAL; GYNECOLOGIST TO COOK COUNTY HOSPITAL

While we must recognize the painstaking efforts that have been made especially in the last decade to discover the cause of cancer, yet we are forced to admit that carcinoma is one of the unsolved problems of the medical profession. We are reaching out with one hand in the hope of better treatment, while with the other we are holding fast to the old in the hope of rendering what practical aid this ineffectual treatment offers. True, some instances of recovery of seemingly advanced cancer, with or without surgery, are observed, but treatment thus far is based upon empiricism. True success in the

treatment of this scourge must be preceded by more intimate and positive knowledge of its etiology, of which we know little more than did Hippocrates, but there are many things that remain unknown merely because they are unsought. Few secrets are hidden so carefully as to resist the light of scientific investigation, and I think we may confidently expect this one to be revealed, as a result of concentrated efforts being exerted in that direction.

The purpose of this paper is to discuss the practical side of carcinoma as it relates to the uterus, as we know it at the present time, and in doing this we must consider some points that pertain to carcinoma in general and others that have special bearing upon carcinoma of the uterus.

First, I think we may very properly assume that there is a causative factor with which we are unacquainted, be it germ or other parasite or other toxic agent. If this be true, as the behavior of the disease would indicate, then, not knowing its cause, we do not know its beginning, and, not knowing these, we do not know the disease, and much of our supposed knowledge must be open to revision. Very properly we must hold ourselves in readiness to change our views as to what the disease really is. Just as we are now compelled to look on the tubercle and a collection of tubercles making a large growth as a tissue reaction against the tubercle bacillus, and as we must now consider inflammatory processes as a fight of the tissue against an invading toxic agent, so we may find that the epithelial cell proliferation which constitutes the well known histological architectural form in what we call carcinoma, is not the disease but the tissue reaction against disease; nor would the fact that the epithelial cell growth sometimes invades vital structures and aids at last in causing death, stand in the way of its being primarily protective, for such as the action of the acute and chronic protective processes, just mentioned. There is perhaps not sufficient grounds yet to maintain that there is a specific agent for carcinoma—certainly we lack the proof of its identification—but there is too much similarity to tuberculous disease and other infectious processes to ignore the possibility or strongly deny the probability, and, should this be true, the weight of the evidence is strongly in favor of the epthelial cell proliferation being a tissue reaction against the infectious parasite. It is plain that an epithelial cell, or a group of epithelial cells, cannot be considered carcinomatous merely because of separation from surface epithelium, otherwise a skin incision or trauma would almost invariably result in cancer, neither must the epithelial cell below the surface be found to have the proliferating properties of a cancer cell, for it is usually by means of this proliferation that it invades the deeper structure. While it takes a certain grouping of epithelial cells to designate them as a carcinomatous growth, yet the epithelial cell which becomes a part of the cancer is a cancer cell whether it is on the surface or imbedded in connective tissue, and it seems fair to assume that it is imbued with activity other than the mechanical or chemical irritation which played a part in instigating the morbid process. Again, it seems probable that the cancer poison, the effect of which upon the host is so characteristic, is due to other than epithelial cell proliferation and would point to some unknown toxic agent.

Pilcher gives the descriptive definition of cancer thus: "It is in the lawless proliferation of preexisting epithelial cells in luxuriant irregularly arranged masses that invade underlying and surrounding tissues, permeating, destroying them, and finally themselves attaining a mass which can no longer be adequately nourished by an accessible blood supply and which itself then falls into central decay while at the periphery the process still goes on, that cancer consists."

This gives the conception that the proliferating epithelial cells when once irritated into action continue to react without continuance of the irritation and act with the irritation or as a supplement to it and against the organism of which they are an integral part rather than react against the irritation and for their own organism, which may represent our present conception of cancer growth, but is decidedly against the law of cell reaction and therefore against reason. Cells respond to stimuli to irritation but for the protection of their own organism and against an invading organism or irritating process.

Does it then seem impossible or improbable that we may be obliged to define what we now call a cancer as a reaction of epithelial structures against the invasion of the specific microorganism? Would this not be just the conception that we have or should have of the tuberculous process, except the reaction against the tubercle bacillus is a connective-tissue reaction? We turn now from the problematic to that which is better known, although revision may have to follow in the latter.

First, and of great practical importance, and, I might say, contrary to a widespread belief, carcinoma is in the beginning circumscribed and not the local manifestation of a general morbid process. This is shown by the complete eradication through early radical removal, as well as the large percentage of local returns when eradication is not complete.

Second, and also of great practical importance, some form of irritation plays a part as an etiological factor. This may be mechanical, chemical, thermal, actinic, etc. This is perhaps shown in the frequent involvement of organs used as reservoirs, as the stomach, rectum, bladder, uterus, etc., as well as by the particular part involved where irritation is more marked, such as the mouth, the larynx, the pylorus, the cervix uteri, etc., but is more emphatically shown in the frequent or occasional cancer, arising in unusual places due to habits of life, occupational or otherwise, as the lip-cancer of the smoker, the mouth-cancer of the betal-nut chewers of India, the face-cancer of sailors from the sun's rays, the chimney-sweep cancer of the scrotum, the epithelioma of tar workers, the tongue-cancer from an irregular tooth, bile-duct cancer from stone, etc.; but still more emphatic than any other as an indication of these influences of irritation is the cancer reaction which results on the skin of the abdomen in charcoal stove wearers of Kashmir. Untraumatized or unirritated, the skin of the body, arms, and legs seldom if ever develops cancer; but in these people and in x-ray workers, and as a result of long-continued irritation, we have, as pointed out by Crile, gigantic experiments which force upon us the truth of irritation as an element in the beginning of cancer. Let us remember, however, that the succeeding phenomena are best explained upon the ground of this irritation serving the means of introduction of some microorganism or agent yet unknown.

Third, and of still greater practical importance, there is usually a benign or protective reaction to the irritation, a tissue reaction which may be con-

sidered a precancerous condition, a condition which if removed would prevent the development of cancer, or would prevent the invasion of the specific microorganism.

Wherever there has been opportunity to observe, some benign process has usually preceded, such as scar, wart, mole (especially pigmented), fibroadenoma, fissure, ulcer, mechanical abrasion, papilloma, erosion, etc. Only in localities of the body poorly observed do we find carcinoma without the history of the preliminary benign pathology.

Fourth, the epithelial new growth whether primarily protective or destructive, spreads by direct growth and by metastasis, and, through the involvement of important organs and interference with important functions, aids the toxic agent in bringing about a fatal issue in the vast majority of cases in which early eradication does not take place.

Fifth, there is no absolute but rather a relative cancer age, an age of greatest frequency, and this is of vast importance in dealing with cancer of the uterus.

Sixth, heredity of susceptibility may have at times been overestimated, though experiments in mice, fish, etc., and clinical histories would lead us to be not unmindful of this factor; yet in a disease of slow development it is difficult oftentimes to separate hereditary influence from possible infection.

Seventh, the characteristic histological architecture of carcinoma is well known and can be diagnosed by the microscope, and can, therefore, receive appropriate treatment. Upon these propositions must be based our present fight against cancer of the uterus.

The future may reveal the exact cause and an adequate cure, but the present knows no specific. So long as we know no specific cure for late cancer the success of dealing with this condition rests upon education. Education of medical men and the public that women should have these organs examined and their conditions determined, that we have enough "guessing" to do after we have found out all that is possible; education that cancer is largely a preventable disease through hygienic measures and attention to precancerous morbid conditions; that early cancer may be eradicated; that late cancer is practically hopeless except in the amelioration of its conditions; that early operations are safe and that in the disease rather than the operation lies the danger; that elective surgery promises much; that last resort surgery promises little; that the "don't believe in surgery" man is an impediment to the wheels of medical progress and a menace to the public. The question is not what does this or that man believe in, but What will correct the pathology in this particular case? Education that the question is not: "Should benign uterine pathology be corrected?" but "Is there pathology?" Education that at the end of child bearing the question is not usually: "Is there benign pathology?" but "Of what does it consist and what is necessary for its correction?" The non-believing doctor and the non-believing patient often just begin to believe in surgery when a cancer becomes inoperable. Every operator has had his proposal for operation scorned when a radical cure might be expected, and has been begged to operate when operation promised little. A great wave of education is needed to show that the vicissitudes of child bearing and the avoidance of child bearing, etc., bring many women to the relative cancer age with conditions amenable to treatment, but which if neglected lead to cancer.

Without this educational movement our treatment of cancer of the uterus must fall far short of meeting the necessities of the case for many benign precancerous conditions will develop into cancer, early cancer will be allowed to develop into inoperable cancer, and inoperable cancer will be operated upon, but operated or unoperated, it will then lead to a fatal issue. The name of him who discovers the cure of cancer will be counted great, but a greater benefactor is he who can lay down the rules necessary for the prevention of the disease. He may be a brilliant surgeon who leads the way to radical removal of the cancerous uterus, but his glory is dimmed by the man who tells us when to act and what to do to make it impossible for the cancer to develop. Amputation of the cervix for benign conditions we believe has prevented more cancers than the most radical treatment has cured.

In addition to a campaign of education, our treatment of this condition must be along three lines: (1) The recognition and removal of all possible sources of uterine irritation before the onset of cancer. (2) The early recognition and radical removal of circumscribed cancer of the uterus. (3) The amelioration of the symptoms produced by cancer which has progressed beyond the possibility of radical removal.

The first is based upon the proposition that there is a benign or precancerous pathology which if entirely corrected would in most cases prevent the development of the cancer. This, while not based upon exact knowledge of the cause of malignant disease, is yet undoubtedly true, and if true is worthy of the most careful consideration.

Erosions, eversions, cystic degeneration, fibroids, polypi, chronic inflammations, etc., which furnish the opening wedge for the invasion of the unknown cancer agent, should be as promptly as possible eradicated. Not only this, but women should be made to understand that this is the time to treat cancer of the uterus and less provocation than that of cancer pain, cancer hemorrhage, cancer discharge, should lead them to give these organs attention.

The necessity of the second, early recognition and radical removal, is based upon the proposition that cancer is at first circumscribed, and removal is possible, while later it is disseminated and fatal.

Dr. Ries has told us that carcinoma of the uterus could always be cured if our surgery could go as low as the knees and as high as the neck, but as the average surgeon has not attained the necessary skill, it is highly desirable to see these cases early. This, at present, is not the case. We have known cancer to be well advanced before the patient observed or heeded her condition. We have also known a patient to be kept under local treatment for many months until total removal was impossible because the attending physician thought it was erosion, and because, in other cases, he did not want to frighten his patient. In the name of humanity, what are we for, if it is not to frighten our patient when she ought to be frightened? How can a patient be brought to do the right thing if she doesn't know her need? Radical removal is desirable when cancer is still within limits, but surgical skill has followed the disease to the limit of human endurance and sometimes beyond. Surgery must find its greater success in earlier opportunities.

The radical operation has here the advantage that we are usually dealing with an organ which has served its usefulness, is not necessary to life or happiness, and can therefore be totally sacrificed and

its immediate neighboring structures can be removed. The growth is nearly always accessible for microscopic examination, and therefore a diagnosis may be made.

Against radical removal are prejudice and prudishness leading to late consultation. The fact that it is not a vital organ causes less urgent symptoms which fail to force the patient's attention. Close proximity of bladder, rectum, and uterus prevents radical removal if the carcinoma is advanced, and yet their very proximity urges the necessity of early removal. The fact of dissemination through the lymphatics also urges our early attention.

Divergence of opinion has arisen as to how radical an operation should be. Ries advocates a very radical removal of lymphatics. Werthelm and others are less radical. Abdominal operation, it would seem, should displace vaginal hysterectomy for this condition. The uterus, tubes, and ovaries should be totally removed. The vagina should be amputated low enough to reach healthy tissue, a considerable number of recurrences being in the vaginal vault. The broad ligaments should be removed to the extent of exposing the ureters and pelvic blood vessels, facilitating removal of connecting tissues, lymphatics, and perceptible glands. The wide distribution of the lymphatics makes it unlikely that all lymphatic glands are ever removed, and yet this does not argue for leaving any that the operator's knowledge and dexterity and the patient's strength permit him to reach.

Instead of keeping as close to the uterus as possible we should take out as much of the broad ligament as possible, grasping the ovarian artery at the pelvic brim and the round ligament at the internal ring. The peritoneum is now laid open and the ureter exposed. I would here urge the placing of a strip of gauze around the ureter that it may be drawn taut at any time to indicate its whereabouts, as it is best not to separate it from its surroundings for too great a distance. Time will not permit a discussion of the care of the ureter, and the disposal of the same if it is surrounded by carcinoma structure or is accidentally injured. Suffice it to say that this structure is an important one in the operation as well as in the decision for or against radical operation.

In cases in which total removal is prevented by reason of involvement of the bladder, rectum, ureter, or bowel, or extensive metastases, quite as much or more is to be expected from thorough temporizing treatment. The pain, hemorrhage, and discharge which characterize late cancer can be effectually stopped by thorough cauterization. Some of the results in badly involved late cases have been truly surprising. I find the ordinary soldering iron more effectual than the Paquelin cautery as it has more body. The objection, however, is that they were made sharp pointed, and square cornered for a purpose, and this is a detriment in the human body as we cannot so readily control the depth. I have had instruments constructed in spherical and oblong shapes which having curves instead of angles cannot so readily do damage, and lacking the length of the soldering iron, we can bring the heat where it is desired without being forced to burn the vagina. These make very useful cauteries in other regions.

Antiseptic and cauterizing chemicals have been used in early and late cancer, and different forms of rays and enzyme treatment have been tried. Some of these, as for example acetone, have relieved symptoms and have seemed to delay the growth, according to Gillhorn, but we know absolutely no medical treatment at the present time that gives such results as to warrant its use except in inoperable cases. The good results obtained by early radical removal we sometimes count due to the removal of every proliferating epithelial cell. When we know the now unknown cancer agent we will then probably see that it is not so much the removal of every cancer cell as it is the removal of microorganisms.

The value of the microscope, the cystoscope, the ureteral catheter, rectal examination, etc., to determine, first, the presence, and, second, the degree of extension, of the cancer must not be overlooked.

Some matters I have necessarily left unmentioned or have touched only lightly. If I have dwelt upon some points of which the present status of carcinoma would not warrant the full acceptance, it has been because there seems to be enough in the behavior of carcinoma to warrant our accepting the possibility of an unknown agent whose introduction into eroded or abraded surfaces brings about as a protective reaction the well-known epithelial proliferation. If there is a possibility that this is true, then it should receive attention in our care of a carcinoma patient and in those patients having conditions which easily become cancerous, and while contending for a point not demonstrable, let us trust that the consideration of it does us no harm.

In conclusion I would emphasize the following points:

1. The epithelial cell reaction, known as carcinoma, is probably due to a microorganism or agent yet unknown.

2. The cell reaction now known as carcinoma may prove to be a primarily protective tissue reaction against the cancer infection.

3. Women come to the age of frequency of cancer with many benign conditions which serve an opportunity for the introduction of this agent or furnish the irritation which lights up the malignant proliferating process, or both.

4. Proper attention to these conditions would decidedly reduce cancer of the uterus.

5. These conditions receive a large amount of neglect from the profession and the laity.

6. Correction of pelvic pathology as it occurs, and especially as a woman nears the end of the childbearing period, will lessen her chances of developing cancer and will otherwise vastly increase her comfort during the 25 or 40 years of life she should have remaining.

7. There is a fair chance of eradicating early cancer, with almost no chance of other than ameliorating late cancer.

8. Education of the profession and of the public upon these points is sorely needed.

9. Honesty and intelligence should combine not to watch precancerous, suspicious, or early cancer pathology, but to eradicate pathology whether benign or malignant. In other words pathology has no place in the human body, much less in an organ of great cancer frequency. We know no tumor, swelling, erosion, ulceration, cystic degeneration, or irritation that is best to go untreated; if it does not yield to simpler means it should be removed.

10. Early radical removal is at present our best method of attack when cancer has once begun, but it is not ideal. We may hope for a better method.

11. Late cancer can often be checked, symptoms ameliorated, nutrition improved, comparative comfort restored, life prolonged, and perhaps occasionally the cancer completely eradicated by single or re-

peated cauterization, and the same results are claimed upon good authority for other measures, but these do not offer enough hope to displace early surgical measures.

12. Surgery must find its greatest success, not in more radical removal, but in earlier opportunity.

32 North State Street.

THIRTY-THREE CASES OF THYROID DISEASE.

By B. DAVIDSON, M.D.,

BROOKLYN, N. Y.

ATTENDING PHYSICIAN AND SHELDON FELLOW IN MEDICINE IN THE MEDICAL CLINIC, CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK.

The following is a report of thirty-three cases of thyroid disease which were treated at the medical clinic of the out-patient department of Cornell University Medical College during the past two years. The work was undertaken primarily with a view of observing the effect of the Rogers and Beebe serum in these cases. After a while, however, a good many cases presented themselves in which serum was not indicated and it was thought advisable to include those cases in this report.

Two years is too short a time in which to determine any permanent effects in a chronic disease such as exophthalmic goiter. Moreover only four of the serum cases remained under continuous treatment longer than six months, as they were all working people and anxious to stop this drain upon their time as soon as any improvement was noticed. However, it was thought advisable to publish this preliminary analysis and follow it up with further reports from time to time as the work progresses.

All of the cases in this series showed distinct symptoms pointing to a disturbance of the thyroid gland at some time while under observation, and they represent various phases of this condition which I attempted to classify. We must remember, however, that it is impossible to draw hard and fast lines between any groups of cases of thyroid disease. The symptoms are so numerous and so varied and the mechanism of their origin is so obscure that any attempt at rigid classification is out of place. However, for purposes of discussion and treatment it was found convenient to arrange the cases in the following gropus:

1. *Simple hypertrophy of the thyroid* with perhaps pressure symptoms, but no signs of hyperthyroidism.

2. *Temporary functional hyperthyroidism.* Any prolonged strain, mental or physical, infectious disease, pregnancy, or menstrual disturbance is apt to produce this condition which subsides on removing the cause and resuming ordinary hygienic life. This is particularly likely to occur in people who had a simple goiter before. I have seen many cases that I felt sure belonged under this heading, but the disturbance being mild and temporary, they did not come to the clinic long enough for me to include them in this report. In this series I have two cases of this type.

3. *Cases of true hyperthyroidism of various grades of severity.* This group corresponds to what is generally known as exophthalmic goiter. In placing cases into this group it must be borne in mind that neither the exophthalmos nor the goiter is absolutely essential for a diagnosis.

4. *Mixed cases of hypothyroidism and hyperthyroidism.* These showed symptoms of both conditions and it is probable that they are cases of hyperthyroidism that are in the stage of crossing the border line into myxedema, although one of these appears to have started as a mixed case right from the beginning.

5. *Cases of hypothyroidism or myxedema.*

6. *Cases of thyroid disturbance* which showed symptoms suggestive of derangements of other internal secretions.

Age.—About two-thirds of the patients were between 28 and 40. The youngest was a girl of 13½ and the oldest a woman of 57. There were five patients below 20, eleven between 28 and 33, and eleven between 38 and 43.

Sex.—Only one male in the whole series and he had hyperthyroidism.

Nation and Race.—Thirteen were born in America, seven in Russia, three in Ireland, three in Italy, and one each in Austria, Germany, and Scotland.

Previous History.—In twenty of the cases previous history revealed nothing of importance. In four of the cases a simple goiter was present for 7, 10, 12, and 25 years respectively previous to the development of symptoms. Two cases gave histories of rheumatism. Two gave repeated attacks of tonsillitis. Uterine trouble in two. Sterility in two.

Family History.—One of the myxedema patients has a daughter with the same disease. Another had a mother with a similar condition. One of the Graves's disease patients has a sister who had the same trouble and their mother had diabetes. Two patients presented histories of cancer in grandmother and uncle respectively. One of the mixed type gave a history of insanity in a grandmother.

Etiology.—It was impossible to find any single factor or group of factors that could be held directly responsible for this condition. However, it is interesting to notice that certain conditions served to aggravate this disease to an extent sufficient to call the patient's attention to it.

Five of the patients first noticed symptoms at puberty, either before or soon after the establishment of menstruation. In one of these cases an attack of rheumatism and in another an attack of tonsillitis preceded the appearance of symptoms. In twelve cases no causative factor could be discovered. Confinement was mentioned as the origin of the trouble in two cases.

Four of the cases had a simple goiter for 7, 10, 12, and 25 years respectively and it suddenly became active. One of these cases gave pregnancy as the exciting cause. In the others no cause was found. Worry, hard work, and nervous strain were mentioned as causes by six patients, while sudden fright was mentioned by four. However, on careful questioning it was elicited that mild symptoms of hyperthyroidism existed previously and sudden fright only served to bring out the condition.

Symptomatology.—The symptoms of each group will be taken up separately.

1. Simple hypertrophy of the thyroid gland.—There are two cases in this group. Both of these patients were well nourished women and the only symptoms they presented were the enlargement of the thyroid and the effect of pressure. In one case the left lobe was enlarged and accompanied by a paralysis of the left vocal cord. In the other case there was a marked enlargement of both lobes and the isthmus, the left being the larger. There was experienced a choking sensation. In both cases operation was advised, but not yet performed.

2. Temporary functional hyperthyroidism.—Two cases of this type presented themselves. In one there was a moderate uniform enlargement of the gland, pulse of 100, occasional palpitation, dyspnea, nervousness, and weakness. All these symptoms followed in a woman after nursing her husband through a severe illness, and improved in two months. The other patient had a simple goiter for ten years and suddenly noticed a slight increase of the goiter, together with some palpitation, weakness, nervousness, and slight tachycardia (96). This patient also improved after one and a half months' treatment and stopped coming to the clinic.

Although this condition is mild and temporary, its importance lies in the fact that if these patients continued to remain under conditions unfavorable to thyroid function, such as nervous strain and worry, they are likely to develop true hyperthyroidism.

3. True hyperthyroidism.—There were eighteen cases of this type in my series. I divide these cases into groups both as regards severity and chronicity, as follows: Mild, 3 cases; moderately severe, 4 cases; severe, 11 cases.

Early, or below six months, 4 cases; fairly early, or six months to one year, 3 cases; chronic, one year or over, 11 cases.

The chronic cases were all severe with the exception of three, one mild, and two moderately severe.

The four cardinal symptoms—goiter, exophthalmos, tachycardia, and tremor—were present in nine of the cases. Six patients showed goiter, tachycardia, and tremor, but no exophthalmos, while in three cases both exophthalms and tremor were absent.

The onset was insidious in all these cases. There were no instances of acute onset. Although four patients claimed to have developed the symptoms within one week after a fright, it was brought out that the disease began before and the fright only intensified the already existing trouble.

Eight out of the eighteen cases presented nervousness, excitement, and irritability as their first symptoms. Tachycardia usually followed in these cases. Goiter was noticed first in six instances. This, however, does not necessarily mean that it was not there first in the others. A good many patients never noticed their goiter until their attention was called to it by a physician or a friend. The other four presented dyspnea, palpitation, feelings of faintness, and attacks of diarrhea as their first complaints.

Thyroid enlargement in some degree was present in all the cases. It was marked in size in twelve cases, moderate in five, and slight in one case. In twelve cases both lobes and the isthmus could be felt while in five cases only the two lobes were palpable, and in one case the right lobe alone was involved. The enlargement was symmetrical on both sides in three of the patients. In thirteen the right lobe predominated and in only one case was the left lobe the larger one. Excitement usually increased the goiter temporarily. The consistence of the gland in all these cases was soft and vascular. Thrill and bruit systolic in character were present in two cases. Visible pulsation of the goiter was observed in ten.

Exophthalmos was present in nine cases. It was very marked in six, moderate in two, and slight in one. In one of the cases with moderate exophthalmos the left eye was a little more prominent than the right. Several of the patients noticed that this symptom became more marked during hard work and excitement. Injection of conjunctivæ was present in two cases. Von Graefe's and Stellwag's signs were present in two cases.

Tachycardia in some degree was present in all cases. It varied from 90 to 140. In one case it reached 148. Excitement, hard work, worry and attacks of indigestion always increased the tachycardia markedly. An intermittent pulse was observed at times in one case.

There was an enlargement of the heart downward in two of the cases. The first sound at the apex was usually of a strong, loud booming character. In two cases a loud, harsh systolic murmur was heard at the pulmonic area.

Tremor was evident in sixteen cases. It was always of a rather coarse, slow character, and involved tongue and hands especially. In two patients the whole body was involved so much that the tremor was communicated to the chairs on which they sat. This symptom too was greatly aggravated by fatigue, worry, or excitement.

Four presented twitchings of facial muscles or muscles of the shoulders. Neuralgia, especially in the back of the neck and over the temples, was complained of in one case.

Restlessness, both mental and physical, was a marked feature in sixteen cases. The patients always seemed on the go, and never getting anywhere. They seemed to have no power of concentration. Thoughts ran through their minds with lightning speed, without leaving any impressions there. Along with this there was marked irritability of temper and in ten of the cases apprehensiveness was a prominent feature.

Defective memory was complained of in a few cases. In these it was probably one of the first signs of the advent of myxedematous characteristics. Sleep was restless and disturbed by attacks of palpitation and tachycardia.

Excessive sweating was a feature in twelve cases. Their skin was always more or less covered with perspiration, even during cold weather. In one case a rash maculopapular in character appeared on the neck and shoulder. It came about every two to three weeks, staying a few days and disappearing as mysteriously as it came.

Digestive disturbances were not numerous. A few complained of intermittent attacks of diarrhea, which came on without any apparent cause and remained for a few days to a week. Stools would vary from 5 to 15 per day, loose in character, and contained no mucus or blood. Diet had little effect. Appetite during these attacks was variable and there was no vomiting.

Menses.—There was only one case in which menstruation became irregular. It came every two to three months, and varied in duration from three to eight days. It was scant and not accompanied by pain.

Effect of Pregnancy.—There was one woman who came under observation, while seven months pregnant, and she stated that her condition became worse since pregnancy began.

Weight.—Loss of weight was a prominent feature in ten of these cases. It varied from slight loss, such as five pounds in a few months to quite marked reduction. In two cases fifty pounds were lost in one year.

Blood.—Anemia was not present except in two cases, in which I considered it a complication. Both were of a chlorotic type. In one case the hemoglobin was reduced to 79 per cent., while in the

other it went down to 40 per cent. Both were improved on the administration of iron. There was a diminution of the white bloods cells in five cases, the count being as low as 4,000. The polymorphonuclear leucocytes were markedly reduced in number, in some cases being as low as 40, while the lymphocytes were increased in three cases.

Urine.—The urinary examination was not particularly significant. It revealed a trace of albumen in two cases, a few hyaline casts in one case, and one or two granular casts in another case.

4. Mixed cases of hyperthyroidism and hypothyroidism.—I have three such cases in the series, and a brief outline of one of these will not be out of place.

E. F., age 42, came to clinic July 2, 1912. In the summer of 1907 this patient had some severe illness, characterized by chills, fever, and sweats. This lasted about a month and left the patient very much weakened, and run down. Since then the patient has gradually increased in weight, but kept on losing strength, and lately has been dyspneic at times. She noticed a goiter in the fall of 1911, which kept on growing slowly. There was slight hoarseness for the last few months, and mental dullness and sluggishness.

The patient was obese, face filled out; lines somewhat obliterated. No pads of fat. Left lobe of thyroid markedly enlarged, right lobe moderately enlarged; consistence firm, no pulsation; pulse 100; slight tremor of hands and tongue; skin and hair dry; no exophthalmos.

This patient was treated with 2 per cent. thyroprotein tablets for three months and a few injections of serum. At the end of that time, pulse was 82, tremor almost gone, dyspnea improved, and patient felt much stronger. The treatment was by no means ended, but the patient stopped coming.

In the other two cases the hyperthyroid symptoms were far more prominent. In fact they were probably pure hyperthyroid cases merging into myxedema. They presented all the typical symptoms of Graves' disease including loss of weight. In one of these the exophthalmos was intermittent. In addition, they both complained of headache and both had dry skin and dry hair, and one of them complained of extreme weakness in her legs. She felt as if her legs were giving way under her. The goiter in both of these cases was hard in consistence.

In both of these cases the serum was relied on mainly, while 1 per cent. thyroprotein tablets were given twice a day at short intervals. These relieved the headache wonderfully. Neither of the two finished their treatment. One of them was quite improved after five months. Pulse came down from 100 to 80, headache improved, goiter was markedly reduced in size, and she felt stronger. The other showed no improvement after one month and stopped coming.

5. Cases of Myxedema.—I have three such cases in my series. Two of these were mother and daughter, and they were previously reported by Dr. Keays. There was nothing peculiar about any of these cases. They were typical myxedema, and improved on thyroid feeding. I tried the 5 per cent. thyroprotein tablets, but they seemed to be without effect.

6. Cases of thyroid disturbance complicated by derangements of other internal secretions.—This is a very interesting group. Our knowledge of the physiology of the ductless glands is very scant, and the symptoms produced during their disturbance have not yet been accurately described. It is therefore very difficult to analyze any of these cases and locate the exact site of trouble.

Two cases in this group are particularly interesting, having developed glycosuria after operations on the thyroid. An outline of each follows:

A. A., age 33, widow, came to clinic January, 1913; previous history negative; exophthalmic goiter five years ago. Thyroid vessels were tied, and this resulted in an apparent cure. She returned, now complaining of nervousness and restlessness. Her pulse was 100, and there was slight enlargement of the thyroid, together with slight exophthalmos. Repeated examinations of her urine showed intermittent glycosuria. She got a few injections of serum, but stopped treatment because she had to leave New York. She showed no improvement.

S. W., age 58; previous history negative; innocuous goiter for 25 years. Five years ago this goiter suddenly became active and patient showed marked symptoms of hyperthyroidism. There was an enucleation of part of the thyroid two years ago, following that there was an apparent recovery from all the hyperthyroid symptoms. She returns now with marked eczema vulvæ, excessive thirst, weakness, and loss of weight. Urine on repeated examinations constantly showed the presence of glucose. Treatment in this case was directed along diabetic lines.

Another case in this group presented a queer combination of symptoms and reacted peculiarly under treatment. A brief outline follows:

S. M., age 39, single. Ailment began four years ago with pains, aches, and stiffness all through body, palpitation, nervousness, and tremor accompanied this, and also intermittent exophthalmos; urticarial rashes coming almost daily, and lasting for a few hours, with marked itching, were a very troublesome feature. She presented a hard goiter, moderate in size, right lobe larger than the left; pulse 120, poor quality; tremor and mental restlessness and confusion; blood pressure 100. Serum made her feel worse even in doses of three minims. Thyroprotein one per cent. also disagreed with her. Her thyroid arteries were finally tied, but even this operation has so far not given much relief.

Of the two other cases in this group, one was a girl of 28, single, who came in complaining of an increase in weight from 120 to 178 pounds in two and one-half years. Along with this she suffered with dyspnea, palpitation, headaches, drenching sweats, and falling of hair. There were no pads of fat. Skin had a sallow color and was moist. Hair was not dry. There was no enlargement of the thyroid, but there was a slight tremor and a pulse of 100. The picture suggested myxedema, but she reacted very poorly to thyroid at the beginning. Various preparations have been tried, but with little or no result. For the past few months, however, we have been giving her thyroprotein, 5 per cent. tablets, and pancreatic extract, and we have succeeded in reducing her weight to 156 pounds without any unpleasant effects.

The other case presented all the prominent hyperthyroid symptoms, together with some hypothyroid symptoms. In addition there was a uniform brownish pigmentation covering her forehead, neck, and shoulders. The serum does not produce any unpleasant effects, but she shows very little improvement. She is also getting some adrenal nucleoproteid at various intervals.

Treatment.—This was already touched upon before to some extent. The patients with simple goiter were advised operation to relieve the pressure symptoms. As yet they have not followed this advice.

The temporary hyperthyroidism was treated on the theory that it was the result of a tired gland trying to meet an increased demand for thyroid secretion. The value of rest and hygiene was repeatedly emphasized. Along with this advice these patients were given some thyroprotein—usually a 1 per cent. tablet twice or three times daily. This was done with the idea of saving the thyroid the work of supplying its secretion and thus resting the gland to some extent. In both cases a decided improvement was noticed although the size of the gland was not affected.

The treatment of true hyperthyroidism will be taken up later in the discussion of the serum.

Treatment of the mixed variety was described before as well as the results noticed. The principle followed was to counteract the abnormal activity of the gland with serum and to supply the patients with thyroid by feeding them thyroprotein in small

doses—usually the 1 per cent. tablets. The serum or thyroprotein was chiefly employed depending as to which set of symptoms predominated—the hyperthyroid or the hypothyroid.

None of the cases in this group completed their treatment. One stopped after one month, unimproved. The other two showed considerable improvement.

The treatment of the myxedema cases was mentioned before.

In the cases in which other ductless glands were involved, the treatment was necessarily indefinite. Various organic extracts were used such as adrenal nucleoproteid and the pancreatic extract, but I cannot say anything about the value of these preparations or about the indications for their use. Serum has been employed in three of these patients with no effect in two, and a little improvement in the third, which was the pigmented case.

It is thus seen that the only cases in this group that were benefited in any way were two—one with hyperthyroid symptoms predominating and the other strongly suggesting myxedema.

Treatment of Hyperthyroidism.—The Rogers and Beebe serum was mainly depended upon in the treatment of this class of cases. The necessity of rest and hygiene was emphasized in each case, but the circumstances of most of the patients were such that they could not follow these directions. Only four of the patients stopped work for a short period. All the others had to continue with their work as best they could.

As two hyperthyroid patients refused serum there were only sixteen to whom it was administered. In addition the serum was given to two cases of the mixed variety, and to three cases in which other internal secretions were affected. In other words serum was administered to twenty-one cases in all.

A few words as to the preparation and method of administration. "The serum is prepared by inoculating either rabbits (preferably Belgium hares) or sheep with nucleoprotein and globulin prepared from human thyroid glands. The inoculation must continue over a period of five or seven weeks, at intervals of about six or seven days before the animal is sufficiently immune to make its serum have decided therapeutic value. At the end of this time the animals are bled and this serum prepared for inoculation in the usual way." (Beebe's "Med. Treat. of Graves' Disease.")

The dose at the start was usually 3 to 5 minims. This was gradually increased a few minims at a time until a full tube or 1 c.c. was injected at a time.

As far as possible the attempt was made to give three injections a week. This interval had to be lengthened at times on account of severity of reactions.

The site of injection was the middle of the arm, the right and left being used alternately. The skin was painted with tincture of iodine, and the serum was injected hypodermically.

Reactions.—Usually after the first few injections reaction took place. This started about six to eight hours after the administration of the serum, and subsided in twenty-four, rarely in forty-eight, hours. The area around the site of injection became red and painful. In one case the whole arm was involved. Itching was marked. Applications of cold wet cloths usually gave relief. As a rule no injection was given while any local reaction was evident. In a few cases in which this rule was not adhered to, the result was another and more severe reaction involving both arms. It was rare to get this reaction after the first few injections.

Under this heading I must not omit to describe a set of alarming symptoms, which followed an injection in one of my cases. This patient had been getting the serum for about six months, and was progressing quite well. About three minutes after the injection the girl complained of nausea and turned extremely pale. Her face became suddenly puffed, and in a few minutes the eyelids were so swelled that the eyes which were exophthalmic appeared sunken and small. The face was covered with beads of perspiration. Respiration went up to 40, and pulse was small and so rapid that it could scarcely be counted. After a few minutes the pulse improved, respiration went down, and the patient complained of cramps. This was followed by five to six loose bowel movements in the next half hour. The injections were stopped for three weeks, and then resumed for another month, when for some unknown reason the patient stopped coming and we lost all track of her.

Effects.—The first effect noticeable after a few injections of the serum was an improvement in the subjective feeling on the part of the patient. The patients came back very frequently after the second or third injection saying they felt less nervous, less restless, and stronger. This was a uniform observation in almost all cases. The next effect noticed was the steady decrease in the pulse frequency. Observing these cases as I did from day to day, the improvement in this symptom was so decided in many instances that I could not escape the conviction that the serum was accomplishing this result. If for any reason the patient omitted a few injections the pulse went right up only to be reduced again on resumption of the treatment. The tremor was the next symptom to be affected, becoming much less marked as the treatment proceeded.

After two or three months of the treatment a reduction in the size of the goiter became noticeable in six cases. Together with this reduction the gland became less vascular and more firm in consistence. In one case the entire right lobe disappeared. In another case it was so reduced that a 12½ collar was substituted for a 14½. Exophthalmos yielded very little or not at all to this treatment. However, in three of the patients a decided improvement was noticed, even in this symptom. Another marked general feature of these patients was the good condition of their nutrition. All with the exception of one stopped losing weight and remained stationary, while four gained 3, 10, 12, and 15 pounds respectively while under treatment. The sweats, the digestive disturbances, and the menstrual disturbances were improved in most of the instances.

The longest time any of the cases remained under continuous treatment was eight months. The shortest period was one month. Two cases started treatment a long time ago, but stopped for long intervals, so that it was badly a fair test.

Summary of Results.—Cured—none. It must be remembered, however, that this work is not yet finished. Some of the patients whom I have under observation at present will, I believe, be cured in time.

Apparently cured—one. This was a very early case, and the only complaints were a growing gland and a pulse of 90. The patient is apparently normal now, her gland having been stationary all the

time, while under treatment, and her pulse is now 70. I cannot, however, vouch for the permanency of this result. She is still under observation.

Markedly improved—two. Following is a brief history of one of these:

R. M., age 38, widower, came to clinic September 3, 1912. Sister had Graves' disease some time ago. He lost his wife early in 1911; since then noticed that he was extremely nervous and irritable. In the fall of 1911, he noticed exophthalmos. Goiter appeared in July, 1912. There were marked sweats, palpitation, and diarrhea (five to six movements daily).

P. E.—Marked enlargement of both lobes, right predominating; marked exophthalmos; tremor pronounced, involving the whole body; very nervous; pulse 130; skin very moist. He stopped his work for three months, because he was not fit to work. He has been under serum treatment fairly regularly since September, 1912. The intervals of injection now are one week. At present the goiter is very much smaller; the exophthalmos is greatly improved. The sweats occur only rarely. His tremor involves only his hands and is greatly improved. His pulse is between 80 and 90. He can attend to his work, which is that of a highway inspector, without any trouble.

By markedly improved I mean that their symptoms have greatly subsided and that they are almost approaching normal. On stopping treatment for any length of time or under any severe excitement or exertion, their condition becomes greatly aggravated, but they yield again to treatment quite readily.

Moderately improved—eight cases.

In these cases decided improvement was noticed, but it was gradual and slow. If for any reason an exacerbation took place it was hard to get them back to improved condition.

Slightly improved—four cases. Of these the pigmented case belonging to the sixth group is one. Another had been under treatment for one and a half months only. All of the others were chronic cases.

Unimproved—six cases. These had remissions and exacerbations, but on the whole remained the same. Of these three stopped treatment after one month, one was a chronic case who had been taking serum at various intervals very irregularly. The other two belong to the sixth group, one of these being the case of intermittent glycosuria, who had serum only for a short while, and the other is that peculiar case I mentioned in which an operation was performed by Dr. Rogers; this case is still under observation.

In looking through this summary it may be noticed that the apparently cured, markedly improved, and moderately improved form 50 per cent. of the cases treated with serum. If we include the slightly improved, we have 71 per cent. showing improvement under serum. The remaining 29 per cent. who showed no improvement either gave the treatment little chance or were cases of the mixed varieties. In other words almost every patient with hyperthyroidism who was willing to try the serum more or less faithfully was benefited by it to some extent, and this under very unfavorable hygienic conditions.

General Impression of the Serum.

1. There is no doubt that the serum has a marked beneficial influence on hyperthyroidism in many instances.

2. Early cases yield more readily to treatment.

3. Faithful regularity in the administration is necessary.

4. Rest and hygiene are most essential aids to the serum.

151 Leonard Street.

SCHOOL MEDICAL INSPECTION IN NEW YORK CITY.*

By S. JOSEPHINE BAKER, M.D.,

NEW YORK.

DIRECTOR OF CHILD HYGIENE, DEPARTMENT OF HEALTH OF THE CITY OF NEW YORK.

In New York City the medical inspection, examination, and treatment of school children is under the control of the Department of Health and forms one of the subdivisions of the work of the Division of Child Hygiene. Five hundred and eight public schools with a registered attendance of 700,464 pupils, and 206 parochial and other free schools with a registered attendance of 124,083 pupils, are under supervision; a total of 714 schools and 824,547 pupils. The total appropriation for this work for 1913 is $364,300, a per capita cost of 44 cents for the full year. This cost per child is inclusive of all branches of the work, including administration and supervision, the full system of medical inspection and examinaton, follow-up visits in the homes, and ophthalmological, surgical, and dental clinics. The present school inspection staff consists of the director, assistant director, superintendent of nurses, 5 borough chiefs, 16 supervising inspectors, 16 supervising nurses, 97 school medical inspectors, 16 clinic physicians and surgeons, 10 dentists, 191 school nurses, 22 clinic nurses, with the necessary clerks and typists for the clerical work, and hospital employees.

Since 1897, when the system was inaugurated for the detection and exclusion from school of children affected with contagious diseases, there has been a continual development of the work, and at the present time its functions include: (1) Early detection and exclusion from school of cases of contagious disease. (2) The detection and treatment of neglected cases of contagious eye and skin disease. (3) Individual and group instruction of the children in personal hygiene. (4) Examination for the detection of non-contagious physical defects. (5) Follow-up visits to homes to insure treatment of physical defects. (6) Clinics for the treatment of eye, nose and throat, and dental defects.

1. *The Early Detection and Exclusion from School of Cases of Contagious Disease.*—With the exception of small schools in the outlying districts of the city, which are visited two or three times each week, each school in the city is visited each morning by an inspector or nurse, and all children who have been found to be ailing in any way are referred by the teachers for examination. Indicated cases are excluded and reported to the central office; a diagnostician is sent to confirm the diagnosis, and either readmit the child to school or keep it under observation until the termination of the illness. In the school a tentative diagnosis is usually made, as experience has shown it is far safer to exclude a few children unnecessarily than to allow any ill child to remain in school. Every case of sore throat is excluded, and a culture taken in each case. In order to doubly guard the opportunity for any spread of infection each supervising inspector receives each day a card giving the name, address, school, date of onset of illness, and date of last attendance at school of every schoolchild in his particular district, who has been reported during the previous twenty-four hours by

*Read before the Fourth International Congress of School Hygiene, August 28, 1913.

any physician as being ill with a contagious disease. The supervising inspectors keep these cards filed by schools and classes. If two or more cases of contagious disease occur in the children in any one classroom, whether or not these children have attended school during the period of incubation, the supervisor visits the classroom, instructs the teacher in regard to the need of precautions and keeps the children under observation until the period covering the time of incubation has passed. If two or more cases of diptheria occur in one class a trial culture is taken from the throat of each child, and if diphtheria bacilli are found the affected children are excluded. The results of this preventive work have been excellent. During 1912 it was necessary to exclude only 4,000 children from school attendance, and in no instance did an epidemic develop. During the four years since the organization of the Division of Child Hygiene it has not been necessary to close any public school in the city on account of the presence of contagious diseases, and in only a few instances have single rooms been closed for a period of a few days for a similar reason.

2. *The Detection and Treatment of Cases of Contagious Eye and Skin Diseases.*—In addition to the cases found at the daily morning inspection the inspector, at the beginning of each term, goes through each classroom, inspects each child and refers for subsequent examination every case of contagious eye or skin disease and every child showing evidence of some physical defect—each case is indexed on a class index card with provision for notes of further care and treatment. Once each month the nurse makes a similar classroom inspection; all children are referred to their physician or a dispensary for treatment. If the latter has not been obtained at the end of twenty-four hours the nurse treats the child in the school, except where the disease is present in an extensive or acute form, when the child is excluded. Trachoma is not treated by the nurse, but neglected cases are cared for at the school clinics and allowed to attend school under the supervision of the nurse if there is no secretion.

The need of care of these neglected cases who formerly were all excluded from school is responsible for the first employment of the school nurse in this country. The first school nurse in the United States was appointed in New York City in 1902. Her value in school treatment of these children, with the consequent lessening of the number of exclusions and decrease in loss of school time, was demonstrated at once. Since then the field of the school nurse has broadened immensely, but her usefulness in this branch of the work is as great as ever. In 1903, when there were only eight or ten nurses employed, 57,655 children were excluded from school for contagious eye and skin diseases; in 1912 only 4,716 children were excluded for this cause. Not only have the exclusions decreased, but with the exception of pediculosis, every type of these diseases shows a marked reduction in the cases occurring. In 1903 trachoma was found in 20 per cent. of the children; in 1912 it was found in only 3 per cent. Notwithstanding the increase in the school population ringworm has been reduced from 5,958 cases in 1908 to 4,108 cases in 1912, a reduction of 31.1 per cent., and an average of only eight cases to each school for the year. Scabies shows a reduction of 17.2 per cent., or from 3,133 cases in 1908 to 2,593 cases in 1912, an average of five cases to each school for the year. During the past year I took a party of students to one of our largest schools in a densely populated Italian district. I had previously instructed the nurses in twelve surrounding schools to bring some typical cases of skin disease to demonstrate. Not one case of ringworm in a school child could be found in this area and only two cases of nearly healed scabies could be produced. The gain in school attendance alone has more than paid for this part of the system of school inspection.

3. *Individual and Group Instruction of the Children In Personal Hygiene.*—The large number of instances of defective primary teeth and the utterly inadequate facilities for free dental treatment have led to a necessarily special method of dealing with this problem. Preventive methods of oral hygiene seem to offer the solution. Each child with defective teeth is given a circular of instruction and is required to bring tooth powder and tooth brush to school. The school nurse conducts "tooth brush drills" with groups of the younger children, teaching them the value of a clean mouth and showing them how to keep it so. Pediculosis, that ever present and so far unsolved difficulty of school life, is cared for by a similar method. The children are given circulars of instructions as to treatment and are required to report to the nurse at regular intervals. If evidence of treatment is not shown they are excluded from school. While the number of cases has not appreciably decreased, owing to continuous home reinspection severe cases with live pediculi are rarely encountered now, though they were formerly common. Out of 184,907 cases found in 1912 only 3,368, or 1.8 per cent., were of the latter type, and therefore excluded. In the classroom, individually and in groups, instructions are given by the school nurse on matters of personal cleanliness and hygiene. In all, during 1912, 160,957 such instructions and treatments were given.

4. *Examination for the Detection of Noncontagious Physicol Defects.*—New York, in common with all cities, has recognized the alarming prevalence of subnormal physical status of the school child. Our problem is probably more intricate than that of many other cities owing to the rapidly changing character of our population due to our prominence as a port of entry and the goal of the larger part of this country's immigration. In discussing the physical defects of school children it is difficult to confine one's self to any part of this complex subject. The physical examination of children in the New York City schools was instituted in March, 1905. At that time no follow-up visits were made to the homes, but the parents were notified of defects found by means of return postal cards, the return half to be used for reporting if treatment had been obtained. Under this system about 6 per cent. of the affected children received treatment. In 1908, with the organization of the Division of Child Hygiene, a staff of nurses was employed to make visits to the homes to instruct the parents in the necessary hygienic measures for the prevention and correction of physical defects and to urge the needed and proper treatment. Since that time, excluding the cases of defective primary teeth which are not made the subject of home visits, an average of 80 per cent. of the children have obtained the needed medical or surgical care. The appropriation for

1912 allowed for the examination of 287,469 children, 41 per cent. of the number enrolled. Approximately this same number have been examined each year since 1908. In addition, each child treated is reexamined to determine if the treatment is effective. In 1912 22,811 boys were examined to determine their physical fitness to take part in athletic contests, and 40,501 examinations were made of children who wished to leave school and obtain employment.

Each child entering school for the first time is examined upon admission, thereafter special cases detected by the medical inspector or referred by the school nurse or teacher are examined, and third, the rest of the children are examined grade by grade. It would, I believe, be wise to provide a large enough staff to allow for the examination of every child once in two years, with special cases examined each year or as much more often as necessary. The function of the school physician is not to make detailed diagnosis. It is not practical in the school to provide the necessary equipment and apparatus for performing refraction, nor for a complete exploration of the nasopharyngeal vault. There is a tendency on the part of specialists in medicine to claim that experts in their particular specialty are needed in order that accurate diagnosis may be made. Such a plan is neither practical or necessary. If carried to a logical conclusion it would mean that each child would be examined by at least six physicians. It is probable that some of the finer defects escape observation. For instance, possibly some of the smaller cavities in teeth may be overlooked, but when we realize that it is only possible to obtain treatment for about 10 per cent. of the cases of defective teeth on account of lack of facilities for dental treatment, are we warranted in spending any added amount for diagnosis rather than for treatment? A community is justified in the expenditure necessary to ascertain that there is some deviation from the normal and for the needed measures of school and home hygiene required to prevent or to cure the wrong conditions. Beyond that the matter should be left to the private physician or dentist to make the detailed diagnosis and provide the proper treatment. Following this procedure in New York City each defect noted is classified broadly as defective teeth, defective vision, defective hearing, and so on. Nasal or nasopharyngeal obstruction sufficient to give objective symptoms of nasal occlusion is designated as defective nasal breathing; true hypertrophy of the tonsils is definitely classified. When any defect is found the parent is notified by means of a special blank form, calling attention to the defect and stating that the child should be taken to the family physician for treatment. Where no attention is paid to this notice, a follow-up notice to the same effect is sent the parents by the principal of the school. If the child still remains untreated the nurse visits the home to explain to the parents the need of attention and to urge that the child be taken to the family physician. Only in case the family are wholly unable to employ a physician is the child referred to a dispensary. In no instance and under no circumstances are the medical inspectors allowed to treat these children. It is of interest to note that an average of 58 per cent. are taken to private physicians, and 42 per cent. to dispensaries.

The incidence of uncorrected physical defects in school children has materially decreased in the past few years. In 1909, 13.1 per cent. of the children examined had defective vision; in 1912 this had been reduced to 7.3 per cent. The number of children suffering from defective nasal breathing has decreased from 18.1 per cent. in 1909 to 7.6 per cent. in 1912, while hypertrophied tonsils were found in 22 per cent. of the children in 1909, and in only 10.4 per cent. in 1912. The children examined during these periods were of approximately the same age groups.

NON-CONTAGIOUS PHYSICAL DEFECTS FOUND AND TREATED.*

	1909		1912	
	New York City	Per-centages	New York City	Per-centages
Number of physical examinations made	251,081	....	287,469	....
Number found needing treatment	172,112	....	206,720	....
Number found with associated defects	102,150	44.2	87,361	30.4
Number found with defects of teeth as only defect	69,962	30.3	119,359	41.5
Percentage of those examined needing treatment	74.48 per cent.		71.9 per cent.	
Defects found:				
Defective vision	30,408	13.1	21 078	7.3
Defective hearing	2,340	1.0	1,206	0.42
Defective nasal breathing	43,393	18.1	21,931	7.6
Hypertrophied tonsils	50,934	22.0	30,021	10.4
Tuberculous lymph nodes	810	0.35	.....	....
Pulmonary disease	744	0.32	335	0.12
Cardiac disease	1,503	0.65	1,597	0.55
Chorea	940	0.40	915	0.31
Orthopedic defect	1,461	0.63	721	0.25
Malnutrition	7,249	3.1	8,303	2.9
Defective teeth	131,747	57.0	142,168	49.4
Defective palate	324	0.14	.....	....
*Number reported treated	84,968	83.2	58,312	66.75

*These figures do not include children reported with defective teeth as the only defect, whose treatment consisted only of instruction in oral hygiene.

5. *Follow-Up Visits to Homes to Insure Treatment of Physical Defects.*—The greatest advance made in school medical inspection since its inception has been the employment of the school nurse. I have already spoken of her value in the school, but her services are of even greater importance in the home. Here social, economic, and racial questions are presented for her power of adjustment. There is hardly a problem in our social system that she is not called upon to solve. The difference between the 6 per cent. of children treated without her employment and the 80 per cent. treated as a result of her efforts bears witness to her efficacy, but her function in prevention of physical ailments is even greater than her use as an agent to secure correction. The relation of home hygiene to physical ill health in childhood is of equal if not greater importance than the relation of school hygiene to the same subject. In the home there is no broad supervision as there may be in the school. Each family, each child, must be considered individually. The diagnosis of a physical defect by the medical inspector is the index: the completed work is the function of the nurse. During 1912 the nurses made 216,554 home and dispensary visits.

6. *Clinics for the Treatment of Eye, Nose and Throat, and Dental Defects.*—During 1912 six clinics for school children were opened. These clinics are in reality small hospitals, having a dispensary service for refraction, contagious eye diseases, and nose and throat diseases, and hospital facilities for operations for trachoma and the removal of adenoids and hypertrophied tonsils. They have been located in the parts of the city having inadequate dispensary facilities. The common method of operating for adenoids and hyper-

trophied tonsils in dispensaries has been unsatisfactory, and in many instances serious results have followed. Anesthetics are rarely used and children are sent home as soon as the operation is completed and the bleeding has ceased. In consequence of the lack of anesthesia the operation is often hurriedly and incompletely performed and the child suffers a severe nervous shock. The early return home results in danger from septic infection and secondary hemorrhage. In the Department of Health clinics the children are required to report the afternoon before the day of operation. They are kept during the night, regularly prepared for the operation which is performed under full nitrous oxide gas and ether anesthesia on the following morning, and the child is then required to remain in the hospital under close observation for the following twenty-four hours. Up to this date 2,492 operations have been performed by this method, with entirely satisfactory results in each instance.

Six dental clinics were opened early this year. In order that the limited facilities might be as useful as possible only those children are treated who are referred by the school inspector. These children are the selected cases where constructive as well as preventive measures offer the best ultimate results. The clinics are all located in separate buildings, each in the center of a group of schools. The need of the increase in the number of these clinics is shown by the fact that more than twice as many children have been necessarily refused treatment as the number possible to care for. In the Borough of Brooklyn alone we now have over 2,500 children on the waiting list for operations for adenoids and hypertrophied tonsils. The parents of these children are unable to pay a private physician, and there are no hospitals in the vicinity.

Five factors are required in the proper working out of our program: The Department of Health, which performs the work; the Department of Education, which has jurisdiction over the schools; the medical profession, who must be responsible for the final corrective medical efforts; the parents, who are the focus of our educational efforts, and the children, for whose benefit and in whose behalf the system is devised. Nothing short of complete and willing cooperation on the part of each and every one of these groups can insure success. The medical inspectors and nurses are required to cooperate in every way with the principals and teachers, and to consult with them in regard to classroom conditions affecting the health of the children. In the schools where an equal interest and readiness to cooperate is found on the part of the principals and teachers, the standard of health of the pupils is very high. In the schools where such cooperation is not obtained the results suffer accordingly.

In New York City the hygiene and sanitation of the schools with matters pertaining to lighting, ventilation, heating, cleaning, classroom furniture, and adjustment of the curriculum to the individual child are under the control of the Board of Education, which has special committees in charge of the various features. So far no adequate program for the proper control and adjustment of these important matters has been made effective. Recently investigations have been made relating to these subjects, and it is possible that needed reforms in the hygiene of the schools may result. The order of the Board of Health that the common drinking cup be abolished has been generally observed in the schools and one of the most prolific sources of the dissemination of contagion eliminated.

School medical inspection has been successful in New York in demonstrating that the schools need not be foci for the dissemination of contagious diseases, and that the incidence of physical ill health and abnormalities may be appreciably lowered by proper health supervision.

33 West Sixty-sixth Street

A COMPARISON OF METHODS FOR THE DIAGNOSIS OF TUBERCULOSIS BY SPUTUM EXAMINATIONS.

By WALTER STROUGH DAVIS, B.S.,

ALBANY, N. Y.

of the State Hygienic Laboratory, New York State Department of Health.

When a bacteriologist is working alone in a matter of diagnosis, the question of methods of technique is so closely interwoven with the personal equation involved that we are quite accustomed to accept the method used by him as at least the best for that individual.

When, however, one has to do with a large diagnostic service, such as the work of Division of Laboratories of the New York State Department of Health, making from 10,000 to 40,000 bacteriological diagnoses per annum, where of necessity more than one diagnostician must be utilized, where each gain of precision or time of process is multiplied by the thousands of specimens to a point of great importance for the economy and efficiency of the laboratory, the exact method used becomes of such value as to merit special study, and in the laboratory mentioned, where the writer has been employed for the last three years, this question of determining the exact precision value and time economy has been an important element of consideration in choosing methods of technical diagnosis in bacteriology.

Of the thousands of specimens examined in that service each year, a very large number are made for the determination of the tubercle bacillus in sputum. The specimens are forwarded in 1 ounce tall sputum jars, known as the New York model, closed with tight-fitting cork, and the vial enclosed within a double tin mailing case.

Most of the specimens are received by mail, the quantity of actual sputum in the vial varying from a mere trace to the full ounce of the filled jar. As a routine procedure, the specimens are opened as received, and each vial is numbered as extracted from the mailing case, the same number being placed upon the identification slip. The specimens are then passed to the bacteriologist for preparation and diagnosis.

The usual method of smear, double stain, and microscopical examination has been carried out in this service for years, but always with a careful scrutiny of its known failures.

The so-called antiformin method has been extensively tried, its failures noted, and its improvement studied. Careful comparison has shown the superiority of Loeffler's improved method of using the antiformin, and this latter has been chosen as the best of the antiformin methods.

The object of the present study has been to apply the best selected methods of sputum examination to a series of specimens of known origin, and

subjecting the material from identical specimens of sputum to treatment by each of the chosen methods, to develop by the comparison of results data that would be of value in determining the relative advantages and exactitude of each form of technique. With these data it was then thought possible to choose the preferable method for the routine use of the laboratory.

In preparation for this work the writer studied and developed to its best his individual technique of each of the methods to be tried, and the plan of the work was then made up as before described; to take from identical specimens of sputum, in continued series and of known origin, as closely identical specimens as possible, and treat each one with the chosen method.

By the kind interest of Dr. Montgomery Leary, Director of the Iona Tuberculosis Sanitarium at Rochester, N. Y., and the care of Dr. Brayton, the Resident Physician there, a series of patients in that institution was selected and the sputum from each one of this series was sent whenever an examination was made.

The following reagents were freshly made up and utilized throughout the serial examinations:

Acid Alcohol.—Hydrochloric acid, U. S. P., 1; alcohol, 95 per cent., 100.

Loeffler's Methylene Blue.—Methylene blue (sat-sol. in alcohol) 30; potassium hydrate (1/100 per cent. aq. sol.), 100.

Carbol-Fuchsin Stain.—Basic fuchsin, 1; absolute alcohol, 10; carbolic acid (5 per cent. in aq. sol.), 100.

Antiform Solution.—Sodium hydrate (15 per cent. sol. in water), 1; sodium hypochlorite, U. S. P., 1.

Egg Albumin Solution.—Egg-white, 1; water, 9; chloroform to saturate.

Alco-Chloroform Solution.—Chloroform, 1; alcohol (95 per cent.), 9.

Ferrocyanide of Potassium Solution, saturated aqueous solution.

Glacial Acetic Acid.

Sodium Chloride Solution, saturated aqueous solution.

Throughout these serial examinations of sputum three methods were employed:

(A) The sputum was thoroughly shaken and of this material a direct smear was made in the usual way.

(B) Another measured portion of the specimen of sputum was placed in a large test tube and to this was added an equal volume of the antiformin solution diluted to make a 50 per cent. aqueous solution. This portion of the sputum with its antiformin addition was digested in a hot water bath at 100° C. until a clear solution was obtained in the test tube. The whole was then cooled in running water and then to this sample thus digested and cooled, three c.c. of the alco-chloroform solution for every 20 c.c. of the material in the test tube, was added and the whole thoroughly shaken and centrifuged. It was then found to show three distinct layers in the centrifuged tube, a top layer of clear fluid; a thin scum layer made up of the chloroform tenaciously holding on its surface any tubercular bacilli that had been in this sample.* The egg-albumin fixative was required for all smears of the antiformin treated specimens.

(C) Of the above specimen of sputum, after shaking, a measured portion was taken into another sputum jar and to this was added an equal amount of the saturated solution of sodium chloride. This sample was then thoroughly shaken until all viscous material had been completely broken up, and the whole left at complete rest for a minimum of six hours. At the end of this time the top of the over surface of the sample was carefully picked up with the platinum loop, and smeared on the glass slide.

In case the sample of this sputum was very thin it was found necessary to use a fixative to maintain the smear on the slide and for this purpose a drop of the egg-albumin solution was placed on the slide, and the smear made in this drop. It was seldom found necessary to use the fixative, sufficient matter generally being in the surface scum to fix quite sufficiently the smear thus made.

Smears from methods A, B, or C were all made in the same uniform size, etc., duplicating conditions as exactly as possible, and treated in the same way on the slide (except the use of fixatve as before noted). The smears were allowed to dry spontaneously in the air of the room, and when perfectly dry were fixed by passing three times through the flame.

The slides were all stained in the same staining bath for each series, and always with controls of known positive smears. They were first stained with carbol-fuchsin, cold—twelve hours in the bath; then rinsed slightly in tap water; decolorized in acid alcohol (about fifteen seconds were found sufficient to give the right degree of decolorization with the reagents used). The slides were then removed from the acid alcohol and rinsed thoroughly with tap water, and then immersed for one-half hour in the bath filled with cold solution of methylene blue.

After washing off the counter stain and the drying of the preparations, they were examined under the microscope with the greatest pains, for the identification of the tubercle bacilli. For greater uniformity of examination and results exactly five fields of every preparation were thus thoroughly examined, and the report of results was made invariably from the examination of exactly this number of five fields.

After this serial examination work of sputa had been underway for some time, it was suggested that the value of the chemical method proposed for the diagnosis of tubercular infection in sputa; *i.e.* the test for albumin reaction to a solution of ferrocyanide in sputum as evidence of tubercular resisting process in the organism, should also be tried here, and for the remainder of this serial work this test was carried out; but further and more extended trials must be made before any conclusions on its value can be offered.

The results of the examination of 104 specimens by methods A, B, and C are here given in tabular form.

Of the 104 examinations tabulated as examined by methods A, B, and C, it is noted that a maximum of 99 of the specimens were found to contain a demonstrable *Bacillus tuberculosis* infection. Of these

*Loeffler described the peculiar affinity of chloroform for the tubercle bacillus, attributing it largely to the binding action of the fat contained in the bacillary body for the chloroform; and because of this strong selective binding action of chloroform for the tubercle bacilli he proposed this use of chloroform to make a selective layer that should hold, extracted from the centrifugal sediment any tubercle bacilli there contained. Our own preliminary study of methods confirmed the advantages claimed by Loeffler for this process, and shown in his own work. This method of using antiformin with centrifugal chloroform extraction was therefore our chosen method where antiformin digestion was used.

\+ Means tubercule bacilli found. −Means bacilli not found

there were therefore possible 90 positives in order of efficiency we find that

Antiformin demonstrated 62, practically finding....62 per cent.
Direct smear demonstrated 90, practically finding....90 per cent.
Salting out demonstrated 98, practically finding....98 per cent.

Antiformin found one positive that the direct smear did not.

Antiformin found no positive that the salting did not.

Direct smear found one positive that the salting did not.

Direct smear found twenty-one positives that antiformin did not.

Salting found nine positives that direct smear did not.

Salting found thirty-six positives that antiformin did not.

Calculated to exact terms of actual findings of possible positives:

Antiformin is proven accurate to.....62.60 per cent.
Direct smear is proven accurate to.....91.00 per cent.
Salting out is proven accurate to.....99.00 per cent.

The work had not progressed very far, before the relatively too frequent failure of the antiformin method to find the known existant tubercle bacilli in the specimens, was noticed and reasons for these failures were sought for.

Three different solutions of the antiformin were utilized. Antiformin preparation *1 had been made about four weeks previous to the time of using it. It was noted that about twenty-five minutes were required for this solution to digest the sputum thus treated.

A fresh solution of antiformin was then prepared, designated as *2, and using this solution *2 about eighteen minutes were required for the digestion of the sputum thus treated.

A further solution of antiformin was made, designated as *3, for which the digestion time for its treated sputum was found to be about twenty-two minutes. Note that specimens

Nos. 1 to 36 inclusive were examined with antiformin solution.. *1:
Nos. 37 to 69 inclusive were examined with anti ormin solution.. *2:
Nos. 70 to 86 inclusive were examined with antiformin solution.. *3:

The available chlorine in the solutions, 1, 2, and 3 was determined by titration, and was found to be for

Antiformin solution ..... *1 only 0.4 per cent.
Antiformin solution ..... *2 only 0.9 per cent.
Antiformin solution ..... *3 only 0.6 per cent.

Realizing the deleterious effect that a prolonged digestion of the bacillary forms in such caustic solution as this used in the antiformin method would have, and particularly the effect on the staining properties; the importance of reducing the digestion time to a minimum was evident, and for further study another solution of the antiformin was made, designated as *4, and showing an titration an available chlorine of 1.1 per cent,; and with this *4 solution a satisfactory digestion with clear solution of the sputum was obtainable in twelve minutes. This was used on specimens 87 to 104.

The importance of realizing exactly the right titration of the solution of antiformin used is shown by the tabulated cases; where solution *1 of antiformin, with a digestion time requisite of twenty-five minutes, found only 29.4 per cent. of positives:

Solution *2, with a digestion time requirement of eighteen minutes, found 90.3 per cent of positives;

Solution *3, with a digestion time requisite of twenty-two minutes, found 43.7 per cent. of positives; and

Solution *4, with a digestion time of twelve minutes found 94.4 per cent. of positives.

The above results show quite clearly that if the operator of the antiformin method is able to keep an exact chemical control of the maximum efficiency point of his antiformin solution, he may expect an accuracy of say 94 per cent. for that method; but without such carefully exercised titration control of his solution the method becomes very unreliable and its accuracy may fall as low as 29.5 per cent. of the real positives.

It would appear that the antiformin method utilized with perfect chemical control of its activity would show an accuracy of 94 per cent. (3 per cent. more than the positive findings by the direct smear method only); but even at this its greatest supervised accuracy, the antiformin method offers no advantage over the salting out method (C) with its accuracy of 99 per cent.

In utilizing the method of separating the tubercle bacilli by treating the sputum simply with an equal volume of saturated aqueous solution of common salt, thoroughly shaking and allowing to stand for six hours, then skimming the surface with the platinum loop and making therewith a smear on a slide, and stained either slowly in the cold or if time is an object by hot stains, the writer believes that a distinctly advantageous and accurate method for the routine diagnosis of bacillus tuberculosis in sputum is offered.

No special apparatus such as shaker or centrifuge is required, the proven accuracy of findings is 99 per cent. (the superior of any other method yet brought forward for comparative valuation) and it would be possible for the attending physician to himself treat the sputum, skim the surface and make the smear on the slide which would then be all that would be requisite to forward to the laboratory for the expert diagnostic stain and examination.

If time is a factor in the technique of staining for miscroscopic diagnosis, resort to hot staining is to be recommended, and in this case, as soon as the specimen is fixed on the slide, immerse the slide in the carbol-fuchsin stain, itself maintained in a hot water bath at 100° C. Allow to remain in the hot stain for three minutes; remove and wash with tap water. Decolorize cold with acid alcohol for eight seconds. Wash with tap water and stain with cold methylene blue for one minute, wash thoroughly with tap water and dry the specimen, now ready for the microscopical examination.

278 Yates Street.

SOME EARLY SYMPTOMS OF MENTAL DISTURBANCES.*

By ARTHUR K. PETERY, M.D.,

NORRISTOWN, PA.

ASSISTANT PHYSICIAN STATE HOSPITAL FOR THE INSANE.

It is really surprising to note the number of physicians who fail to recognize the symptoms of mental disturbances in cases which they are called upon to treat, and how often patients are treated for various ailments, which exist only in their imaginations. This may be due to one of two reasons: first, an incomplete and hurried examination of the patient; and second, a lack of experience with mental cases. This subject unfortunately is somewhat slighted in the average medical school. If this is due to the first reason there is no excuse, but there is an excuse for the second, for while mental disturbances are more or less common, the average practitioner does not have enough of that class of work to keep him alert as to the conditions to expect, and the object of this paper is to point out some of the earlier symptoms with which one might come in contact, and the character of the patient in whom one might expect to find mental disturbances.

Too much stress cannot be laid upon knowing as much as possible about the family and personal histories of our patients. Work along the line of eugenics shows that traits of insanities are transmitted from generation to generation. It has been demonstrated that where two mentally deficient people marry the offspring has a poor chance of escaping the parent affliction. It is surprising how much faster the mentally deficient multiply in proportion to the number of normal individuals. A very striking example of this has been demonstrated recently in a report of the "Kallikak family" by Dr. Goddard of the Vineland Training School.

In considering these deficiences in children one may note first the imbeciles of the various grades. In these there is a history of sluggish development. They are late in learning to walk and talk, and in the higher grades they may have advanced further and have been sent to school, but their stay in school is short on account of an inability to learn. Hence they stay around home and acquire what knowledge they possess only by actual experience. Then there is another group of children who are termed feeble-minded. These children apparently develop well, start in school at the usual age, and get along fairly well up to a certain period. This period varies according to the inborn ability. There is also a disability to advance further; the pupil fails to be promoted; he may drag along in the same class for several periods, and then leaves school because he can't get along or because his fellow pupils make fun of him. He has reached his limit and this break usually comes rather abruptly.

Dr. John J. Thomas of Boston in an excellent article on "Retardation and Constitutional Inferiority in Connection with Education and Crime," discusses another grade which he terms retardation. He excludes from this class such cases that fall behind in the school routine, which failure is caused by absence from school on account of acute disease of various kinds, and also of removal from one school to another where the dropping back in grades can be accounted for by lack of correspondence in the subjects taught in the different schools. This observance also omits the children who are unable on account of defects of the special senses which can be remedied. Adenoid disease in his opinion aside from its effects in causing absence from school or impairment of hearing is never the cause of any serious retardation in school work. He also feels that a large proportion of children reported by the teachers as retarded because of inattention, laziness, and immaturity are undoubtedly imbeciles.

To decide whether a child is really deficient is sometimes very difficult, for we have nothing definite as a standard with which to compare the child. The Simon-Binet tests have been devised as a possible standard, but they are only arbitrary, and do not apply to adult imbeciles. Usually the standard considered by the laity is the average child's ability to get along, an individual being classed as sound mentally when he is able to adapt himself to his environment and to get along well

*Read before the Montgomery County Medical Society, June 25, 1913.

under these circumstances. With this failure of adaptation the child is regarded as deficient, but the adult is classed as insane. The term insanity really means nothing more than this. To judge properly of abnormalities we must take into consideration the whole history; the origin and social position of the patient, the environment in which he is brought up, his former illnesses, as well as the result of the mental and physical examination. A single act, instance, or symptom usually means nothing, and its significance can only be recognized when it is judged in its relation to other facts. Goddard believes that there are different levels of intelligence and that these levels are transmitted from generation to generation. Prostitutes and paupers to a high degree are feeble minded, and there are instances on record in which grand parents, parents, and children were found in the same detention.

In discussing the psychoses it might be well to consider them in their respective classifications, taking up the Præcox group first. In most cases of mental disturbances occurring before or during the period of adolescence, we first think of the possibility of their belonging to this group. In going back over their history we usually find that they have progressed well in school and frequently are reported as having been unusually bright. Their general attitude is noticed to be changing, they become irritable, indifferent to their surroundings, and harder to get along with. Frequently we see a preliminary period of depression, when they become less active, forsake their former pleasures, and their personal appearance suffers accordingly; occasionally they have some insight into their condition, realize that they are different from usual, but are unable to explain this. One striking case in mind is that of a medical student who while at college wrote to his father that he was becoming insane; he was eventually placed in this institution, a typical præcox case.

Their condition is noted by their lack of interest in things notwithstanding their correct observations. The change in the character of their movements is very striking, they may be stiff and awkward, or stand about in strained attitudes; their attention becomes impaired; while they correctly note objects these pass immediately from their observations, and they make no attempt to study them. Frequently in the early stages they complain of headache or of a sense of tightness and often of something "snapping" in the head. As the cases progress their memory deteriorates, the train of thought becomes looser, and eventually quite rambling, and in some forms shows evidence of stereotyped phrases; the patient grasping an idea, and then repeating it over and over again; their conduct is disturbed, they are inclined to perform acts on the impulse of the moment, and this is usually one of their most troublesome symptoms, for they may strike without warning, destroy clothing or furniture, and occasionally attempt or do commit suicide. One case observed recently committed suicide by hanging. He had been to a dance the evening before, and was apparently enjoying himself; the following morning nothing unusual was noticed and that afternoon he was found hanging in a room. Often these acts are the result of hallucinations or delusions which are quite prevalent and abundant in this condition. The physical symptoms of this psychosis are rather vague, but an increase of the reflexes and vasomotor changes, such as cyanosis of the extremities, seems to be quite common.

About this age and extending into later life we also find the Manic-depressive grouping of cases, and the percentage of admissions of this class of patients to hospitals is rather high. A study of the heredity of the case usually gives us a clue as to the diagnosis, for frequently we find their progenitors as having been afflicted with the same condition. The defective basis in some cases is often apparent before the onset of the psychosis. The patients may have been more or less moody in their temperament, easily set back in their plans by some minor incident, and inclined to be easily depressed, or again overactive and talkative by spurts, but not enough to cause trouble, or even be noticed at the time, but on their admission to hospitals their friends are able to look back and recall these incidents.

This disease is usually precipitated independently of external causes, and Kraepelin claims that women are affected far in excess of the percentage of males. In the manic phase of the disease they become overactive, they keep themselves busy, but accomplish very little, their attention is easily distracted, they are unable to elaborate on any one impression because there are so many striking stimuli that these crowd each other out before they have time to develop and this is responsible for their rambling conversation. Hallucinations are rather rare and their delusions are varying, but they are usually exalted, boasting or exaggerating their abilities.

In the depressed phases we find just the opposite. The onset is more or less gradual, they may appear lazy, their ability to think becomes lessened, they become quiet and not inclined to talk, their supply of ideas become more and more limited, their work appears enormous to them, and they find difficulty in performing their various tasks and usually give up their positions on this account. They can see nothing but the dark side of everything. Frequently they realize their condition but explain that they don't feel able to pull themselves together. The physical symptoms are usually negative with the exception of a loss of weight, and other symptoms of an autointoxication.

I believe that there are more mistakes made in early cases of Paresis than in almost any other psychosis. How often do we read of persons being arrested on the streets for some offense and particularly drunkenness, who after a period in jail are sent to some institution for the insane suffering from paresis. Their staggering gait, their inability to articulate properly, and their general feeling of well-being I suppose is responsible for their being taken as an ordinary drunk. Kraepelin claims paresis is a disease of modern civilization and seems to be most prevalent in Western Europe and North America and more prevalent in large cities. Prostitutes to an extremely large degree are subjects of this disease; occasionally husband and wife may be similarly affected, and I recall seeing such a duality presented recently by Dr. Dercum at one of the Society meetings, and within the last six years in this hospital there have been three instances.

The average age of onset of this condition is between thirty-five and forty-five years of age, although it may occur earlier. At the beginning these cases often show a tendency towards sleepiness, they become confused and usually show an increased irritability. They are annoyed by minor actions of

their families, they may become more talkative than usual, and their general attitude becomes that of well-being. A very frequent thing for them to do is to purchase large orders of unnecessary furnishings, clothing, etc., without a thought as to the necessity for them or the money with which to pay for them, and usually the rule is that they have not the money and the orders have to be countermanded by their friends. There is an increasing difficulty of receiving external impressions, their memory also shows a progressive impairment, and as their condition advances this failing is replaced by their imaginations and fabrications. Hallucinations play an unimportant part. Their delusions vary with their emotional attitude, the majority being of the exalted class, while occasionally the delusions are depressive in nature.

The physical symptoms may appear before the mental symptoms, but both are usually found coincident. Of the sensory symptoms, headache may be among the earliest, the special senses may be more acute and there may be some visual disturbances Of the motor symptoms, frequent attacks of dizziness or even severe convulsions may be present at the onset, and these attacks often leave the patient in a condition of advanced deterioration, occasionally there may be a transient paralysis of one side or of a group of muscles following these convulsions. In a large percentage of cases the pupils are unequal in size, and react poorly to light and often when there is a reaction the pupil immediately dilates again, the muscles of the face lose their tone and give the washed out expressionless features, the speech becomes slurring and in the early stages this may not be noticed during an ordinary conversation, but in using words containing an excess of consonants, particularly the m, n's, and r's, this feature shows up. Tabetic symptoms are often seen in paretics and have a tendency to confuse the diagnosis. These symptoms may precede the paresis for several years but are more or less typical of tabes dorsalis. One case admitted to this hospital recently and diagnosed as a tabo-paretic, prior to admission had been operated upon on two different occasions for the relief of a gastric ulcer and was committed with a psychosis, the result of using morphine. He had been inclined to complain of numerous ailments. The pains on which his operations had been based appeared very much as if they had been the girdle pains of the tabetic, and his excessive use of morphine was an effort on his part to relieve the intense pain. At the present time this patient is in the advanced stages of paresis and still complains of the gastric crisis of tabes.

The Wassermann and Noguchi reactions are also valuable diagnostic points and usually give a positive reaction, as this condition is usually found in patients who have been infected with syphilis. Occasionally in clear clinical cases a negative reaction may be obtained, but often this may be explained by a previous rigorous course of antisyphilitic treatment, and then in other cases a short course of treatment is necessary to stir up the condition as to cause a reaction to take place.

In the older patients we expect to find involutional psychoses and among the most prominent are melancholia and senile dementia. Melancholia is really a depressive phase occurring during the early senile period, this same condition occuring during earlier life would probably be classed among the manic-depressive group. The majority of cases are found between fifty and sixty years of age. External influences seem to play an important part as the exciting cause. The onset is rather slow and the early symptoms rather indefinite. The chief among them being a progressive difficulty to perform their usual work, they lack ambition, become sad, somewhat fearful, and frequently complain of feeling badly. Their facial expressions give evidence of their worry and oftentimes they lose control of themselves, become restless and quite agitated. Their ideas of self-accusation become prominent, while in some cases they are hypochondriacal in nature. Hallucinations of both sight and hearing may also be present in this condition but are rather indefinite. In cases of senile dementia we see the condition coming on about this same period, but usually it is later. The onset is gradual; they become puerile in their actions, become slower in their observations of their surroundings, are easily disoriented, become restless, and particularly at night they wander aimlessly about and are quite prone to light matches or play with the fire. Their memory shows a progressive deterioration, and this may be one of the earliest noticeable symptoms. They go out and lose their way home, cut holes into their pockets to get into them, and do various other stunts similar in nature. Frequently they develop ideas of persecution, that they are old, that they are worth nothing, and that their relatives do not want to bother with them, and frequently as a result of this they may attempt self-destruction.

The symptoms and characteristics that have been given above are only the ones most commonly seen in the early stages and cover the more principal forms of mental disturbances with which we come in contact most frequently. Of course we often find a mixture of symptoms which complicate the case and make it more difficult to diagnose early, but in many cases a diagnosis cannot be made until after a period of observation, and to the average practitioner this is not possible, for on account of the troublesome acts of the patient it becomes necessary to commit them to some institution when they pass from your care unless you take the time and trouble to follow them up.

The popular idea held by some physicians that neurasthenia, psychasthenia, and hysteria are often early signs of insanity does not appeal to me as being correct.

VACCINE THERAPY OF PERTUSSIS.

By PAUL LUTTINGER, M.D.,

NEW YORK.

Whooping-cough has shown, in the spring and summer of this year, a tendency to recrudescence in New York City. Two hundred and sixty-four deaths were recorded by the Department of Health from February 15 to August 17, 1913, while only 287 occurred during the whole year of 1912. During the above 28-week period 2,451 cases of whooping-cough were reported.

In the early part of April I had occasion to see quite a number of severe pertussis cases in the central part of the Bronx. The ordinary treatment internally with antipyrine, belladonna, quinine, potassium bromide, camphor, as well as inhalations of eucalyptus oil or creosote, did not seem to afford, in most cases, any permanent relief. I finally decided to try the pertussis vaccine. This vaccine, which is

VACCINE THERAPY OF PERTUSSIS—SUMMARY OF PREVIOUS REPORTS

Author	No. of Cases Reported	Age	Surroundings	Duration, Treatment in Days		Source of Vaccine	Millions			No. of Injection	Intervals in Days	Duration in Days	Results
				Before	After		Min. Dose	Max. Dose	Total Dos.				
P[illegible]an, 1...	*(1,000 test inoculations)	*	*	*	*	From a Bordet-Gengou strain given by Dr. Bordet.	¼	20	*	*	*	*	*Vaccine Cases* / *% Control Cases* Much better 31 / 21.55 Better 37.1 / 34.55 Unchanged 15.7 / 23.9 Worse 15.2 / 18.15 Much worse 1. / 1.85
Ladd, 2	9	7 weeks to 6 years	Hospital	7–56	21–56	Bordet-Gengou bacillus emulsion grown on blood agar 24 hours, heated at 60° C. for 1 hour.	20	40	37 to 170	3–8	5 to 14	..	Apparently shortened course and diminished attacks.
Graham, 3	24	2 months to 8 years	Private, except one hospital case	5–60	....	Commercial "Pertussin" (Pro bably Bordet-Gengou cultures.)	20	40	.	6–8	2–4	..	17 apparrently benefited (71%), 7 apparently not benefited (29%). Diminished severity and number of attacks shortened course.
[illegible]arnberger, 4.	6	. . .	Clinic	.....	13–30	Commercial "Polyvalent." (Probably Bordet-Gengou cultures.)	20	40	..	5–15	2–4	28–42	Rather lessens severity than shortens duration. The earlier treatment begins, the tbe better.
Scott, 5	2 out of 17 cases treated	1–2½ yrs.	Clinic	35	26	Commercial. (Probably Bordet-Gengou cultures.)	10	40	40 to 100	3	3–7		One great success, on p rtial failure; vomiting disappeared; young infants give quicker results.
Wilson, 6	24	*	Institution	.....	.....	Commercial. (Probably Bordet-Gengou cultures.)	20	40	..	*	*	9–48	Apparently shortens duration and severity. Kink disappears one week before cough.
Sill, 7	33	1 month to 6 yrs.	Clinic	7–49	10–64	Commercial. (Probably Bordet-Gengou cultures.)	20	60	..	3–12	1–7	.	Diminishes markedly number and severity of parox. and vomiting. Early cases responded better.
Nicolle & Conor, 8...	104	*	Tunis Epidemic	*	*	48-hour Bordet-Gengou culture heated to 46° C. for ½ hour; hence *living* bacteria.	1	5	*	2–5	2–3	..	Cured 35.7; 78% cured 3-12 days; improved 38.46; stationary. 25.96.

*Not given.

said to be made from cultures of the Bordet-Gengou bacillus of pertussis, was obtained from a well-known commercial firm, and is put up in 1-c.c. bulbs, containing 50,000,000 killed bacteria. Following the directions of the manufacturers as to dosage, I gave hypodermic injections of 20,000,000 to 40,000,000 bacteria every four to seven days. The results obtained were indifferent. I could not satisfy myself that the vaccine had either shortened the duration of the disease or lessened to any great extent the severity of the symptoms. The impression was gained, however, that it would be worth while to give the vaccine a more extensive trial.

In looking up the literature on whooping-cough in connection with studies undertaken by a group of workers at the Research Laboratory of the Department of Health, it became apparent that other experimenters had had better results.

Above is a summary of previous experiments with pertussis vaccine.

These reports encouraged me to try the vaccine again, this time in much larger doses and at shorter intervals than heretofore given. From the beginning of June to the middle of August I administered the vaccine to ten whooping-cough cases and to one healthy child (as a prophylactic) with the following results:

Case	Total Duration of Disease, Days	Duration After Treatment, Days	Number of Injections	Total Dosage	Maximum Dose
1	23	14	4	350,000,000	125,000,000
2	28	14	3	300,000,000	150,000,000
3	37	16	6	750,000,000	175,000,000
4	16	12	2	150,000,000	170,000,000
5	34	12	1	200,000,000	200,000,000
6	27	13	4	500,000,000	200,000,000
7	27	13	4	500,000,000	200,000,000
8	18	16	4	500,000,000	200,000,000
9	43	15	6	750,000,000	150,000,000
10	22	8	3	350,000,000	200,000,000

All these patients were seen and treated in private practice, and with one exception were children of working people. They ranged in age from one and a half to four years. I experienced considerable difficulty in most cases in persuading the parents to try the vaccine treatment. The notoriety which a recently exploited tuberculosis vaccine attracted seems to have inspired them with distrust. Added to this is the natural awe in which ordinary people stand of "needles."

With the exception of Case V, the initial dose was uniformly 50,000,000 bacteria (1 c.c.). In Case V I had intended to give a dose of 100,000,000, but inadvertently injected double that amount. The child did not seem to have suffered any ill effects from this rather high dose. The highest single dose

given was 250,000,000 (Case IX), and the highest total dosage was 750,000,000 (Case IX); the lowest total dosage was 150,000,000 (Case IV).

In some cases injections were given as often as every twenty-four hours. Those showing symptoms suggesting a negative phase or other complications had no injections until these disappeared.

A slight elevation of temperature of 1 or 2 degrees and an increase in the number and severity of the attacks of whooping may be the only indication of the reaction, and even this is wanting in many. In none of the ten cases was there a local reaction at the site of the inoculation.

Method of Administration.—The skin of the arm or of the gluteal region is thoroughly washed with 5 per cent. carbolic acid solution or alcohol. Phenol has the advantage of producing some anesthesia of the parts. The bulb containing the vaccine is thoroughly shaken and the contents drawn through a sterile needle into a syringe that has been boiled. The contents are then injected hypodermically, the needle is withdrawn, and with a piece of cotton gentle massage is made over the site of inoculation. Fifty million bacteria is a safe initial dose which can be followed the day after (unless a negative phase develops) with another dose of 100,000,000. From two to four days after the second injection a third dose of 200,000,000 may be administered. Two to seven days can now elapse before the last dose of 300,000,000 is given. Should a slight cough persist I would recommend a fifth dose a week after the fourth injection.

Prophylaxis.—Only in one case (the twin brother of the patient in Case VIII) did I have the opportunity to use the pertussis vaccine as a prophylactic. While it would be preposterous to draw any conclusions from one case, the result obtained is too striking not to warrant further experimentation along this line. In hospital, schools, and similar institutions an extensive experiment along the prophylactic treatment of whooping-cough would soon settle its merits or uselessness.

Case I.—J. R., female, 2½ years old, whooping for nine days, about twenty paroxysms in 24 hours. On June 6, 1913, 1 c.c. pertussis vaccine containing 50,000,000 bacteria given hypodermically in left arm. June 7, coughing worse than ever (negative phase?), some fever, loss of appetite. June 8, temperature normal, 1.5 c.c. vaccine hypodermically in right gluteal region. June 12, number of whoops, 12; 2 c.c. given hypodermically in left gluteal region. June 15, no whoops at night; 3 c.c. vaccine under left scapular region. June 20, stopped whooping but continued to cough a little. June 21, child is entirely well.

Case II.—M. F., female, aged 2 years. Contracted disease two weeks before the first injection. Temperature, 101. A few moist, scattered râles were heard. Has had over twenty-five whoops in 24 hours. June 10, 1913, 1 c.c. vaccine. June 11, mild attack of gastroenteritis; injections postponed. June 15, whooped fourteen times yesterday; 2 c.c. vaccine injected. June 16, only ten whoops which are much milder in character. June 17, 3 c.c. vaccine given. June 24, two to three very mild whoops; mother thinks the baby is well now and refuses further "needles."

Case III.—L. T., male, 3½ years old, delicate child; has been whooping for three weeks, severe case. June 25, 1913, 1 c.c. vaccine injected. June 27, 1.5 c.c., no improvement. June 28, no improvement; 2 c.c. vaccine given. June 29, no improvement. July 2, marked improvement, whoops suddenly became milder and fewer in number. Mother superstitiously refuses to count them. July 2, 3 c.c. vaccine given; still whoops "a little." July 4, 3.5 c.c. vaccine administered with the hope that it may shorten period of decline and prevent sequelæ. July 10, child is not whooping any longer.

Case IV.—C. F., female (cousin of Case II), 1 year and 9 months old; duration of disease, four days. June 14, 1913, 1 c.c. vaccine. June 15, whoops increased in number (from 8 to 14). June 16, improving somewhat. June 17, 2 c.c. vaccine administered. June 24, aunt of patient (mother of Case I) informs me that "she is getting along fine" and had not whooped for two days.

Case V.—E. M., female, 2 years old; sick for three weeks. Parents refuse a course of four to five injections but agree to "try" one. July 13, 1913, 4 c.c. were injected hypodermically in the gluteal region. July 20, a postal from Rockaway, where the family is summering, states that the child is feeling much better. July 26, another postal informs me that "last night and to-day the child did not cough at all."

Cases VI and VII.—G. and D. R., twins, female, 1½ years; contracted disease in Coney Island, notwithstanding the fact that they live almost in front of the ocean. July 20, 1913, 1 c.c. of vaccine administered to each. July 21, there being no negative phase, 2 c.c. additional are given. July 24, 3 c.c. injected; improvement. July 27, improvement continues; 4 c.c. vaccine administered. July 30, improved to the extent of two and four coughs respectively. August 2, children do not whoop any more.

Case VIII.—M. H., male, cousin of preceding two cases, living in same house, 3½ years old. At the time injection was given to Cases VI and VII, I offered to give him and his twin brother, Frank, a prophylactic dose. Frank readily submitted but Morris raised such a hubbub that I was obliged to desist. Ten days later he began to whoop, while his brother remained well. August 2, 1913, initial dose of 1 c.c. given, followed with 2 c.c. on the 3d and 3 c.c. on the 7th. He began to improve markedly after this and on the 12th the last dose of 4 c.c. was injected. August 16, child is reported to be still coughing a little. On August 18 reported to be entirely well.

Case IX.—H. G., female, 2 years old, very severe case. Mother cannot count the large number of paroxysms. Child has had disease for four weeks. July 25, 1913, 1 c.c. vaccine was injected. July 26, seems to have become worse. July 27, is still very bad. July 28, no improvement. July 29, began to improve a little; 2 c.c. vaccine given. July 30, further improvement; 3 c.c. vaccine injected. August 2, improvement continues but at slow rate; 4 c.c. given. August 4, another injection of 5 c.c. August 7, improvement is very marked. August 8, child did not cough at night. August 9, child is well.

Case X.—J. J., male, aged 4 years. Contracted disease in midocean while on the steamer returning with his mother from Europe. Has had disease for two weeks. Patient recommended for treatment by Dr. Louis Goldstein. August 16, 1913, 1 c.c. vaccine injected. August 17, no change; 2 additional c.c. administered. August 18, mother thinks that he whoops more than before (negative phase after second injection). August 19, number of whoops decreased from 20 to 9; 4 c.c. vaccine injected. August 21, night whoops stopped. During the day had seven mild whoops. August 22, 4 mild whoops. Mother refuses further injections. She believes child will get well anyhow. September 14, child had stopped whooping on the morrow of last visit.

It is not within the scope of this article to discuss the etiology of whooping-cough. The bacteriological findings of these and other cases are included in the studies on whooping-cough which are now being made in the Research Laboratory of the Department of Health.

Conclusions.—1. Pertussis vaccine, used in ten cases of whooping-cough, apparently reduced the severity and shortened the duration of the disease.

2. To be effective the vaccine should be given in much larger doses and at shorter intervals than hitherto recommended.

3. A dose of 50,000,000 bacteria should be tested as a prophylactic.

TURBINOTOMY.

By EDWIN A. GRIFFIN, M.D.,

BROOKLYN, N. Y.

LARYNGOLOGIST AND RHINOLOGIST AT THE LONG ISLAND COLLEGE HOSPITAL DISPENSARY, LARYNGOLOGIST AND OTOLOGIST AT THE BROOKLYN CITY AND NEW UTRECHT DISPENSARIES AND SAMARITAN HOSPITAL

TURBINOTOMY, or partial excision of the turbinated bone, seems to have been discarded in nasal surgery since the submucous septal operation has come into vogue. If I have a case, however, of nasal obstruction, with its accompanying symptoms of dry throat, postnasal dropping, frequent "colds in the head," winter cough, etc., and I find a moderately large inferior turbinate and a slightly deflected septum I always attack the turbinate rather than touch the septum.

The submucous operation is a good procedure in those cases where the septum is profoundly deflected and where there is no other way of giving more air-room. The damage to the mucous membrane, the danger of perforation, flat nose, and synechia formations is not a trivial matter to be laid aside. These complications are liable to happen in the hands of the most expert rhinologists.

Turbinotomy is a simple procedure compared to the submucous operation on the septum and gives the patient what he wants, more air-room, and stops the postnasal dropping. Even in cases of chronic hypertrophic rhinitis where the bone is not enlarged, I advise turbinotomy, removing only a small ridge of bone with the redundant mucous membrane. The operation seems to be preferable to that of the snare, inasmuch as there is less granulation-tissue formation. The cautery, either electric or chromic acid beads, even if employed lightly, causes a marked edematous condition the next day, which takes about two weeks to disappear. Cauterization is not a complete procedure for nasal obstruction. Those cases which would respond to the cautery would respond to any alkaline cleansing nasal douche.

Turbinotomy is also extremely beneficial in ear cases, even where there is practically no evident complaint of nasal breathing; that is, in chronic intermittent otorrhea and chronic catarrhal deafness in adults. The congestion around the Eustachian tube orifice is removed and promotes better drainage and aeration in the middle ear. I have performed this operation in many cases of catarrhal deafness and chronic intermittent otorrhea, with very beneficial results. I speak of intermittent otorrhea because in most cases it is due to some obstruction around the Eustachian tube in children and is very apt to be caused by adenoids.

A chronic nonintermittent aural discharge which does not respond to the ordinary procedure, not forgetting the value of the polyvalent vaccines, means that a posterior drainage operation through the mastoid process is necessary.

The technique of turbinotomy is as follows: (a) Prepare the case the evening before with a calomel purge to relieve congestion, to be followed in the morning with the usual saline cathartic. A moderate meal before the operation is advisable as the patient does not seem to be so nervous from the effects of the cocaine as he would be on an empty stomach. The tolerance to cocaine of each patient should be determined by having the case come to the office for about three or four visits before the operation and the nasal cavity should be swabbed out with cocaine at each visit. This will also familiarize the operator with all the eccentricities of the patient and also give him time to study that particular nasal cavity.

(b) The nasal cavity is carefully swabbed out with warm saline solution or a spray may be used very gently. Various antiseptic solutions are not necessary as they do no good in mild strength and in strong solutions they only irritate the mucous membrane, lowering the power of resistance to infections. After the nasal cavity is thoroughly cleansed it is cocainized in the usual method with a 10 per cent. solution. Adrenalin with cocaine may be employed if desired. After 20 minutes the cocaine cotton tampon is removed and the operation is begun.

(c) An incision is made through the mucous membrane from the posterior tip of the inferior turbinate to its anterior tip, along its internal surface with a scalpel down to the bone. The mucous membrane is then peeled downward from the bone; in many cases it will drop down immediately after the incision, as it is not very adherent to the bone. The bone is then sawn through from its internal surface with a fine flexible saw, the operator being careful always to have the saw running parallel with the inferior border of the septum, and not to have the point running outward, as damage to the Eustachian tube orifice might result therefrom. In some cases it is easier to saw the bone through from its external surface inward and upward. This is optional with the operator. Now the snare is passed around the cut segment and it is removed *en masse*. Rarely is it necessary to remove more than about one-third or one-half of the bone, and hence there is no danger of any atrophic condition resulting as might happen after a complete turbinectomy. Now the nasal cavity is gently swabbed out with a 20 per cent. argyrol solution, and then packed with iodoform or plain gauze saturated in 5 per cent. argyrol. In the ordinary case all the packing can be removed on the second day. The patient can resume his business on the fourth day. The after-treatment is practically like that of any postoperative wound.

340 STUYVESANT AVENUE.

Meningeal Hemorrhage During Parturition.—J. Euzière and F. Bonnet report the case of a primipara aged twenty who during the course of labor passed into a deep coma, which gradually disappeared after the instrumental delivery of her child. The following signs indicating meningeal involvement were present: rigidity of the neck, Kernig's sign, headache, photophobia, and a moderate rise of temperature. Lumbar puncture revealed bloody fluid. Complete recovery ensued in four weeks.—*Gazette des Hôpitaux.*

Cases of Congenital Ocular Lesions.—E. H. Harries Jones reports the following cases: Case I: Aged 9 years. Right eye: Persistent capsulopupillary membrane (pigmented). Left eye: Pigmented area on anterior capsule of lens. Case II: Aged 23 years. Right eye: Coloboma of iris and choroid downward and inward (usual kind). Case III: Aged 23 years. Right eye: Coloboma of iris and choroid (downward and inward). Left eye: Marked microphthalmos, with coloboma of iris and choroid. Case IV: Aged 11 years. Left eye shows persistent hyaloid artery—not blood-bearing—passing from the optic disk to the posterior pole of the lens. Case V: Child showing congenital dislocation of crystalline lenses, outward and downward.—*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

TUBERCULOUS INTERSTITIAL NEPHRITIS.

THE question whether tuberculosis may give rise to a primary chronic interstitial nephritis is one that presents many points of interest. It is well known that a large number of tuberculous individuals develop a secondary tuberculosis of the kidneys. Renal tuberculosis of this character is strictly of surgical significance. It is a clearly defined entity, recognized with little difficulty and when unilateral, responding to appropriate surgical treatment. On the other hand, little attention has been paid to the possibility of tuberculosis being the cause of a parenchymatous or interstitial inflammation of the kidneys. Landouzy and Bernard described a primary tuberculous parenchymatous nephritis with albuminuria, hematuria, and edema. Jousset referred to a "néphrite scléreuse interstitielle atrophique," of tuberculous etiology. Tamayo examined the kidneys of 279 tuberculous individuals, and whereas he found a definite renal tuberculosis in 39, nevertheless, in 98 cases investigated histologically, he was able to demonstrate in 86 cases the presence of parenchymatous and interstitial changes of chronic or acute type. The German clinicians who have studied this subject have obtained similar results. Frerichs found in the kidneys of tuberculous individuals cloudy swelling, anemia, and in some instances chronic interstitial changes. Heyn concluded that the tubercle bacillus may give rise in the kidney to foci of inflammation which may not go on to caseation, but which may heal with the formation of scars. He described a contracted kidney *sui generis* in tuberculous patients. Salus found in 28 cases of tuberculosis the presence of albuminuria in 44 per cent. and casts in 51 per cent. and characterized these as evidence of a renal involvement. Herxheimer concluded from his investigations that in adolescence tuberculosis is the most important etiological factor in the causation of hyaline degeneration of the glomeruli of the kidney.

S. Schönberg (*Zeitschrift für klinische Medizin*, Vol. 78, Nos. 5 and 6) has studied this subject anew, his opportunity being afforded by a patient in whom the manifestations of a chronic interstitial nephritis dominated the clinical picture from the outset. A woman twenty-eight years old presented throughout the entire course of her illness of one year a mild uremic condition characterized by headaches, marked vomiting, and occasional vertigo. There was an increased secretion of urine, of low specific gravity and containing albumin and casts. The blood pressure was 230. There was a pronounced albuminuric retinitis. Death occurred during an attack of uremia. Autopsy confirmed the clinical diagnosis. The kidneys were contracted, giving the appearance of a combination of the arteriosclerotic and the contracted kidneys. The poles of the kidney were not involved. Foci resembling tubercles were present in the kidneys, but there was no evidence of tuberculosis in any other part of the body. Microscopic examination of the kidneys showed hyaline degeneration of the glomeruli, reduction of the parenchyma, and atrophy of the uriniferous tubules. The interstitial connective tissue was increased in amount and rich in cellular elements. In the areas that contained most of the latter there were numerous tubercles which were also in close contiguity to the glomeruli. The presence of tubercle bacilli was demonstrated.

The questions arose: what type of interstitial nephritis was presented by the above case and what relation did it bear to tuberculosis; was this an etiological or a complicating factor? The atypical character of the pathological picture and the presence of localized areas of transformation of the tuberculous granulations into fibrous tissue led Schönberg to conclude that the nephritis was the direct result of tuberculosis. Among the various causes of chronic nephritis, he thinks tuberculosis must be included as a possible etiological factor.

DIABETES AND CIRRHOSIS OF THE LIVER.

CLAUDE BERNARD, who discovered the glycogenic function of the liver, was the first to point out the close relationship between a disturbance of this organ and diabetes. Jaccoud, Cantani, and Lecorché were able to demonstrate pathological changes in the liver of diabetics, but threw no light upon the morbid mechanism involved. Hanot and Chauffard delineated as the cardinal symptoms of "le diabète bronzé," cirrhosis of the liver, melanodermia, and diabetes. Bouchard noted the great frequency of hypertrophic cirrhosis of the liver in diabetics. It was Glénard, however, who brought considerable clinical evidence to show the important rôle played by the liver in the production of diabetes, maintaining at the same time that every instance of hepatic diabetes is the result of chronic alcoholism. Gilbert and his pupils distinguished two varieties of diabetes: that caused by hepatic insufficiency, in which the liver is unable to store up the ingested sugar; and that caused by an excessive functional activity of the liver. The former type is benign, but the latter represents a severe grade of diabetes and, according to Gilbert, includes bronzed diabetes, the diabetes associated with acromegaly, certain traumatic forms of diabetes, and pancreatic diabetes. Contrary to the views of Gilbert, Marcel Labbé recognizes only the type of diabetes characterized by hepatic insufficiency.

Basing their opinion upon two cases of diabetes associated with cirrhosis of the liver, Bouchut and Volmat (*Revue de Médecine*, October 10, 1913), believe that whatever may be the rôle which the liver plays in diabetes, there is nevertheless a definite clinical type, namely, a diabetes associated with cirrhosis of the liver. Found in most instances in chronic alcoholics this cirrhosis is almost always of the hypertrophic type. It develops as a rule without ascites or icterus. In general the diabetes is benign, resembling the "diabète gras" or the arthritic diabetes, and frequently the glycosuria diminishes during the terminal stage of the cirrhosis. Occasionally the diabetes may be of severe type. It is difficult to decide clinically in any given case which process has started first, the cirrhosis or the diabetes; sometimes the one, and sometimes the other being the first manifestation, and sometimes both conditions being detected simultaneously.

The interpretation of the above relationship is no more definite than the present-day conception of the pathogenesis of diabetes. One fact has been established, namely, diabetes is the expression of a complex disturbance of the sugar-regulating mechanism of the body, a mechanism of which the pancreas, liver, kidneys, suprarenals, and other organs form a part. Sometimes one organ, sometimes another, may provide the disturbing factor. At any rate sufficient pathological data have been gathered to show that the fault may lie mainly in the pancreas or in the liver.

AN ANTIVIVISECTION ORGY.

The newspaper reports of the meetings of the International Antivivisection and Animal Protection Congress would indicate that the members of the Congress are no less adept than formerly in their use of misstatement and misrepresentation and no more restrained in the expression of their prejudices or distorted beliefs Mrs. Florence Waring, the organizing secretary, for instance, is quoted as saying: "We are in this work for the protection of all helpless creatures, both human and dumb, who are to-day in our own country at the mercy of a class of medical men accountable to no law but their own." Mr. Edward H. Clement of Boston is quoted by the *New York Times* as follows: "Here in the United States is the largest mass in the world of 'tainted' wealth, and the whole toppling mass stands crowned with the Rockefeller Institute There is enthroned man's superior cunning and power, wreaking itself on animals, as erstwhile on humanity"; while Senator Gallinger of New Hampshire is reported to have said that there was every reason to believe that in some hospitals pauper children were "inoculated with loathsome diseases to see the results that will follow"; and that "the dog which turned and lapped the vivisector's hand after a red hot iron had been run into his eye, stands a better chance to reach paradise than the brutal human being who so needlessly tortured the dumb animal." "Human vivisection is a fact and is so widespread as to be called general." Mr. Frank Stephens of Philadelphia is reported to have stated, while Mr. F. P. Bellamy of Brooklyn also called attention to the practice of inoculating children with loathsome diseases and of performing dangerous tests on healthy and ignorant people, which he apparently considered to be a common one.

Mr. J. Howard Moore of Chicago drew a sad picture, as reported in a dispatch to the *Sun*, when he stated that: "Vivisectionists in an earlier day would have been slave dealers or in a still earlier stage of development would have been cannibals ready to eat alive their grandmothers or grandfathers"; while even more tragic was the statement of Mr. D. C. Beard, president of the New York Camp Fire Club, quoted in the *American*: "As 33 per cent. of our physicians are victims of some form of drug habit, they should not be permitted to make dangerous experiments on human beings or even on animals." Even the great Pasteur was not exempt, for in criticising the Pasteur treatment for hydrophobia as "injurious and responsible for many deaths," Mr. Charles W. Dulles of Philadelphia said that "although Pasteur has made most valuable contributions to science, which have been of great service to humanity, in regard to this particular subject, he is a charlatan and an ignoramus."

On top of all this it is rather disconcerting and disappointing to read that at the opening session President Wilson was quoted as having expressed himself in sympathy with the antivivisection movement and as willing to do what he could to further it, and that Secretary of State Bryan on behalf of the President welcomed the delegates to Washington.

THE PSYCHIC VALUES OF LIGHT, SHADE, FORM, AND COLOR.

The human feelings, emotions, and sensations are profoundly influenced by light, shade, form, and color, and it therefore follows that the methods of illumination should be in consonance with such sensations, or at least should offend them as little as possible. In an interesting paper read before the Illuminating Engineering Society and published in their Transactions for October, F. Park Lewis brings out these truths. Referring to the mental and moral effects of light and shadow, Lewis says: "The difference produced upon our state of mind by the glaring brilliancy of an unshaded Welsbach light, especially an old one, or the soft glow of even a yellow illumination is felt by every one, although by no means always recognized as a cause of nervous irritation. In some of the most persistent cases of eyestrain after the ophthalmologist has employed the highest degree of skill in determining the correct combination of lenses to be employed it will be found that the discomfort is due to a badly placed lamp, to the improper use or absence of shades, to an insufficiency or an excess of light, to some specular reflection, or other local fault in the illumination about which he has not been advised. There is probably no one simple element that more deeply concerns the welfare of the people than correct lighting."

Putting aside the esthetic effects of light and color which in themselves have a very considerable influence upon health through the nervous system, the

harm done by too glaring lighting, by badly placed lights, or by insufficiency of light to the vision itself is very great. In these days the fault is generally a too glaring light or an excess of light. The object seems to be to have as many brilliant white lights as possible, and even in public libraries shaded lights are not infrequently conspicuous by their absence. There is little doubt that a considerable amount of the nervous irritation which is so prevalent is largely due to or greatly aggravated by present day methods of lighting.

Practical Eugenics.

Practical eugenics is a problem which is not only as yet unsolved, but is still very far from solution. In fact, no absolutely workable scheme in the direction of preserving the race at a high standard of physical and mental excellence or of checking the widespread deterioration which is taking place in the population of the cities of all civilized lands has been even suggested. It is, however, the worthy aim of leaders of thought in every branch of human endeavor to set forth a means of regenerating the race. A paper of much value has been contributed by Sir James Barr of Liverpool to the November issue of the *American Practitioner*. He points out that the science of eugenics has the positive aspect of encouraging the multiplication of the morally, intellectually, and physically fit and the negative aspect of preventing further degeneration by discouraging or preventing the multiplication of the unfit. Attention is drawn to the fact that the latter, if widely and wisely executed, would be a great point gained and could be easily attained if society would only wake up to a sense of its enormous responsibilities. Barr rightly lays great stress on the necessity for preventing the propagation of the feeble-minded. Such persons are generally prolific and in them the sexual instinct is developed often to an abnormal extent, the consequence being that the feeble-minded increase at a menacingly rapid rate. The great danger of the situation is that the least fit, who are possessed of no sense of responsibility, increase in a far greater proportion than the fit. The logical assumption would, therefore, be that in course of time the fit would be overwhelmed by the burden of supporting those who so far as the welfare of the race is concerned had better never have been born. Fortunately, however, what does happen is not always what logically ought to happen, and as the world has jogged along through the ages improving a little all the time, it probably will continue to do so, though a temperate application of eugenic principles will no doubt accelerate the rate of progress.

Our Present Knowledge of Pellagra.

From many points of view our progress towards a definite knowledge of pellagra is halting and disappointing. As C. H. Lavinder points out in the issue of Public Health Reports for November 21, our actual knowledge of the disease leaves very much to be desired; and the etiology of pellagra remains in obscurity. While the Italian school still holds to the corn theory, the American school appears inclined to regard pellagra as an infectious disease of some undetermined character. Although, as said before, nothing is accurately known regarding the etiology of the disease Sambon's fly theory seems as worthy of consideration as any other. Sambon has shown, for instance, that there are several cases of the disease in the British Isles where the habits of living and kind of food eaten do not favor the corn theory. As for a specific for pellagra, Lavinder remarks that there is none for pellagra as there is none for the vast majority of diseases, and the treatment recommended by him is largely summed up in the removal of the patient from his surroundings, if possible, and preferably to an institution; proper diet, properly regulated rest, hydrotherapy, and intelligent attention to general symptomatic treatment without the employment of too many drugs. The fact is noticed that such a treatment implies the need of institutions, of which we have none in this country. Lavinder utters a timely word of warning with regard to the ready use of arsenic in the treatment of the malady and especially does he advise caution in the employment of the so-called arsenical preparations, such as atoxyl and salvarsan. This latter preparation, valuable as it has thus far proved to be in the treatment of certain forms of syphilis, is coming to be too much regarded as a panacea for a variety of diseases and it is certainly no specific for pellagra.

News of the Week.

City Vital Statistics.—During the week ending December 6, the total number of deaths reported in New York City was 1,372, giving a death rate of 13.32 per thousand of population, as compared with a total of 1,420 deaths, and a rate of 14.32 for the corresponding week of last year. There were only 194 deaths of infants under one year of age, during the week. For the first forty-eight weeks of the year the death rate is given as only 13.77, which indicates a record low rate for the year.

Health Department Report.—In the December issue of the Monthly Bulletin of the New York Health Department, some of the doings of the department during 1913 are enumerated. In the enforcement of the pure food laws, for instance, although the corps of inspectors is totally inadequate, 11,529,899 pounds of foodstuffs were condemned during eleven months. There are now 19,000 places in the city where food is handled, prepared, or sold, and all of these require thorough inspection; for this a force of at least 150 men is needed, whereas there are at present but forty. The percentage of cases of tuberculosis kept under observation by the department increased from 12 in 1908 to 25 in 1913. Tuberculous children are now excluded from school, scrub women are employed to disinfect premises previously occupied by consumptives, and stereopticon tuberculosis exhibits have been given at night in various parks. The system of supervising the health of children in schools and public institutions has been largely extended, and six dental clinics have been established. The department maintains fifty-five milk stations, to which the reduction in infant mortality is largely credited; and the adoption of a milk grading system as a part of the Sanitary Code has resulted in a great improvement in the quality of milk supplied to the city. Every can or bottle of milk coming into New York must now bear a label explaining just what quality and grade of milk it is. The steady fall in the death rate under the present administration of the city is also pointed out. During 1909 the death rate per thousand was 16; during 1910, 15.98; during 1911, 15.13; and during

1912, 14.11. For this year it promises to be below 14, which will almost approximate the 13.52 rate for London in 1912, the lowest on record.

Ambulance Crash.—In a collision between an automobile and a Fordham Hospital, New York, ambulance last week, the ambulance surgeon, the patient, and a policeman were all severely hurt.

Death from Diphtheria Antitoxin.—A verdict of death from asthma complicating an injection of diphtheria antitoxin was rendered recently by a Coroner's jury in the city of Philadelphia in the case of a young man who died following a prophylactic injection. It was shown that from childhood the man had shown marked susceptibility to the presence of horses, developing asthmatic symptoms on exposure.

Civil Service Examination.—The United States Civil Service Commission announces an open competitive examination for men only, for the purpose of filling a vacancy in the office of medical assistant in the Bureau of Chemistry, Department of Agriculture, Washington, at a salary of $1,800 per year. The duties of the position will be to study the claims and representations made in conjunction with proprietary remedies, to look up medical literature, and to assist in preparing cases, etc., under the Food and Drugs Act. A knowledge of French and German is desirable. Candidates will be rated by general education and medical training, practical or professional experience and fitness, and publications or thesis. Graduation from a medical school of recognized standing and at least three years' subsequent experience in the practice of medicine or two years' subsequent experience in either pharmocological investigations or the actual examination of drug products with reference to the claims made therefor by manufacturers, are prerequisites for consideration for this examination. Further details may be obtained by application to the United States Civil Service Commission, Washington, D. C.

Model Milk Ordinances.—The rules of the New York City Department of Health for the control of the milk supply have been recommended for adoption in Johannesburg, South Africa.

Social Work Among Insane.—The Long Island State Hospital, Brooklyn, N. Y., has secured funds allowing for the employment of a social worker in connection with the hospital for the purpose of preventive and after-treatment care among the insane in the city of Brooklyn.

Ecuador to Clean Up.—The Government of Ecuador has recently signed contracts for the carrying out of the sanitation of Guayaquil, which has long been known as the "pest hole" of the Pacific. The plans call for the expenditure of several million dollars, and if properly executed should result in the elimination of yellow fever, bubonic plague, typhoid fever, and malaria, all of which are now prevalent there. For many years the State Department at Washington has attempted to force Ecuador to adopt proper sanitary measures, since the condition of Guayaquil has been a menace to the entire western coast, and its success now is largely due to the opening of the Panama Canal. The contract for the work has been obtained by an English firm, because of the great hostility to Americans in Ecuador, it is said; but it is probable that the actual work will be done, mainly by sanitary engineers from this country.

New Sanatorium Open.—The Metropolitan Life Insurance Company has recently opened the sanatorium which it has built at Mt. McGregor, N. Y., for the care of employees of the company suffering from tuberculosis. The sanatorium is located 1,200 feet above sea level, on a plot of 420 acres. In seeking legal approval for the use of its money for the erection and maintenance of the sanatorium, the company obtained from the Appellate Division of the Supreme Court a decision in which for the first time was laid down the proposition that it is not only within the powers of a corporation to assume the care and treatment of such of its employees as are afflicted with tuberculosis, but "the reasonable care of its employees according to the enlightened sentiment of the age and the community is a duty resting upon it, and the proper discharge of that duty is merely transacting the business of the corporation."

American Red Cross.—At the ninth annual meeting of the American Red Cross in Washington, announcement was made of the completion of the $300,000 fund, which was necessary in order to secure the $400,000 appropriated by Congress for the erection in Washington in memory of the women of the Civil War of a building to be used as headquarters for the Red Cross. This assures erection of the memorial at an early date.

Centenarian and More.—Hannah Koskoff, an inmate of the home of the Daughters of Israel, New York, celebrated last week what was said to be her 116th birthday. She was born in Russia and came to this country sixty-four years ago.

Medical Licenses.—As the result of the November examinations held by the South Carolina State Board of Medical Examiners, eighteen of the candidates received licenses to practice medicine. The examinations were taken by forty-four applicants for licenses.

Sex Plays.—The production of the modern sex plays was severely criticised and condemned at a recent meeting in New York of the Society for Sanitary and Moral Prophylaxis. Even those members of the society who approved in the abstract of the presentation of these questions upon the stage joined in disapproval of the plays now being offered in the city.

Personals.—Dr. Livingston Farrand, professor of anthropology at Columbia University, New York, and a graduate of the College of Physicians and Surgeons, New York, in 1891, has been elected president of the University of Colorado, Denver, to succeed President James H. Baker, who will retire on January 1.

Dr. Louis Laberge, medical health officer of Montreal, has resigned his position after twenty-seven years of service.

Dr. Biggs Resigns.—After twenty-six years in the service of the City of New York, Dr. Herman M. Biggs on December 3, resigned his position of chief medical officer of the Department of Health, and his resignation was accepted to take effect on December 31, 1913. Dr. Biggs will devote himself to the duties of chairman of the Public Health Council of New York State, to which he was appointed on the creation of the Council last year. During his long service in the city department Dr. Biggs has introduced many reforms, and much of the excellent work of the department is credited to him. In his new office he may be expected to do for the State what has already been done for the city.

Society of American Bacteriologists.—The annual meeting of this society will be held in Mon-

treal, on December 31, 1913, and January 1 and 2, 1914, under the presidency of Professor C. E. A. Winslow. On the first and last days the meetings will be held in the new Medical Building of McGill University, and on January 1 the society will meet at Macdonald College. On the same evening the annual dinner will be held at the University Club, Montreal, and the President's address on "The Characterization and Classification of Bacterial Types," will follow. Further details of the meetings, to which all those interested are cordially invited, may be obtained from the secretary, Dr. A. Parker Hitchens, Glenolden, Penn.

Charitable Bequests.—By the will of the late Mary H. Russell, of Philadelphia, the sum of $5,000 is bequeathed to the Germantown Hospital, and the residual estate, amounting to about $60,000, is bequeathed to the Children's Homeopathic Hospital, to construct and maintain additional buildings.

The Late Dr. Peiser.—At a meeting of the Medical Board of the Bronx Hospital and Dispensary, held on November 11, 1913, the following resolutions were adopted:

Resolved, That we deeply deplore the untimely death of our colleague and fellow member, Dr. Louis Peiser. We recall his cheery and happy disposition, his unfailing courtesy, his constant endeavor for the uplift of his profession, and his scientific interest therein. We shall miss his sage counsel and sincere willingness to bear his share of the work in the building up of our institution, and we tender our most respectful condolences to his bereaved family. Be it further

Resolved, That a copy of these resolutions be sent to his family and the medical press, and be entered in our minutes.

EMIL MAYER, M.D.,
ROBERT I. FRANK, M.D.,
HENRY HEIMAN, M.D.

Obituary Notes.—Dr. HARRY M. HAYES of Peoria, Ill., a graduate of the Rush Medical College, Chicago, in 1894, and a member of the American Medical Association and the Illinois State and Peoria County Medical Societies, died at the Proctor Hospital, Peoria, from typhoid fever, on December 2, aged 42 years.

Dr. RICHARD CRANCH GREENLEAF, formerly of Lenox, Mass., a graduate of the Harvard Medical School, Boston, in 1870, and a member of the Massachusetts Medical Society and the Berkshire District Medical Association, died at his home in Lawrence, Long Island, N. Y., on December 3, aged 68 years.

Dr. ROBERT ALVIN WALKER of West Monterey, Penn., a graduate of the University of Wooster, Medical Department, Cleveland, O., in 1877, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Clarion County Medical Association, died at his home on November 26, aged 59 years.

Dr. HENRY P. HOWARD of Dallas, Tex., died at his home on November 21, aged 82 years.

Dr. WILLIAM HUTCHINSON MERRILL, retired, of Peperell, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1886, died at his home on December 2, aged 52 years.

Dr. JOHN DECKER FRAZER of Danton, Va., a graduate of the University College of Medicine, Richmond, in 1902, and a member of the American Medical Association and the Medical Society of Virginia, was killed on November 26, when, while making his round of visits, the horse which he was driving took fright and ran away.

Dr. THOMAS J. CROFFORD, formerly of Memphis, Tenn., a graduate of the Hospital College of Medicine, Louisville, Ky., in 1870, and a member of the Tennessee State Medical Association, the Shelby County Medical Society, and the Southern Surgical and Gynecological Association, died at his home in Los Angeles, Cal., after a short illness from pneumonia, on November 24, aged 54 years.

Dr. HENRY M. WINANS of Muncie, Ind., a graduate of the Medical College of Ohio, Cincinnati, in 1880, and a member of the American Medical Association and the Indiana State and Delaware County Medical Societies, died on November 23, from cancer of the throat.

Dr. HENRY FREDERICK MUELLER of Sauk City, Wis., a graduate of the Kentucky School of Medicine, Louisville, in 1889, died at his home on November 23, aged 55 years.

Dr. ABBY SWAN MORSE of Gloucester, Mass., a graduate of the Boston University School of Medicine in 1875, died in the Addison Gilbert Hospital, Gloucester, from appendicitis, on December 2, aged 68 years.

Dr. FITZWILLIAM SARGENT WORCESTER of Peabody, Mass., a graduate of the Harvard Medical School, Boston, in 1873, died in the Josiah B. Thomas Hospital, after a lingering illness, on December 7, aged 62 years.

Dr. ALFRED LAYMAN of Philadelphia, a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1882, and a veteran of the Civil War, died at his home on December 6, aged 70 years.

Dr. CHARLES A. USILTON of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1882, died at his home from nephritis on December 3, aged 59 years.

Obituary.

JOHN GREEN, M.D., LL.D.

SAINT LOUIS.

Dr. JOHN GREEN died of pneumonia at his home in St. Louis on December 7. He was born in Worcester, Mass., April 2, 1835. After graduation from Harvard in 1855 he studied medicine and at the beginning of the Civil War entered the medical service of the Western Sanitary Commission; later he served as acting assistant surgeon in the Army of the Tennessee and in Maryland with the Union Army. At the close of the war he resumed his medical studies and received his M.D. from Harvard in 1865. After a further period of study in Europe he began practice in St. Louis, where he was a pioneer ophthalmologist. He was professor of ophthalmology at the St. Louis Medical College of Washington University since 1886. In 1905 he received the honorary degree of LL.D. from Washington University, and in 1906 from the University of Missouri. Dr. Green was one of the organizers of the American Ophthalmological Society. He was also one of the founders of the St. Louis Academy of Sciences and of the Archeological Society and was a trustee of the Missouri Botanical Garden. Dr. Green was not only a skillful and learned ophthalmologist, but a man of broad general culture and ripe scholarship, deeply interested in the world and its inhabitants and ever striving for its and their betterment.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RADIUM FOR THE HOSPITALS—POISONING BY LEAD—ORGANISM OF RHEUMATOID ARTHRITIS—KING EDWARD'S HOSPITAL FUND—G. M. C. INSURANCE—OBITUARY.

LONDON, November 28, 1913

YESTERDAY the Court of Governors of the Middlesex Hospital had before them the report for six months when Prince Alexander of Teck said that he had asked the committee of King Edward's Hospital Fund to see if they could purchase radium for all the hospitals to use the emanations and he had offered to arrange for the Middlesex to prepare the emanations in their cancer research laboratory and supply tubes at the cost of their preparation. This would reduce the cost of treatment tenfold and save institutions from trenching on capital. Sir A. Pearce Gould supported this scheme with enthusiasm and gave some information as to what they had done with radium treatment at the Middlesex. He said they must speak guardedly as to its use in cancer, but they could say it had influence on the growth of the body cells—it could stimulate or inhibit growth or destroy living tissue (radium burns). On the cells of malignant growths its influence was much stronger, but its action was by no means uniform. In some cases a single application had a striking effect, in others treated from the same tube none whatever. He knew of one case where half an extensive area of disease was removed at the first application of radium and the other half unaffected though equally exposed. In some burns readily occurred, in others the tissue resisted. He had applied it to the brain for hours without result, but a man to whom it was used on the hip had a great hole burnt into his thigh because he had a bunch of keys in his pocket. It would be misleading to speak of radium as a cure for cancer in the way some drugs may be said to cure specific diseases. But so long as cancer was a single localized disease, and it was sometimes so for a long time, radium offered a brighter, more confident hope than had ever attended the use of any remedy except operation. Money spent on radium for hospitals would be a good investment as it did not get any poorer by giving off emanations.

Sir Thomas Oliver, who is our leading authority on plumbism and other forms of metallic poisoning, has been giving a course of lectures at the Royal Institute of Public Health, dealing with this and other points of industrial hygiene. He said lead was used in about 100 trades and was the metal most hurtful to health. Between 1900 and 1912 no less than 8,523 cases of poisoning by it were recorded, of which 394 were fatal. Compulsory notification had proved very valuable by leading at once to investigation of every case and its surroundings. Lead mining itself was not a cause, but the miners were often tuberculous. The danger of plumbism began with the smelting of the ore in which about 40 per cent. of the lead went into the flues in the form of fumes and there was deposited as dust, so that cleaning the flues was more dangerous even than the smelting. Lantern slides were shown illustrating the methods employed in the manufacture of red lead. White lead was the most dangerous of all and only men were allowed to work in its processes and they had to wear respirators and the lead was watered to lay the dust. In pottery the prevalence of poisoning led to an inquiry in which the lecturer took part and better regulations were made, less white lead was used and it was fired with silica or boric acid. Painting for indoor decoration could be done as well with zinc oxide. Whether in our climate it would do as well as it has done in France was now being considered by a commission. The lead entered the system by three ways: (1) by the skin—not very often, as plumbism was not common among glaze dippers who were all day plunging bare arms into lead; (2) through the respiratory system, the worst cases being thus brought about; (3) through the alimentary canal, often from workers eating with unwashed hands. The early symptoms were pallor of the face with a rounded look and expressionless appearance—anemia due to interference with the blood-making. Next came the blue line round the edges of the gums and their receding, loss of appetite, metallic taste, and after a time abdominal pains. A blue line might occur from other causes—as *e.g.* bismuth given for ulcer in the stomach. Headache, extremely severe, was another symptom of lead poisoning, in addition to which blindness was apt to occur, and it was most difficult for one thus suffering to recover sight. Lead seemed to affect the brain and had direct action on the retina. Many women workers had been blind for twenty years. Other symptoms were wrist-drop and paralysis. In Hungary the worst cases could be seen, for in that country the workers lived and slept where they did their work and many children showed plumbism of the brain type and died of convulsions and coma.

As regards the prevention and treatment Sir Thomas urged the closest attention to the Home Office regulations, which were superior to those of most countries. He then described the electrolytic method by which it is attempted to eliminate lead from the system, and Mr. Clegg, who had been working with him on this method, then gave a demonstration of the apparatus with which he had removed salt from his own body. The last plan was to have two baths, one for the feet and one for the arms, thus securing a controllable current that can be borne by the patient. Experiments carried on for three years on a rabbit which had been paralyzed by lead given in its food was successful, the paralysis being cured and lead found in the bath. In the same way workers suffering from plumbism had been cured. Sir Thomas held that whether the lead was all removed or not the treatment deserved further trial for under it the anemia disappeared, the muscular power returned, and it gave a tremendous stimulus to nutrition. Further, the workers were able to continue employment and earn their living—so saving immense sums for compensation.

Dr. H. Warren Crowe brought before the Pathological Section (R. S. M.) on the 18th inst., his investigations into the etiology of rheumatoid arthritis. Further research has confirmed the result he had previously obtained as the organism which he was led to regard as the primary cause of the disease. It is similar in appearance to the pyogenic staphylococcus, but may be distinguished in the growth on a medium of egg slightly tinted with neutral red. The pyogenic staphylococci produce rose-red colonies which turn to vivid orange, but the other organism's colonies remain rose-red or only become paler; both produce indentation of the medium: the color and indentation being diagnostic.

Dr. Crowe's paper considered the questions whether his organism was causal or casual and in what group of germs it should be classed. Previously he called it staphyloidcoccus A. Now as the result of further work he regards it as pathognomonic of rheumatoid arthritis and gives it the name *M. deformans*. It seems to be a variety of the *M. epidermidis*, the only difference being that it liquefies gelatin at a slower rate. Now as to the evidence of its causal influence, the complement fixation reaction was employed not only by the author but by Fleet-Surgeon Kilroy, who performed independent tests without knowledge of the sources of the sera—a service for which Dr. Crowe expressed his very deep gratitude. Surgeon Kilroy's extensive experience with this testing in the Wassermann reaction must be familiar to your readers. In 26 cases of rheumatoid the organism was found in all, cultured in 22 of them and demonstrated by positive complement reaction in the other 4. In 14 doubtful cases it was found in 11, being cultured from 9. Adding to these cases of neuritis, which many consider so closely related if not identical, the total number is 48, the incidence 45, *i.e.* 93.75 per cent. Besides Dr. Crowe's organism streptococci were present in 21 of the cases and *B. coli* in 7. But it must be added that it occurs in other diseases, Dr. Crowe having himself found it in mild septicemia, in rheumatism, and in neurasthenia. Agglutination tests did not prove so decisive, but the evidence was considered satisfactory, as far as it went. Opsonic data were also corroborative of the speaker's theory.

Dr. Crowe related how he discovered the organism; three years ago he first saw it in the blood of a phthisical woman of 34 who suddenly developed acute arthritis in one knee with brachial neuritis and who for three years previously had had a temperature of about 101° F. Treated by a vaccine from the organism the knee joint got well, the neuritis disappeared and the temperature became normal. A year later the same organism was found in the urine of two women with acute rheumatoid arthritis and a vaccine was followed by the same result. Next he saw his *M. deformans* in the urine of a male rheumatoid patient, who also had a chronic nasal discharge and in him a vaccine was effectual. These four cases, hitherto unpublished, set him to work on systematic investigation, choosing the urine as *materies morbi* with the result stated above—a germ incidence of 93.75 per cent. in all cases, obvious or suspected. Regarding rheumatism proper (by no means confusing it with rheumatoid arthritis), as caused by the streptococci found in the urine so constantly but producing no kidney disease, he assumed them to be circulating in the blood and they are also common inhabitants of the digestive tract. But though innocent they may acquire virulence for they have been isolated from the blood in acute rheumatism. If then a common saprophyte of the bowel on gaining access to the blood produces rheumatism, Dr. Crowe offers the parallel that his *Micrococcus deformans*, belonging to the epidermic group, a common saprophyte of the skin, reaching the blood becomes the cause of rheumatoid arthritis.

An "at home" was held on Wednesday at St. James' Theater by Sir G. and Lady Alexander in aid of the League of Mercy, an auxiliary of King Edward's Hospital Fund, which has contributed in its thirteen years' existence nearly £200,000. Sir G. and Lady Alexander are presidents of a district which has raised £11,000 in the last three years. Several hundred guests were invited to the at home. Lord Willoughby de Broke presided and remarked that such a magnificent meeting showed the voluntary system was not dead whatever government might do. He would regret if a mechanical, inanimate set of state hospitals took its place and thanked the host and hostess for organizing this meeting. Mrs. Mateo Clark, in appealing for workers and also subscriptions, suggested that the dead should pay for the living by the government subsidizing the fund out of the death duties.

On November 10 a total of 2,230 insured persons were being treated under the act—841 of them in sanatoria or other institutions. Of course the numbers treated outside were enormous. Allegations of malingering were made and the committee appointed six part-time referees to examine, who have reported on 208 cases that 167 were incapable of working. Of those capable 30 per cent. had been certified for debility, anemia, weakness, etc., and 15 per cent. for rheumatism and dyspepsia. Of the capables it is said not many were malingerers in the ordinary sense, but from lack of nourishment are in a state of invalidism or inertia and cannot be certified as fit although they cannot equally be certified as incapable. The few cases of obvious malingering were generally in receipt of low wages. The report adds that apart from invalidism or malingering the period of incapacity is often prolonged by neglect of the patients, especially those with hernia, ulcer, varix, rheumatism, and dyspepsia. Fourteen complaints made against the panel doctors were investigated by the Medical Service Sub-Committee, who reported that one was "technically substantiated" from maintenance as to receipt of a message, one committed an error of judgment, one refused to visit an insured person and is severely criticized and the patient transferred to another practitioner, one was not in a fit state to provide adequate treatment and is no longer on the panel. In the other cases the complaints were not substantiated.

The General Medical Council has been sitting during the week. Sir Donald Macalister was prevented by illness from taking his place as president. Accordingly the treasurer, Mr. Tomes, presided. Prof. G. Elliot Smith took his seat as representative of the Victoria University as successor of Prof. Lorrain Smith, who had resigned.

Dr. Clement Godson, consulting physician to the City Lying-in Hospital, vice-president of the League of Mercy, and late president of the Gynecological Society, died on November 26. Born in 1845 he graduated at Aberdeen and took the M.R.C.P. in 1874. He served for a time as assistant obstetric physician at St. Bartholomew's Hospital and was physician to several hospitals and charities. He was a colonel of the R.A.M.C. (territorial force) and commanding officer of the Second City of London General Hospital of the same force. He was Knight of Grace of the Order of St. John of Jerusalem. He had been examiner in obstetrics at the universities of Aberdeen and of Durham. He contributed to St. Bartholomew's Hospital Reports, Quain's Dictionary, and the Transactions of the Obstetrical Society on Gynecological Subjects. In his presidential address to the Gynecological Society (1895) he discussed the "Evolution of Obstetrics and Gynecology."

OUR PARIS LETTER.

(From Our Regular Correspondent.)

THE TRANSFUSION OF BLOOD—ITS EFFECT ON HEMOPOIESIS—COLITIS IN THE ADULT; ITS SURGICAL TREATMENT—THE ADVANTAGE OF APPENDICOSTOMY—THE VACCINE TREATMENT OF WHOOPING COUGH — GONORRHEAL SPERMATOCYSTITIS — THE DEATH OF PROFESSOR COYNE.

PARIS, October 15, 1913.

THE transfusion of blood, which for many years has been relegated to obscurity despite the efforts of Professor Dieulafoy, has again come into favor. Carrel has shown that normal salt solution cannot replace blood to a satisfactory degree. The intravenous injection of blood does not act merely by virtue of the mass of the latter; it is really a corpuscular graft which acts upon hemopoiesis. Professor Legnou recently devoted one of his clinics to show the benefits that one may derive from transfusion. A case reported by Robineau before the Surgical Society July 28, 1913, is particularly interesting. The case was one of severe anemia consequent upon hemorrhoidal bleedings, in which case normal salt solution and horse's serum stopped the hemorrhages without improving the general condition. The patient got progressively worse. Robineau resorted to transfusion. The operation lasted 13 minutes. The patient's color rapidly improved and he felt better. One hour and a half after the transfusion the erythrocyte count rose from 1,115,000 to 2,480,000. Then during the next eight days the count fell to 1,800,000. On the eighth day there then occurred a sudden improvement that gave the impression of a true resurrection. The erythrocytes rose to 2,000,000, then to 2,600,000, and then to 3,800,000. There was therefore an initial phase of hemolysis, then a period of intense activity in the formation of red blood cells. The hemoglobin percentage underwent similar changes. From 25 per cent. before the operation, it rose during the transfusion to 40, 50, and then to 60 per cent. During the following few days it fell to 50 per cent., but finally rose again to 60 per cent. It seemed as if the transfusion had restored to the patient the hemopoietic power which he had lost. The method is therefore to be regarded as a heroic one in the treatment of anemia resulting from repeated hemorrhages.

In a series of articles in the *Gazette des Hôpitaux*, July, 1913, Mathieu publishes the results of his observations on the severe forms of colitis in the adult. Usually the reverse of what are observed in childhood, the local phenomena, tenesmus, bloody stools, and hemorrhages are more pronounced than, and predominate over, the symptoms of a general toxemia. The symptoms may be grave from the outset and may threaten a fatal outcome, or there may result a chronic ulcerative colitis more or less pronounced. A most detailed clinical examination is necessary in order that one may make a differential diagnosis of this condition from paratyphoid infection, cancer of the rectum or of the sigmoid and rectum, tuberculosis of the rectum, syphilis of the rectum and sigmoid, or simple ulcer of the rectum. Bacteriological examination may enable one to diagnose a bacillary or an amebic colitis, but in a large number of cases rectoscopy yields the best results. It shows in the most recent cases a red, swollen mucosa, particularly in the region of the rectal valves whose thickened edges present a marked contrast to their usual sharp border. In the old cases one notes the smooth, dry surface of the mucosa. This is red and friable and no mucus is present. These are the signs of a pronounced atrophy and of irreparable lesions. In cases that have lasted a number of months the lesions may be quite superficial; there may be a diffuse redness and a friability of the mucosa. In these cases the clinical signs afford no criterion as to the gravity of the disease, and the rectoscope alone is of value in the diagnosis and treatment.

The treatment is medical and if this fails, surgical measures must be resorted to. In the medical treatment Mathieu favors the use of irrigations of nitrate of silver in the strength of 0.2 to 0.30 gms. per liter. The rectoscope is useful in permitting a direct application to the accessible ulcerations. A milk and cereal diet should be given. The surgical treatment has the following double aim: (1) To set the colon at rest and to prevent it from becoming the seat of putrefactive changes and of the development of anaerobic cultures; and (2) to enable one to institute lavage from above. Of the various surgical measures proposed—colostomy, ileosigmoidostomy, and appendicostomy—Mathieu favors the last. It meets the indication in every case, offers no difficulty, gives rise to a minimum of discharge, and enables one to carry out lavage of the entire colon from above downward. The slight accompanying inconvenience enables one to maintain indefinitely the appendicular opening. The credit for this operation belongs to Robert F. Weir of New York. It represents a distinct step in the treatment of colitis and should be resorted to more frequently than it has been.

Since the discovery in 1906 of the pertussis bacillus by Bordet and Gengou different forms of specific treatment have been attempted without yielding any absolutely reliable result. C. Nicolle and I. Conor have just communicated to the Academy of Science the result of their new investigation on this subject. In the course of an epidemic in Tunis they injected under the skin of children suffering from pertussis 1 to 5 drops of an emulsion of the bacilli, representing 1,000,000 to 5,000,000 microorganisms. These were obtained from 48-hour cultures, washed in normal salt solution, and heated to 46° C. for one-half hour, which did not affect their vitality. The inoculations were repeated every two or three days. On an average two to five injections were sufficient. They were well borne and produced no reaction. The experiments were made on 104 children. Thirty-five per cent. were cured, 38 per cent. were improved, and 26 per cent. received no benefit from the treatment. Noteworthy was the fact that the cases in which the diagnosis of whooping cough was incontestable included the largest number of cures. On the other hand, the doubtful cases included the largest number in which only an improvement or no improvement at all was noted. It was only at the end of the second week of the disease that the vaccine treatment began to be of any value. This fact and time necessary for the treatment to be carried out limits the practical value of this method of treatment.

Georges Luys in *La Clinique*, August 22, 1913, describes in great detail the symptoms of gonorrheal spermatocystitis, a frequent and, as yet, little known complication of gonorrhea, and the one that lies at the basis of many of the rebellious cases of this disease. Frequently the fundamental condition, because of its latency, eludes the observation of the practitioner. In other instances it may pre-

sent one of the following symptoms: increased frequency of micturition; constant perineal and prostatic pains, independent of urination; frequent seminal emissions or more or less pronounced impotence, and painful or retarded ejaculations. In some cases blood ejaculation, or recurrent attacks of epididymitis, furnish a valuable clue to the diagnosis. The urine may be clear but most frequently contains long shreds, principally in the first and last glasses. Methodical examination alone permits one to make an exact diagnosis of this condition. (1) Rectal palpation should be performed with the patient standing, his legs outstretched and his trunk inclined forward. The examining finger introduced deeply and above the cornua of the prostate will detect the changes in the consistency of the seminal vesicles—their induration, etc., and will occasion the expulsion from the urethra of vesicular molds. Sharp pain will be elicited at two points: at the region of the diseased vesicle, and between the two prostatic lobes, in the region of the verumontanum. (2) The olivary-tipped explorer elicits a sharp pain on passing the verumontanum. Occasionally it is arrested by spasm. (3) After dilatation of the urethra the urethroscope shows an enlarged verumontanum, which may be inflamed and polypoid, and mirrors the condition of the seminal vesicle. The surgical methods of treatment: vesiculotomy, vesiculectomy, and vasotomy are in most cases ineffectual. It is necessary to treat methodically the vesiculitis itself: (1) By means of proper and prolonged massage, carried out for a large number of sittings. (2) By means of dilatation of the ejaculatory orifice by direct urethroscopic medication. (3) By means of catheterism of the ejaculatory duct, which as the result of an inflammatory stenosis prevents the vesicular contents from being expelled.

Professor Coyne of Bordeaux has just died at the age of 71. He rounded out a life that was devoted to science. A pupil of Vulpian and of Leon Labbé, he had been an assistant in the clinic at Paris, and then chief of the laboratory in the Charity Hospital. In 1876 he left Paris to teach pathological anatomy and histology at Lille. Two years later he became professor of pathology at Bordeaux and for the next 34 years his life was dedicated to the laboratory and to teaching. He wrote important works on normal and pathological histology. His doctorate thesis on "The Structure of the Laryngeal Mucosa" is to this day an authoritative work; and this is likewise true of his treatise on the "Benign Tumors of the Breast" which he wrote in collaboration with Leon Labbé. His numerous investigations on the structure of the internal ear led to the discovery of the accessory ganglion of the auditory nerve which has since been described by the textbooks under the name the "ganglion of Coyne." In pathological anatomy one may cite among others his writings on pulmonary syphilis, the adenoid growths of the palatal vault, and the mixed tumors of the salivary glands. He collected his lectures as given at Bordeaux in a "Treatise on Pathological Anatomy." The first edition of this important work appeared in 1894. Professor Coyne's career was an inspiration in its devotion to science.

Tuberculin Therapy.—H. Aronson notes that in the tuberculin treatment of human beings immunizing reactions are not produced. The good effects of tuberculin depend upon the stimulation which this substance exercises upon the white blood cells.—*Archiv für Kinderheilkunde.*

1. The Nervous Irritability of Chronic Nephritis.—W. H. Robey reports a series of cases illustrating the fact that pronounced nervous symptoms may constitute the earliest manifestations of chronic renal disease. When a man forty or fifty years of age who has been active and successful in business begins to complain of headache, to be nervous and irritable, or to have any other change in disposition, thorough and repeated examinations of his heart, blood-vessels, blood-pressure, and twenty-four-hour urine are imperative. It should be borne in mind that the toxemia of chronic disease of the kidney may exert an influence upon the nervous system either as a very early sign or one occurring after the renal condition has become fairly advanced. In the toxemia of bacterial infections analogous manifestations may be noted. The pneumococcus may invade the body in a variety of ways. In acute articular rheumatism the earliest manifestation may be in the nervous system; later the skin, joints, or serous cavities may be involved. When middle-aged individuals show signs of nervousness, or a change in disposition, such as irritability and nervousness, the heart, blood-vessels and kidneys should be thoroughly and repeatedly examined.

2. Promoting the Efficiency of Out-Patient Departments.—M. M. Davis and E. W. Barron refer to the fact that a large proportion of the patients that attend the dispensary do not return for treatment. This seriously limits the efficiency of the dispensary. At the Boston Dispensary a plan has been adopted by which a close watch is kept of the return of patients. This watch is facilitated by the use of a visible index, in which the patient's record card is posted under the date on which he is expected to return. If the patient does not return a postal card is sent to him requesting him to return on a definite date. If two postal cards are sent without response, the case may either be dropped or referred to the Social Service Department for investigation.

5 Uses of Digitalis.—W. R. Steiner quotes Hirschfelder in the statement that digitalis should be given for dilatation of the ventricles and for fibrillation of the auricles. In valvular disease the drug is required only in broken compensation. In subacute and chronic cases of heart disease its use is often accompanied by brilliant effects, though some instances of mitral stenosis prove refractory to it. In aortic lesions, contrary to the teachings extant since the time of Corrigan, digitalis is not contraindicated, but in prolonged use strengthens the heart by increasing the tonicity. Bradycardia or arrhythmia, however, should be carefully looked for in these cases, as its presence indicates cumulative effects. In juvenile or respiratory arrhythmia, digitalis is contraindicated if the heart is not dilated, but in heart block, or atrioventricular allorhythmia, it should be employed if the block is complete, as Bachman and Hewlett and Barringer have shown that digitalis increases the automaticity of the ventricles. The drug, however, should be used with caution. In extra-systole it should be given, if this condition is accompanied by dilatation, on account of the effect upon the latter, and also in pulsus alternans, as digitalis increases the force of contractions, which is weakened in this type of

arrhythmia. In the remaining variety of irregularity—auricular fibrillation—the action of digitalis is magical by virtue of the slowing of the ventricular rate from an inhibitory effect upon the fibrillating auricles or from a depressing action upon the conduction of impulses from the auricles to the ventricles, through the atrioventricular bundle or muscle of His. The best effect of digitalis is seen when the pulse is rendered quite slow, that is between 50 and 60, for which purpose large doses may be necessary for a considerable period of time. Windle, for instance, estimates that five to eight drams of the tincture may have to be given in fifteen minim doses for about ten days before the maximal slowing is noted. If, however, still larger doses are given, the same result can be accomplished in two or three days. In acute intoxications either from acute infectious diseases or from the action of poisons or from acute fatty degenerations from other causes, digitalis is distinctly contraindicated. In partial heart block, also, it should not be used, because it is likely to bring on complete block suddenly and with it there is danger of an attack of the Adams-Stokes syndrome.

2. Oil-Ether Anesthesia.—J. T. Gwathmey states that oil-ether colonic anesthesia is an evolution from intravenous anesthesia. The advantages claimed for this method of anesthesia over other methods are: (1) The element of apprehension and fear caused by placing a mask over the face in inhalation anesthesia is avoided. (2) No expensive apparatus is required. (3) The after effects of the anesthetic are reduced to a minimum. (4) A more complete relaxation is secured than with any other known method of administration. (5) The limits of safety are widely extended, compared with other methods. (6) A more even plane of surgical anesthesia is automatically maintained than is possible by any inhalation method—unless administered by a skilled anesthetist using a perfected apparatus. The technique of the oil-ether rectal anesthesia is as follows: the mixture (two ounces of olive oil and six ounces of ether) is given with the patient in bed on the left side, in the Sims' position, a convenient lifter having previously been placed under him. It is not always necessary that he should know that an anesthetic is being administered. A small catheter, well lubricated, is then inserted three to four inches within the rectum; to this catheter a funnel is attached. The mixture should be poured slowly into the funnel, at least five minutes being consumed in administering eight ounces, the usual amount required. It is best not to withdraw the tube immediately, but to wait until the patient is partly unconscious and the muscles are relaxed. From five to twenty minutes (according to the percentage used) should be allowed for the anesthetic to take effect, before the patient is moved. The patient should then be lifted gently on a stretcher and carried to the operating room. The anesthetist at this time should see that a clear airway is maintained when necessary, by placing a finger under the symphysis of the lower jaw. If the patient shows signs of approaching cyanosis, loss of lid reflex, stertor, or embarrassed respiration of any kind, two or three ounces of the mixture should be withdrawn by the small rectal tube already mentioned, placed four to six inches up the rectum. If the breathing is easy and regular, with the reflexes active, the patient will be found to be relaxed and in surgical narcosis as far as the operation is concerned. At the end of the operation, the two small rectal tubes already mentioned should be placed in position, as high up the colon as convenient without traumatism, and cold water soapsuds should be injected into one tube and drawn off through the other; two to four ounces of olive oil should then be introduced into the rectum and the tubes withdrawn. The patient should be gently returned to bed, with as little jolting or handling as possible, the room should be darkened, and free ventilation should be secured.

6. Hyperthyroidism and the Nervous System.—A. C. Buckley notes that by far the majority of patients suffering from hyperthyroidism present mental symptoms in some degree. In fact, mental symptoms may be the earliest noted, that is before the cardiac or ocular symptoms become manifest. The most commonly noted are an intense and indefinite agitation with more or less mental and motor restlessness. The patient is unable to settle down to any occupation, and complains of being distressed by any sudden noise, or unexpected news, this being accompanied by a palpitation that may last for several hours. Other patients suffer with marked excitement, restlessness, sleeplessness, hallucinations, incoherence, violence, refusal of food, dirty habits, emaciation, diarrhea, and exhaustion which may terminate fatally. In 1883 Savage reported several cases of insanity with Graves' disease, with the conclusion that when insanity is associated with exophthalmic goiter the prognosis as to life is very grave.

7. High Frequency Cauterization in Treatment of Urethral Caruncle.—S. Wiener describes the technique of this procedure as follows: The caruncle and contiguous mucosa are anesthetized by the surface application of a five per cent. cocaine solution. An ordinary insulated wire electrode is used with a spark of medium intensity. The tip of the electrode is held about one-eighth of an inch from the surface of the growth, and the spark is passed successively over every part of this surface. The normal mucosa should be avoided. The entire application need not take longer than one minute. No pain whatsoever is experienced by the patient provided the cocaine has had sufficient time to act. There is no reaction after the effects of the cocaine have worn off; in fact, where dysuria and tenesmus are present, the very first urination following the treatment is less painful than those preceding it. Only very small caruncles can be destroyed at a single sitting. Usually two or three applications will be necessary. These should be made at intervals of five or six days. In one case, of the flat angiomatous type, involving almost half the circumference of the meatus and extending a considerable distance upward along the posterior urethral wall, the growth was made wholly to disappear in three treatments.

11. Genital Tuberculosis in Children.—O. Lyons believes that primary tuberculosis may occur in the male generative organs, but is rare compared with secondary infection. Primary tuberculosis in the seminal vesicles and prostate is a rare occurrence. The frequent localization of the tuberculous lesions in parts of the body not readily exposed to external infection must be regarded as congenital. The entrance of the tubercle bacilli through the urethra is very rare and the history of tuberculosis in childhood is generally against any exclusive port of entry. The onset may be sudden or gradual and when confined to the genital organs may give rise to no symptoms calling attention to it. A discoloration or swelling is perhaps the first symptom. Acute tuberculosis of the epididymis or testes is rare and begins suddenly with acute symptoms. It has probably been preceded in some cases by preexisting tuberculous nodules that were unnoticed.

In the differential diagnosis, congenital syphilitic orchitis is the most common and the most difficult disease to exclude. The chief aids are the other signs of congenital syphilis and the therapeutic test. Sarcoma is the next most frequent disease, but can usually be recognized; clinically the treatment would be the same. Hydrocele usually presents no difficulties, but should be remembered as it is often a symptom of tuberculosis. Benign tumors are so rare they need little consideration. The prognosis of primary tuberculosis of the genitals in children is usually favorable and it is important to know that tuberculosis of these organs remains almost always the only tuberculous focus in the body, differing in this respect from that in adults. Operation, therefore, may produce permanent cure though this is not certain. It should always be advised.

1. **Shock.**—By G. W. Crile. (See MEDICAL RECORD, June 28, 1913, page 170.)

2. **Certified Milk.**—By T. C. McCleave. (See MEDICAL RECORD, June 28, 1913, page 1193.)

4. **Pathology of the Prostate.**—E. O. Smith concludes that the prostate gland has five distinct glandular areas, which may be termed lobes. Pathological changes in the seminal vesicles are often overlooked and the prostate alone considered, when in fact both are involved. Tuberculosis of the prostate is seldom found without the same infection of seminal vesicles. Prostatic hypertrophy is usually a simple adenomatous growth which crowds the normal prostate, so as to form a surgical capsule. In the roof or anterior portion of the prostatic urethra these new growths are covered with but little more than mucous membrane. Malignancy of prostate is confined to the posterior lobe.

7. **Systemic Blastomycosis.**—R. T. Morris reports a case of this condition. The patient was a medical man and the infection seemed to have originated in Texas or in Chicago. He was operated on for liver abscess in a London hospital and came back to this country. The diagnosis of liver abscess was still made and further operations did not relieve the general condition. Superficial abscesses appeared elsewhere, containing thin yellowish or brownish pus. A culture of blastomyces from one of these abscesses definitely established the diagnosis of systemic blastomycosis. Potassium iodide was given but was ineffective as was also neosalvarsan injected intravenously. Vaccines were being prepared for trial but before they were completed the patient died. The author remarks that systemic blastomycosis is probably not so very rare but that the diagnosis is not often made.

9. **Intraabdominal Complications Following Laparotomy.**—A. E. Benjamin points out that postoperative intraabdominal pain is usually due to some interference with the function of the alimentary canal from inflammation of the peritoneum, adhesions, kinks, or obstructions. It is essential to determine whether the function of the stomach or intestines is interfered with. In cases of mucous colitis thorough irrigation of the colon, either in the knee-chest position, the elevated hip position, and the right-sided flank position materially lessens the intraabdominal postoperative distress. This is especially the case with a membranous pericolitis in which the operator has been obliged to separate bands of adhesions or liberate the ascending colon from an adhering transverse colon. These constitute the majority of cases which give the operator later trouble and postoperative adhesions are increased if the surgery is incomplete. The state of the muscle tone of the abdominal wall is also a factor of later trouble and it should be built up as far as possible before operation and supports should be used afterward, the tonic treatment being continued. As long as there is any infection in the abdomen and there is destruction of endothelial cells adhesions will follow. It is especially important to leave no raw surfaces or denuded areas within the abdomen, and such should be covered by peritoneum or detached omental grafts as far as possible. When the actual cautery can be used on a denuded surface adhesions are less likely to occur, because when the scab separates there is usually a healthy membrane left. The author objects to leaving the stump of the appendix loose in the abdomen and to the use of non-absorbable sutures. Operative traumatism which is likely to occur in most operations and undue exposure of the viscera are also causes of later trouble. To avoid any possibility of leaving any foreign substances in the abdomen only large pads should be used for sponging it and three-yard wet rollers of gauze used to cofferdam the field of operation. As regards drainage, the author would drain for perhaps forty-eight hours if there was a large amount of bloody exudate in the abdomen. Gauze drainage is seldom if ever indicated. Adhesions of the omentum and intestine to the suture line used in closing the peritoneal opening are far too frequent. Operators often overlook the presence of the fascia layer back of the recti in closing median incisions. In the postoperative management one of the first factors in causing intraabdominal tension is acute gastric dilatation.

Generalized Emphysema in Childhood.—Lucien Rivet reports two cases of this condition. The first was that of an infant seven and a half months old in whom an acute generalized interstitial emphysema complicated a bronchopneumonia. Death occurred. The second case was that of a four-year-old child in whom rupture of pulmonary alveoli occurred in the course of a severe bronchitis and laryngitis. The resulting emphysema involved the subcutaneous region of the upper part of the thorax and the base of the neck. The emphysema disappeared in eight days. In the treatment of this condition the author notes that compression of the affected area, and minute puncture of the skin with aspiration of the air have been advocated. But these procedures are associated with a risk of infection. The best measure is to limit the extension of the emphysema by allaying the cough and the dyspnea with hot formentations applied to the thorax, with inbalations of oxygen, and respiratory sedatives. In severe cases of interstitial emphysema in which the swelling is so excessive that there is a risk of sudden death, the author advises that puncture of the skin may be cautiously attempted.—*Gazette des Hôpitaux.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE IMPORTANCE AND DETECTION OF TEMPORARY GLYCOSURIA.

Individuals afflicted with diabetes recognize the futility of applying for life insurance and very seldom present themselves for examination. Alimentary or temporary glycosuria is the form commonly encountered by examiners, and it happens that this class of cases often creates more or less perplexity and concern as to how often the sugar is present.

It is accepted by practically all companies that the frequent recurrence of glycosuria is a decidedly unfavorable sign, and the fact that an applicant is affected in this way should be known whenever possible. This feeling is engendered by an experience which shows an excessive mortality among insured lives with a history of repeated glycosuria. Death in these cases is usually due to intercurrent diseases which the patients are apparently unable to resist through lack of vitality. Actual diabetes plays a considerably smaller rôle as the cause of death.

It would seem that a healthy man's capacity for the proper assimilation of carbohydrate food has certain limits, and that the digestion of large or even moderate amounts of these articles of diet sometimes becomes too great a task in certain individuals, one of the results of which is the presence of sugar in the urine. The conditions under which this physiological capacity is diminished are not understood except that they are apt to be associated with certain disturbances or abnormalities, such as gout, the liberal use of alcoholics, obesity, etc., and, furthermore, they may eventually evolve into true diabetes. In other cases this capacity may be lessened temporarily in an apparently healthy individual from some trivial reason. While the task is often difficult, an effort must be made to distinguish one set of cases from the other, for it may safely be assumed that those persons coming in the first class and who cannot tolerate certain ordinary articles of food or drink without the frequent production of sugar in the urine are uninsurable.

The following procedures have been suggested for the purpose of ascertaining whether the assimilating forces of a certain subject are competent to dispose of carbohydrates in the regular way.

1. The examination of several specimens of urine. They should not be obtained at the same hour on the different days. The specimens should be voided about one and a half to two hours after meals. The best plan is to obtain these samples on three successive days, the first one after breakfast, the second after lunch, and the third after the evening meal. The applicant should not be informed of the time of day when the urine is to be called for unless it is positively necessary to make an appointment.

2. A statement should be signed by the applicant to the effect that he has or has not been under treatment or on a restricted diet for any urinary disturbance during the past year. One has to add with regret that this statement is not always a true one, and that if the applicant is willing to conceal the fact that he has had glycosuria, he is usually ready to sign a false statement.

3. The administration of a test dose of from 100 to 200 grams of glucose, the urine to be examined one hour and again in four hours after giving the glucose. This plan is emphatically condemned. That it is misleading has been proved by persons who have tested themselves in this way after having found their urine to be negative by repeated analyses previously; a marked glycosuria was produced in many of these experiments.

4. The most satisfactory method in suspected cases of recurrent glycosuria is to induce the applicant to partake of a test meal with a medical representative of the company. The meal should be composed of a generous quantity of carbohydrate food, starches and sugar, including fruits and a glass of sweet wine; in other words, of good ordinary food. The writer has been recently interested in the administration of these test meals in twelve cases with a history of recurring glycosuria, the subjects having denied treatment and restricted diet in signed statements and having furnished normal urine at the time of the examination. The applicants were persuaded in a courteous way that could give no offense to submit to the meals. A decided reaction for glucose was obtained in urine procured one and a half to two hours after the meal in ten out of the twelve cases. The urine was again examined four hours after, and sugar was still present in four of the specimens.

The Insurance of Defective Individuals.—Feilchenfeld evidently does not refer to what we term substandard risks, although at times his defectives amount to the same thing. Naturally all defectives are substandard risks. He begins with the effects of infantile diseases, such as rachitis, which sometimes increases the risk. Scrofula in childhood, however, is not necessarily a menace in adult life. A history of convulsions, seemingly outgrown, the patient's stock having been sound, although the fits point to epilepsy or hysteria, does not necessarily mean a defective adult. A history of acute infectious diseases of childhood does *not* increase the risk, provided no pernicious sequelæ have developed. Diseases gone through in later life have more significance, for typhoid, erysipelas, pneumonia, etc., have on one hand a tendency to leave serious sequelæ or—as in the case of erysipelas—to recur indefinitely. Pleurisy is a malady of interest in this connection, as the serous form is more unfavorable for after years than the purulent if the latter is properly treated. The author no doubt refers to frequency of tuberculosis as a sequela of simple pleurisy, but he only mentions hemoptysis. Acute articular rheumatism naturally has a number of complications which may prejudice the risk, and malaria is equally notorious in this respect. The author now discusses other forms of defectiveness. Emaciation and obesity both increase the risk. Emaciation, however, means nothing if a family trait, or trained athletes, or those forced by their labors to perspire constantly, or those on low caloric diet. Obesity always involves defectiveness, in regard to a tendency to arterial disease, cardiac, and renal disease. Statistics show that slight glycosuria in childhood shows no tendency to shorten life. Of especial significance is the prognosis in functional albuminuria; this is good if the urine lies between 1016-1025; albumin minimal; absence of all formed elements except an occasional hyaline cast; absence of indican; occasional disappearance of albumin at times. These people may be insured for ten to fifteen years.—*Blätter für Vertrauensärzte der Lebensversicherung, May-June,* 1913.

Book Reviews.

Early Pulmonary Tuberculosis; Diagnosis, Prognosis, and Treatment. By John B. Hawes, 2nd M.D.; with Preface by Richard C. Cabot, M.D.; 114 pp. Price $1.50 net. New York: William Wood & Co., 1913.

This is a small volume but it contains much that is good for the man in general practice and the student who desires to specialize in tuberculosis. Chapter I gives the "Classification of Patients," adopted by the National Association for the Study and Prevention of Tuberculosis and in the subsequent chapters the history, signs, and symptoms are dealt with. The author devotes considerable space to discussing the best method of physical examination. The various tuberculin tests are reviewed and it is refreshing to see again a warning against the instillation of tuberculin in the eye. He very categorically says "Practitioners are advised not to use this method." The chapter on differential diagnosis, which the author calls conditions which may simulate tuberculosis, is rather brief and to be of real value needs elaboration. The chapters on prognosis and treatment form an excellent review of our present knowledge of these subjects. The rest of the book contains some interesting illustrations of cases with *x*-ray photographs. Appendix "E" is a reprint of Dr. Carrington's directory for living and sleeping in the open air with illustrations of porches, window tents, reclining chairs, etc. All in all, the book is what Dr. Cabot calls it in his preface "small yet authoritative." Print and illustrations are excellent and the division in sub-chapters makes it a very practical volume for the busy man.

Die Korperliche Erziehung des Kindes. Von Prof. Dr. Hans Spitzy, Wien. Mit 104 Textabbildungen. Berlin and Vienna: Urban & Schwarzenberg; New York: Rebman Company. 1914.

This book deals with every phase of the physical development of the child from earliest infancy. The transformations occurring in the bodily structure during the early months of life, the nutritional requirements at this period, the development of standing and of locomotion, and the growth of individual groups of organs are all fully and tersely described. The child during the years preceding the school age presents important problems in physical development which are not overlooked in this book. The author next discusses the school child and the numerous questions of school hygiene, such as fatigue, the school seat, and the influence of the school upon the development of the child. The future of school children's physical culture in the schools, postural exercises, are next discussed in detail. Gymnastics, games, summer and winter sports, the training of teachers of physical culture, orthopedic gymnastics, the physical training of the feeble-minded, the school physician, puberty and the school, are all topics that are fully discussed by one whose knowledge of his subject is both sympathetic and profound. The book is profusely illustrated. It cannot fail to be of value to the general practitioner, the pediatrist, the orthopedic surgeon, and the school physician.

Burdett's Hospitals and Charities. Being the Year Book of Philanthropy and the Hospital Annual. Containing a review of the position and requirements, and chapters on the management, revenue, and cost of the charities, an exhaustive record of hospital work for the year. It will also be found to be the most useful and reliable guide to British, American and Colonial hospitals and asylums, medical schools and colleges, nursing and convalescent institutions, consumption sanatoria, religious and benevolent institutions and dispensaries. By Sir Henry Burdett, K.C.B., K.C.V.O., London: The Scientific Press, Ltd., 1913.

This, the twenty-fourth year of publication of Burdett's "Hospitals and Charities," sees this work brought thoroughly up to date. More than six thousand institutions are therein dealt with and information of great value concerning each of them is given in succinct form. Perhaps the most notable feature of this edition is the chapter devoted to British hospitals in their relation to the Insurance Act, and it is significant to read the statement "that the overwhelming majority of opinion among all classes in Great Britain is that the voluntary system of hospitals must be maintained and extended upon wise lines."

This very useful book has a niche of its own and no higher praise can be given to the present edition than to say that it is an improvement upon former editions.

Manual of Operative Surgery. By John Fairbairn Binnie (Aberdeen), Surgeon to the General Hospital, Kansas City, Mo.; Fellow of the American Surgical Association; Member de la Société Internationale de Chirurgie. Sixth Edition, Revised and Enlarged, with 1,438 Illustrations, a number of which are printed in colors. Price $7.00 net. Philadelphia: P. Blakiston's Son & Co., 1913.

Dr. Binnie, in the sixth edition of his well-known manual, has rewritten the chapters devoted to operations on the stomach, and paid particular attention to the anatomy of the gastrointestinal lymphatics. A new chapter has been inserted covering the treatment of tumors in general, one on the surgery of the upper lip and one on the excision of cervical ribs. Far more space has been given to such rare and difficult operations as hypophysectomy than to more ordinary surgical interventions, this having always been the writer's policy. There are 103 additional illustrations.

Lehrbuch der Haut- und Geschlechtsleiden, einschliesslich der Kosmetik. II Band, Lieferung 1 und 2, Geschlechtskrankheiten, von Sanitätsrat Dr. S. Jessner. Vierte sehr erweiterte Auflage mit zahlreichen abbildungen im text und auf 22 meist farbigen Tafeln. Price, Lieferung 1, 5 marks; Lieferung 2, 2 marks. Würzburg: Curt Kabitzsch, 1913.

This is the second volume of Jessner's work on Diseases of the Skin and Genitourinary Tract and is divided into two parts. The first deals with syphilis and its complications. After the usual introductory discussion of the spread of the disease, its prevention, sociological aspects, etc., chancroid receives passing attention. With true Teutonic love of order and wealth of detail, the author develops his subject in all its breadth, from the appearance of the initial lesion to hereditary manifestations. Under separate headings are described lesions of the skin and mucous membranes, circulatory, lymph, gastrointestinal, respiratory, genitourinary, and nervous systems. Syphilis of the liver, pancreas, peritoneum and the special organs of sense are accorded adequate consideration. The treatment described and advised is that of all modern syphilographers, the inunction method of administering mercury receiving preference.

Gonorrhea, its complications and sequelæ occupy the second portion. Here, the author is less successful. His text is full, complete, and well arranged but he adds little or nothing to the mass of scientific facts presented by previous writers. His has been the path hewn by Oberlaender and Kollman. The full page illustrations in color, mostly of syphilitic lesions are especially worthy of honorable mention. They accurately mirror Nature. The literary style is clear and concise and will be gratefully acceptable to such readers whose German is none too fluent.

Genitourinary Diagnosis and Therapy for Urologists and General Practitioners. By Dr. Ernst Portner, Specialist for Urology, Berlin, Germany. Translated and edited by Bransford Lewis, M.D., B.Sc., Professor of Genitourinary Surgery, Medical Department of St. Louis University, St. Louis; Genitourinary Surgeon to St. John's Hospital and Frisco Hospital; Member of American Urological Association; American Association of Genitourinary Surgeons; American Medical Association, etc. Forty-three illustrations. Price $2.50. St. Louis: C. V. Mosby Company, 1913.

The translator's preface says: "It embraces a wealth of practical, valuable information hardly credible." There is no denying the verity of this claim, but the deed is accomplished through the omission of many important directions and instructions in technique, together with a terseness permissible only in cablegrams. The author gives occasional advice which cannot pass unchallenged. He permits (page 15) "small quantities of red wine and light beer" to his acute gonorrheal patients. His methods of diagnosing urethral stricture (page 59) by means of a metal catheter number 20 is by no manner possible. The editor should receive thanks for interpolating the Kollman dilator in the paragraph on after treatment of stricture. The procedure described (page 70) for the puncture of prostatic abscess through the rectal wall is unsurgical and obsolete. After the instructions for self-catheterization (page 87) he writes: "Many patients live this 'catheter life' without serious discomfort for the rest of their days." How interesting it would be if the author had told us what period of time "the rest of their days" represents with his patients. The appendix consists of a chapter of excellence by A. Sophian of Kansas City on the serological diagnosis and specific (vaccine) treatment of gonococcic infections. The work does contain many excellent classifications, indications for and contraindications in surgical conditions.

Society Reports.

SOUTHERN MEDICAL ASSOCIATION.

Seventh Annual Meeting, Held at Lexington, Kentucky, November 17, 18, and 19, 1913.

THE PRESIDENT, DR. FRANK A. JONES OF MEMPHIS, TENNESSEE, IN THE CHAIR.

The South's Most Important Public Health Need.—DR. CRESSY L. WILBUR of Washington, D. C., urged the citizens of the South to stop at nothing short of success in their effort to establish a perfect system by which all deaths and births should be accurately reported. The records of births and deaths, interpreted in the light of progressive sanitary science, were not dry figures, dead and dusty mementoes of the past, but were living facts pregnant with a message of helpfulness and life-saving for the men, women and children of the present and future.

Vital Statistics.—Dr. OSCAR DOWLING of New Orleans read a paper in which he made the following recommendations: 1. Transmission by this committee to the legislature of each southern State, where needed, a petition for the consideration of (1) the adoption of the model law in full. (2) Appropriation of adequate funds to establish an effective system of collection, compilation, analysis and application of vital statistics data received. (3) Designation of a date for thirty minutes' discussion of reliable vital statistics, the basis of commercial sanitary and social progress in the South. (4) Personal effort by members of this committee to have modification of model laws, where they existed, brought more closely into conformity with the provisions. (5) Aid to popularization of payment of fees to every local registrar.

The Sanitary Milk Surveys in Kentucky.—Mr. R. M. ALLEN of Lexington, said Kentucky was the first state in the Union to abolish swill dairies. The pure milk work in that state saved consumers annually nearly a million dollars worth of water. There were only about 62 dairymen now in Kentucky who watered their milk, and they were all listed and closely watched. All of the dairies in Kentucky were listed on the score card and the work included bacteriological examination among the dairies to teach them what it meant and to show them how to protect their milk. Pasteurization was necessary for most of the milk going into the large cities. The ideal plan was to fill the baby's bottle direct from the bucket milked from a healthy cow in a clean stable. The cooled bottle could then be shipped anywhere.

Eugenics.—Dr. LEE A. STONE of Memphis defined eugenics as that science which taught all people how to best improve the races that were to come, and develop a higher state of mental and physical perfection among all peoples by teaching perfect breeding. Marriage, the blending of two souls together to make more perfect the future soul of one who was to be born, was the object that nature had in mind when she gave the world beings of opposite sex. When that time came in our civilization, when men and women before they married would carefully investigate all that might be known of the lives of each, with a view of reaching a perfect union, there would be born as the result of that union the perfect man. Then would the dreams of eugenists come true, and a finer and truer philosophy of life be born.

The Negro in Relation to Public Health.—Dr. C. E. TERRY of Jacksonville, Florida, reported that only a few southern States kept complete and reliable statistics in reference to the negro, and hence much of scientific value was lost. The high mortality rate among negroes from communicable and preventable diseases was a great menace to the general health of the South. Statistics showed that typhoid fever, malaria, measles, scarlet fever, whooping cough, diptheria, tuberculosis, and pneumonia were responsible for more than 40 per cent. of all deaths among negroes. These same diseases also were responsible for more than 26 per cent. of deaths among the whites. The high mortality rate among the whites was directly traceable to the prevalence of these diseases among the negroes. The necessity for raising health standards among the negroes and of inaugurating a campaign of prevention was imperative. Negro citizens lived under the worst sanitary conditions through poverty, racial inferiority, and neglect. But they mingled with the white population in stores, factories, kitchens, and nurseries and so spread the diseases which were prevalent among them. The health of the negro was the most important subject before the South today.

In the general discussion which followed, the burden of this problem, it was pointed out, devolved on public officials, sanitarians, and sociologists. Accurate observation of living conditions and experimental methods were urged. The speakers declared that no field was so barren of sanitary achievement as the bettering of the health and condition of the negro, and that none was more worthy of painstaking effort, presenting as it did the promise of far-reaching results of the utmost importance to the southern States. If landlords could be induced to build better houses, if municipalities would insist on better sanitary conditions, if the negro was given more information, and was better educated with reference to social hygiene, there would necessarily be an improvement in the race and this to the benefit to his fellow-being, the white-man.

Cerebrospinal Meningitis with Special Reference to Certain Signs or Measures.—Dr. RANDOLPH LYONS of New Orleans read a paper based upon an analysis of twenty-one cases of cerebrospinal meningitis with the particular object in view of determining the relative importance of eight signs or measures in adults. The actual value of the procedures described could not be accurately judged by so small a series of cases, nevertheless the results were suggestive and appeared, in general, to be in conformity with the experience of others in the adult form of cerebrospinal fever. The relative importance of Brudzinski's signs had not, to his knowledge, been carefully determined in adults. From the point of view of early diagnosis the eight measures fell into the following order of importance: Lumbar puncture stood first amongst the special measures. The first puncture established the diagnosis in 95 per cent. of the cases. Next in importance was rigidity of the neck. This could be demonstrated in twenty out of the twenty-one cases on first examination or 95 per cent. Kernig's sign came third. It was present on first examination in 90 per cent. of the cases and at some time during the disease in 100 per cent. The "neck sign" fell into fourth place. They found that Brudzinski's statement with regard to the relatively greater value of his "neck sign" over Kernig's sign in children, did not hold good for adults. It was found positive on first examination in 76 per cent. of the cases and could be elicited at some time during the course of the affection in 90.4 per cent. Brudzinski's contralateral (identical) reflex came fifth on the list, being present on first examination in only 33.3 per cent. of the cases. Babinski's sign occurred in but three cases or 11.6 per cent. at some time during the disease. In two of the cases it was positive on admission. Macewen's sign was found to be of practically no value in this series. It could be demonstrated in but one instance. This patient was the only child (5 years) in the group. The field of usefulness of this sign seemed to be limited to meningitic affections of early childhood. Lastly, the presence or absence of the patellar reflex was found to be of no apparent diagnostic importance.

Meningococcus Carriers.—Dr. WILLIAM LITTERER of Nashville, Tennessee, drew the following conclusions: (1) The viability of the meningococcus isolated from carriers varied greatly in different epidemics. (2) The variability in the resistance of the meningococcus was not a reliable index as to the degree of toxicity of the microorganism. (3) The meningococcus appeared to be of so short vitality and so fragile an organism outside of its natural habitat (the human body) that it led to the inference that direct transmission (droplet infection, etc.) was probably the only means of conveying the disease. (4) The great majority of healthy persons who harbored the organism could resist the infection. Only 2 per cent. of the carriers in their series developed the disease. (5) The spray could not reach all the deep recesses of the upper air passages, nevertheless it was imperatively indicated in all carriers, for the reason that it either destroyed or mechanically cleaned out all cocci with which it came in direct contact, thereby lessing re-infection, at the same time reducing droplet infection to the minimum. (6) The autogenous vaccine very probably played a prominent part in effecting a cure in two cases of the "persistent carrier" of six months' standing. (7) There were apparently no means at their command in which the "persistent carrier" could with any degree of regularity be rendered free from the carrier state. (8) In institutional epidemics the wisest procedure was a prompt isolation of all patients and the search for carriers and their detention, together with the general use of the spray.

The Bacteriology of Cerebrospinal Meningitis.—Dr. K. R. COLLINS of Atlanta, Georgia, stated that primary cases of pericarditis, joint lesions, iritis, etc., had been reported where the meningococcus was found to be the only invading organism. Cases of cerebrospinal meningitis, due to the typhoid bacillus, bacillus of tuberculosis, bacillus of influenza, the pneumococcus and pyogenic organisms, could in most instances be differentiated by finding any one of

the above organisms in the spinal fluid. Such cases might be found coincident with epidemics of meningococcal origin. Secondary cases of cerebrospinal meningitis were found in many of the infectious diseases, following lesions of pyogenic origin. Henry reported a case following super and submaxilliary abscesses due to the fungus actinomycosis. Such cases might sometimes puzzle the physician when occurring in the midst of the epidemic form. It was rarely possible to wait for bacteriological examination to be made before treatment was instituted, but in cases where anti-meningitis serum was used, the laboratory findings could frequently be obtained before the second dose was given.

The Intrameningeal Treatment of Tabes Dorsalis and Cerebrospinal Syphilis.—Dr. Thomas R. Boggs and Dr. R. R. Snowden of Baltimore spoke of the desirability of direct application, by intraspinal injection, of antisyphilitic drugs in the treatment of cerebrospinal syphilis which had long been recognized. Bichloride, salvarsan and neosalvarsan had all proved too irritating for direct use except in very minute quantities. They reported the results obtained in eight cases treated by the intraspinal injection of serum removed one hour after the intravenous injection of salvarsan or neosalvarsan. This method was first employed by Swift and Ellis and their technic was followed, with one important exception; Swift and Ellis added normal saline to the serum and injected a forty per cent. solution, whereas they injected larger doses of the undiluted serum. It had been shown by Plaut, Gonder, Swift and Ellis and others, that such serum had a decided spirochetical activity, especially if heated at 56° for half an hour. When injected into the spinal canal it was but mildly irritating and its beneficial effects were striking. In carrying out the treatment, blood was withdrawn one hour after the intravenous adminstration of salvarsan and allowed to clot. The next day the serum was removed, centrifugalized and heated at 56° for half an hour. Lumbar puncture was then done, cerebrospinal fluid withdrawn and exactly enough serum injected to replace this fluid. The amounts varied between 20 and 35 c.c. and the treatment was repeated every ten to twenty days until the spinal fluid was normal in respect to the cell count and Wassermann. Eight unselected cases were treated in this manner, five cases of tabes dorsalis, and three cases of cerebrospinal syphilis. In every case there was marked improvement, the cell count dropping to normal and the Wassermann becoming less marked and in most of the cases entirely negative. They felt this method of Swift and Ellis was a step forward in the treatment of cerebrospinal syphilis. In their cases the reactions were not, as a rule, severe, though more marked than those treated with diluted serum, as reported by Swift and Ellis. They point out the interesting fact that in two of their cases, where they injected into one patient serum obtained from another, that patient suffered a very violent reaction, while the patient receiving his own serum, at the same time, had no reaction. The most constant result was the disappearance of the lightning pains and other sensory disturbances and this resulted in a more cheerful mental attitude and a corresponding improvement in the appetite and nutrition. The effect on locomotion was slower in development, and less marked, but definite, and in some cases very great improvement was achieved, rather more pronounced, apparently than in patients treated by smaller doses of diluted serum.

Dr. R. H. Von Esdorf of Mobile said the best thing to do in cases of cerebrospinal meningitis was to try and establish a hospital and get the cases isolated as early as possible, surround them with the best conditions that could be had, which many individuals could not get at their homes. Particularly was this the case in the colored race, where he had seen two children down with the disease in the country in one bed and being treated with serum, with no hospital facilities, and the bed reeking with filth and wet with urine from the children, etc. If a small hospital could be established and the cases isolated, it would lower the mortality from this disease very materially.

Dr. V. H. Bassett of Savannah had been unable to find an authenticated case of infection of the meninges by the gonococcus in his review of the literature. But owing to the fact that the meningococcus in smears closely resembled the gonococcus, he would suggest that they be on the lookout for infection of the meninges by the gonococcus.

Dr. Lillian H. South of Bowling Green mentioned a case in which a diagnosis of meningitis was made from a swab of cotton sent in a sterilized container to the laboratory, and from this one case there developed one hundred cases in one town, with thirty-five deaths. Three counties were infected. A physician told her at the time that there was only one case of meningitis in that town or county. The child from whom the swab was taken died before it could receive the serum. Another child in the same family was seriously ill from meningitis.

Dr. C. C. Bass of New Orleans maintained that rigidity of the neck was an important sign in connection with the diagnosis of meningitis. Meningitis was accompanied constatntly by fever. These two signs or symptoms of themselves were sufficient on which to suspect the presence of meningitis. If there was sufficient ground on which to suspect meningitis, lumbar puncture was indicated, with examination of the cerebrospinal fluid.

Dr. E. C. Thrash of Atlanta, Georgia, claimed that physicians were controlling the active diseases very well, but they had not scratched the surface of germ carriers. Tuberculosis, diphtheria, typhoid fever, were diseases that were disseminated by carriers, and not so much by the active disease. The sooner they began to wake up to the importance of these germ carriers, the more good they would be able to do.

Dr. L. E. La Fétra of New York City held that one thing that occurred which would oftentimes disturb the physician who dealt with children was pneumonia. Occasionally they would find retraction of the neck, a high leucocytosis and fever with pneumonia, with no signs, they could discover, and the signs might not come out for two or three days. If there was suspicion of meningitis lumbar puncture should be made. Another thing was that certain cases of poliomyelitis would give them fever and, at times, leucocytosis and stiffness of the neck. These were the cases which had marked sensory symptoms and hypersusceptibility of the nervous system generally.

Dr. Molloy, from the Philippine Islands, wished to call attention to the danger of using cocaine solution which, in the great majority of cases, might not be sterile, into the operative field, thereby carrying some infectious material into the spinal canal and endangering the life of the patient thereby.

Dr. L. W. Elias of Asheville, North Carolina, said that the classical directions were to give one dose of the serum every day for four days, and if the case improved, to wait and watch. Other directions which seemed to him to be more accurate were to give the serum until the fluid was germ free. One case impressed him very favorably. A little boy, six years of age, in a hopeless condition, was given three or four doses of the serum, shortly after which the fluid contained but few germs, and his recovery was uninterrupted.

Dr. C. C. McLean of Birmingham stated that one thing they had to consider in treating meningitis was sudden death following the injection of the serum. He had seen two cases of sudden death from injection of the serum. The blood pressure should be taken along with the injection of the serum, and as soon as the blood pressure began to rise the injection of the serum should be stopped.

Dr. J. R. Dowling of Albany, New York, emphasized the effect of trauma in connection with this disease. He had had two cases in which trauma played a part. When cases were submitted to the nose specialist for operation they must consider the possible dangers which might result from such a condition. Both of these cases were instances of cerebrospinal meningitis excited by operations performed by him.

Dr. Arthur T. McCormack of Bowling Green, Kentucky, spoke of the importance of spraying the noses and throats of children. In no instance in which a child's nose and throat were sprayed did meningitis occur. This spraying could be done by teachers under the supervision of the health officer.

Dr. Henry Hanson of Jacksonville, Florida, maintained that the use of autogenous vaccines, according to Theobald Smith, was not of much benefit in carrier cases. The carrier case, as a rule, was immune to the organism. A great many of these carrier cases were simply mechanical carriers and the organisms were not very definitely closely associated with the circulation in the system of the individual, and it would be unusual to expect a vaccine to be very efficacious in cases of this kind. Another point to consider in such cases was the virulence of the organism in carrier cases.

Dr. C. E. Terry of Jacksonville said that they had recently had in Jacksonville a small epidemic of diphtheria, and four months ago they began to handle these cases in a different way from what had been the custom in the past. They began making a search for carriers, and whenever a case was reported from a home they took swabs from every member of the family and servants in the house, and segregated the carriers from the non-carriers. While the work was too new to draw any conclusion, they had found out that wherever they had had diphtheria in a neighborhood the proportion of carriers found in that neighbor-

hood had far exceeded the number of carriers found in school rooms where diphtheria was not present in the neighborhood, and presumably the carriers found under those circumstances were virulent.

President's Address: Medical Resurrection and Reconstruction in the South.—Dr. Frank A. Jones of Memphis said that previous to the war of 1861-5 the medical schools and the medical men were to the fore. They took equal rank with the schools and men in other sections of this great land. They had men in those days untrammeled and unshackled. They had schools without endowments and professors without pay who gave to the world some of the greatest men of the present age. After the Civil War things were in a chaotic state. Medical schools sprang up all over the land, good, bad, and indifferent. They had no state support nor any private funds. This condition of affairs in a great measure brought them into disrepute with some of their neighbors who had not suffered the ills of a devastating and all consuming war. Old things were passing away. New blood and new life were being instilled. They could see the medical schools and the medical men coming to the front and taking their places where they rightfully belonged, when their influence would, as in the days of yore, be felt. The day was not far distant when medical schools could and would demand recognition, and when they could and would dictate their own standard of medical education and not according to any one man unit of merit for entrance. Much yet remained to be done in adjusting the medical colleges and standards to the rapidly changing conditions. The Southern Medical Association in its influence for good should have the hearty co-operation of every southern physician. It should be for the physicians, by the physicians, and of the physicians. Every southern medical college worthy of living, though its lot might be hard for a few years, should be handled with justice.

The Importance of Pediatrics as a Special Study.—Dr. L. E. La Fétra of New York City said that there was an enormous mortality before the normal time of birth, due to miscarriages, prematernity and still-births. An investigation made in Philadelphia showed that in 1911 there were 39,975 babies born, and of these 2,131 or about 5 per cent. were still-born. There were also 559 premature births and in which the baby died, and there were during the same year 10,666 miscarriages. This meant that one out of every five of these pregnancies resulted in a miscarriage or still-birth. Just think of the blasting of hopes, the discouragement of womanly effort these figures implied! Something must be done to prevent this enormous loss of life before its portals were fully entered. Secondly, they had a very large mortality during the first few days and weeks of life. The health officer of Washington had stated that in 1911, out of 957 deaths in the the first years of life 151 occurred on the first day, 130 between the first and seventh days, and 114 between the seventh and thirty-first days; that is, 395 or about 40 per cent. of the deaths of the first year occurred during the first month and about 1-6 on the first day. These figures were not exceptional, for in 1910, out of 1,070 deaths 150 occurred on the first day, and in 1909, out of 1,042 deaths, 140 occurred on the first day. They could set down 1-6 of the mortality of the first year as occurring on the first day, and almost 1-3 of the first year mortality as occurring during the first week. This first week's mortality was not due to the milk or the manner of feeding, but to earlier acting causes, such as hereditary weakness or disease, malformations, difficult or mismanaged child-birth and septic infection. Thirdly, they had a large mortality during the remainder of the first year. This was due to difficulties with nutrition and to infection, particularly to gastrointestinal and respiratory diseases. Along with this mortality there went a morbidity whose prevention was possible to a large degree.

The Importance of Regulated Rest and Play to School Children.—Dr. James D. Love of Jacksonville, Florida, stated that every school child needed individual supervision and guidance in order that the nature and extent of rest and play might be adapted to the physical requirements and limitations of the child. Cooperation between the physician and trained amusement directors and physical instructors was essential in order that best results be secured. The physical director should be possessed of sufficient medical training to enable him to delegate to the individual child the form of play best suited to his physical development. In the average public school, which was supplied with a physical director, much more time was devoted to the vigorous and promising young athlete than to the child who was physically defective and, therefore, in great need of regulated exercise and rest. Physical training was too often given without consideration of the child's needs and capacity for exercise. Clubhouses should be maintained on every public playground, supported by state or county funds and provided with one or more physical directors who, operating with the family physician, might regulate the rest and play of every child of a community. In these clubhouses instruction might be given parents regarding the nature and amount of play and rest suitable for their children. Supervision might, in this way, be maintained over the child throughout the entire year, play be made educational and elevating to the child's morals. As far as was consistent with a child's physical needs and capacity, freedom should be accorded him to select a form of play that most appealed to his taste and inclination. A child's unstable nervous organization was frequently made to suffer by too sustained mental effort and unduly long study periods. Frequent cessations of study and recesses must be regarded as a necessity for every growing child rather than as a special privilege to be awarded the brightest and best behaved. Any school system was faulty which included as forms of punishment the curtailing of a child's period of play and the "keeping in" after school hours.

The Importance of Medical Inspection of Schools.—Dr. Philip F. Barbour of Louisville, Kentucky, said that the state owed to the child a healthy environment while that child was in the school under the supervision of the state. The best way to prevent damage by a contagious disease was to protect the child from infection by recognizing and excluding contagious diseases. This required medical inspection. Inspection should exclude all contagious diseases, whether febrile, as scarlet fever, etc., or cutaneous as scabies, etc., or trachoma, etc. Inspection should also recognize defects of vision and hearing or other bodily defects. School nurses were necessary to follow up the inspector's orders. The medical inspector needed special training and should have adequate remuneration.

Medical Inspection of the Children in Rural Schools.—Dr. William M. Jones of Greensboro, North Carolina, stated that medical inspection was an established fact in most well organized city schools, the rural schools, as a rule, having no inspection and, consequently, no safeguards to protect them from contagious epidemic diseases. Those few schools that had inspection, or examination, had no regular plan and no way of checking results. The rural school had been neglected on account of ignorance, prejudice, and economic consideration of the communities. To the rural school medical inspection and examination were more necessary and, consequently, more important than to the city school. City parents were more likely to notice defects in their own children and to have them corrected than were country parents. The reason for this was that the city parent had constantly before him on the streets, in parks and other places, large numbers of children and he was forced to see and note defects, whereas the country parent saw only his own children and those of one or more neighbors, and, consequently, did not have defects called to his attention as did the city parent. Medical inspection should consist of an inspection of the school buildings, grounds, privies, water supply and means of dispensing. The pupils were examined for eye, ear, nose, throat, teeth, skin and special defects. Cards were given informing the parent or guardian of the defect, ordering him to carry the child to the family physician for treatment and advice. The physician was to return the card, but the majority failed to do so and the cards were lost. However, a record was made of all children to whom cards were given, and when the school was revisited the following year these cases were inquired into, and, if necessary, a second card was given and the parent or guardian had the defect called more forcibly to his attention by a letter telling him of the danger and necessity for treatment. To impress on the children some idea of disease, its cause and prevention, lectures were delivered, illustrated with slides whenever possible. This made a permanent impression. Teach the child and he would teach his parents.

Milk and Its Relation to Infant Mortality.—Dr. Henry Enos Tuley of Louisville spoke of the great importance of the prevention of infant mortality, and said that while there were many causes of the heavy mortality among infants under five years of age his remarks were limited to the question of milk. He stated that breast milk was the ideal food for the infant, but for many unknown reasons this supply was too often a failure and there was much artificial feeding among the infants after the third month. He then told of the idea of certified milk and the milk commission as conceived by Dr. Henry L. Coit and which had been so practical and one of the most potent factors in the reduction of infant mortality, by providing

a clean milk. The formation of infant welfare associations, which carried the gospel of clean milk and infant hygiene into the homes of the poor and ignorant, was pointed out as one of the ways to reduce infant mortality. Dr. Tuley stated that the medical profession was remiss in not taking a more active part in all social service movements and should help organize an association for the distribution of clean milk. The work of the nurse in the homes was also commended as a great help. The author stated that under no circumstances should swill be fed to dairy cattle, even if legislative enactment was necessary before the practice was stopped. He stated that recent investigations had pointed out a new menace, viz.: the infection of cows' milk with the bacillus abortus, and that it had been advocated that certified milk, as well as market milk, be pasteurized, or preferably boiled under official supervision. He brought out the fact that milk was a carrier of contagion and the possible rendering safe of market milk supply by pasteurization or sterilization, but that procedure should be under the supervision of municipal control and the consumer educated in the care of milk in the home. He stated that the flash process of pasteurization did not destroy any of the pathogenic bacteria but did destroy the lactic acid bacilli, allowing the milk to decompose, such milk being unsafe for infant feeding. The author was unable to state the relative nutritive qualities of cooked and uncooked milk, but that the highest authorities disclaimed that there was any deleterious effect from heat. He was not ready to agree that certified milk should be heated to render it safe. In closing the author made an appeal for organization of those interested in child welfare work in each community and the gospel of clean milk and child hygiene into the homes of the poor in order to stem the tide of infant mortality and save those babies to society.

The Management of Carbohydrates in Infant Feeding.—Dr. L. W. Elias of Asheville spoke of the method of Dr. Clock of New York, which consisted in displacing the intestinal bacteria with lactic acid bacilli. An essential to success was that the genuine Bulgarian lactic acid bacilli should be used, since they passed through the stomach uninfluenced by the gastric juice. These were administered in a sugar solution in which they developed best. The entirely new feature about Dr. Clock's method was that the treatment was carried on without any change from the diet which the infant was on when taken ill. His success both in private and out-patient cases was nearly 100 per cent. This method was interesting, aside from its phenomenal percentage of cures, in that it eliminated the usual starvation of the first day or so, and this was in line with the latest ideas in treating typhoid cases. A treatment including feeding from the start should be evolved for summer diarrhea. In a very limited experience with this method last year Dr. Elias was led to believe that there were large possibilities in it. To see a feverish baby with frequent green stools, containing mucus and blood, and, thirty-six hours later, to find the temperature down near normal and the stools in normal yellow, free of blood and mucus with the baby looking as if it were a healthy one, substituted since the last visit, was most striking and impressive.

(To be continued.)

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 27, 1913.

First Vice-President, Dr. T. Passmore Berens, in the Chair.

Resolutions upon the Death of Dr. Ellsworth Eliot.—Dr. Wendell C. Phillips read these resolutions upon the death of Dr. Eliot, who was president of the Society from 1872 to 1873.

Resolutions upon the Death of Dr. John S. Warren.—Dr. Charles H. Richardson read these resolutions upon the death of Dr. Warren, who was treasurer of the Society from 1889 to 1904.

Neoplasms of the Bladder and Remarks on Operative Treatment.—Dr. Francis R. Hagner, Professor of Genitourinary Surgery, George Washington University, Washington, D. C., read this paper by invitation. He declared that it would be a great advantage if the term benign tumors of the bladder were eradicated, as this gave rise among many unfamiliar with them to the impression that there was a class of bladder tumors clinically benign, whereas all tumors of the bladder were clinically malignant. Unless they were removed by some operative means they would either directly or indirectly cause the death of the patient. The operative treatment of the papilloma was divided into excision by open operation and intravesical operations. The open operations in multiple papillomata had not been very satisfactory as metastases were so apt to occur along the whole line of incision. Nitze's results in the intravesical operation in these growths gave a smaller percentage of recurrences than those operated on by the open method; this was especially true in the multiple papillomata. There were a few cases reported in which the growth had been removed suprapubically and the base cauterized by the Oudan current that had given favorable results. Unquestionably the majority of genitourinary surgeons were using either excision with an operating cystoscope followed by cauterization, or else the high frequency cauterization by the Oudan current. They had had several of these cases, and, while they had not extended over a period sufficient to draw accurate conclusions and while small recurrences had been noted in two of the patients, they had been readily removed by another application of the current. While no one could speak positively on the value of this treatment, all were agreed at this time that it seemed to offer better chances of success than any of their earlier treatments. It was imperative to examine these cases cystoscopically at regular intervals, and to remove at once any evidences of recurrence. The frequency of malignant tumors of the bladder in relation to those in other parts of the body had been given as 3.9 per cent. by some authorities and 7.6 per cent. by others, so there was some variance in personal experience of various observers. Dr. Hagner said he had purposely avoided describing the symptoms of benign growths because the symptoms of malignant and non-malignant growths were the same. Hematuria was the cardinal symptom but it was often not present until the case was far advanced. The hemorrhage had distinct characteristics, being generally abundant, of long duration, and occurring irrespective of injury, violent efforts or straining; it was obstinate in yielding to threapeusis and finally disappeared for as little reason as it apparently took place. It might recur in a few days or not for several months. As a general rule carcinomatous tumors gave more persistent bleeding than the so-called non-malignant types of bladder tumor. Pain was a most constant symptom; it might be entirely absent, but later on it usually became severe and constant. Tumors distant from the urethral orifice produced less pain than those at the orifice. Reflex pain due to pressure on the nerves was very common in this condition, radiating to the thighs, perineum, and epigastrium, but it was usually a late symptom. The tumor mass might be so large as to act as a foreign body and thus cause pain. Although the fundus of the bladder was supposedly a comparatively rare location for new growths, Dr. Hagner said his personal experience led him to feel that they occurred in this portion of the bladder more frequently than was usually described. Statistics showed that the lower one-third of the bladder was the location of two-thirds of the vesical tumors; if this was true, the operation that the author had used in these cases was applicable in one-third of all malignant tumors of the bladder. One of two facts was certainly true, either bladder tumors were more frequent, or else their methods of diagnosis at this time were more accurate. The cases to which special attention was directed were those involving the fundus or lateral wall of the bladder. All of the author's cases were operated on by the methods described in the *Annals of Surgery*, November, 1910. Inability to remove the friable mass in the first case without breaking the tumor mass suggested the method of removal which had been used in the subsequent cases. The operation was impracticable for tumors of the bladder base. The method of procedure was as follows: The bladder was irrigated, and, if bleeding, adrenalin 1-10,000 was instilled and allowed to remain for five minutes. The bladder was then distended with salt solution, and a Nitze cystoscope introduced. This was held in place by an assistant while a suprapubic incision down to the bladder wall was made. The prevesical fat was well separated and the tissue well retracted by wide lateral retractors so as to give a good exposure of the bladder wall. At this stage it seemed possible by illuminating the bladder with the cystoscope to outline the tumor mass by transmitted light; although iridescence was caused by the illumination of the fluid, the outline of the tumor mass could be made out. The growth was then inspected through the cystoscope, which was held by the left hand. With the right hand a threaded needle was pressed on the fundus of the bladder, and the

dimpling caused thereby was readily seen through the cystoscope. The needle was carried first to the left of the growth at a sufficient distance to give a margin of healthy bladder wall. It was then plunged into the bladder and the suture drawn through, being held taut by an assistant. The same procedure was employed at the right and at the lower border of the growth. An incision was made through the bladder wall around the inner side of the three traction sutures, the portion of the bladder wall to be removed being clamped as the incision was advanced. The bladder wall containing the growth was lifted up by the clamp and held by an assistant. The fluid left in the bladder was removed by a large syringe through the suprapubic wound to prevent its entrance into the peritoneal cavity and the cavity of the bladder was packed with gauze. If the parietal peritoneum was to be removed (and if it was adherent to the bladder wall it should be removed) the incision in the bladder wall was then carried upwards into the peritoneal cavity and the portion of the pritoneum covering the growth was removed. The bladder and peritoneal wounds were then closed by two rows of chromic gut sutures, a suprapubic drain being left in the bladder, although in the last case the bladder was completely closed and drained by a retention catheter through the urethra. If the lateral wall was the seat of the growth it might not be necessary to go into the peritoneal cavity, while, on the other hand, if the tumor was located in the fundus of the bladder near the median line or backwards towards the posterior wall, it was safe to carry the incision upwards directly into the peritoneal cavity and to remove the peritoneum covering the bladder over the location of the growth. Results in the last case before referred to made it seem perfectly safe to close the bladder wound completely. It was the author's belief that many bladders that they did not close could be closed providing the patient had a urethra that could stand continuous bladder drainage. Dr. Hagner reported in detail his eight cases of cancer involving the fundus of the bladder or the lateral walls. Three had been operated upon by the method here described and all were alive and well. One was operated upon March 10, 1910, one November 11, 1910, and the last one March 18, 1912. This operation had not been tried before so far as the author knew. It was applicable to the upper two-thirds of the bladder. It had certainly made the operative treatment much more satisfactory than guessing at the point of location of the tumor, making an incision, having the bladder wall collapse, finding the sutures were too near or too far from the growth, and then having to introduce the finger into the bladder to make out this line of incision and having the growth break up. In conclusion Dr. Hagner stated that he felt that every patient who presented blood in the urine, unless there was a definite known cause for its appearance, should be examined at once and the location of the hemorrhage ascertained. If this rule were followed one would not see so many cases of hopeless late vesical neoplasm.

Dr. Edward L. Keyes, Jr., said that Dr. Hagner's series of cases of excised carcinoma of the bladder, without recurrence within one year, was certainly very brilliant. The method gave a new hope in this desperate pathological condition. Not being able to criticise what Dr. Hagner had done Dr. Keyes made some observations on the symptoms, diagnosis, and treatment of papillary bladder tumors. He had been struck more than once by the disparity between the pathological condition and the symptoms of hemorrhage. The bleeding might be fast and furious when the tumor was small. It might be zero and the tumor large. He had seen two tumors of the bladder in patients who were supposed to have nothing more than neurasthenia and were cystoscoped for demonstration to students. Thus some cases did not admit of an early diagnosis because there were no symptoms. Dr. Keyes had seen three cases of papilloma growing from the trigone which did not have hemorrhage as a primary symptom. They showed only pyuria and frequent and painful urination. They were all cured by the employment of the high frequency current. Dr. Keyes called attention to the distinction he had previously endeavored to make between which tumors of the bladder were clinically benign and which malignant. That pathologists were incompetent to determine the clinical malignancy of a bladder tumor had often been illustrated. In one reported case, for instance, the tumor removed at a first operation was classed as carcinoma. It clinically lived up to this classification by relapsing; but when excised a second time the same pathologist (one of the best in the country) called it papilloma. Therefore the speaker preferred to classify tumors as benign or malignant in accordance with their reaction to treatment by the high frequency current. Those that could be destroyed by the current he classified as benign; the others as malignant. But this method of diagnosis would entail a dangerous delay, if we had not some criteria to help us judge which tumors would probably prove amenable to this treatment and which would not. In the speaker's experience there were several cystoscopic features of bladder tumors that denoted malignancy fairly well. Among these the most striking were two: First, sloughing on the tumor. A tumor that had not been treated and showed a sloughing surface was clinically malignant. Second; severe and intractable cystitis of an intense character that resisted all treatment to alleviate it was apparently always malignant. Certain other features should of course be taken into consideration, such as grave debility or a hard tumor, palpable by rectum or by bimanual examination. The presence of either of these showed malignancy, but their absence did not exclude it.

Dr. Leo Buerger said he wished particularly to emphasize one point brought out in Dr. Hagner's paper, the importance of an early diagnosis. There was another point he wished to dwell upon, and one about which most of them were more or less skeptical, that was, the possibility of obtaining a definite pathological diagnosis, telling them whether or not they were dealing with a malignant tumor of the bladder or with one that was benign. In the treatment of these cases it was most important to determine whether its pathological examination showed it to be a carcinoma or a papilloma. This was in many instances a difficult proposition. It seemed to him almost a hopeless task to trust to the pathologist or to the clinical history alone, but the safest data in making up the diagnosis of carcinoma of the bladder was revealed by the use of the cystoscope. They all knew that frequently papilloma was benign; also that it frequently occurred as carcinoma. How should they consider this question? How could they report to the pathologist and ask for a diagnosis? In his experience he found that they were dealing with varied types as follows: (1) The pure papilloma, single or multiple; (2) papilloma which showed early signs of degenerative changes in the epithelium; (3) tumors which showed changes which penetrated into the muscles, or with small collections of cells in the vessels; (4) papilloma in the body of a carcinoma; (5) tumor that had been invaded by carcinoma; (6) tumor which was a papilloma, but which the pathologist would term carcinoma; (7) tumors starting elsewhere, but associated with papilloma. All these tumors were either papilloma, or papilloma plus carcinoma. Could they help the pathologist in determining which tumor was papilloma and which carcinoma? Yes. Fulguration should not be employed because it was slow. One should bite off as much of the base of the tumor as possible, as well as some of the surrounding tissues. If the tumor grew deeply in the muscular tissues, it was carcinoma; if the tumor invaded the muscles, it was a malignant growth. He said that they should bite off with the forceps or with the snare as much of the tumor as possible, especially at its base. If they found that it grew in the muscle, it was a carcinoma. If atypical cells were present, it was a carcinoma. The cases mentioned could have been easily diagnosed by biting off a piece. Another important point Dr. Buerger mentioned was that there was in these cases a surrounding edema; there practically always was to be noted an area of edema and the microscope would show edema plus carcinoma. He recommended that in every case they should look for this edema. He made a plea for a more definite pathological diagnosis by the aid of the cystoscope and the aid of the pathologist.

Dr. Alfred T. Osgood thought that the method of operating employed by Dr. Hagner was a very ingenious one and that the subject under discussion had been very well covered, but there was one point which it seemed to him might be made more impressive. Upon the early diagnosis of tumor depended the salvation of many of these cases. The impression that the entire symptom-complex or at least the cardinal symptom must be present before tumor was suspected seemed to prevail. A tumor might exist in the bladder without symptoms or the signs of slight vesical irritability only be aroused by it. Symptoms of cystitis were frequently due to or caused by the presence of a tumor of the bladder. The cardinal symptom of hemorrhage was very frequently absent entirely or for a long period of time. Sometimes these cases would be treated for months and even years before a tumor of the bladder was discovered. It was the early diagnosis of these malignant tumors that Dr. Osgood wished especially to emphasize. Many of these could

only be helped by the early discovery of the cause of cystitis.

Indications in Renal Surgery Which Demand Immediate Operative Intervention.—Dr. Louis E. Schmidt, Professor of Genitourinary surgery, Northwestern University, Chicago, Ill., read this paper by invitation. He stated that his object was to endeavor to show the great discrepancy between the results of their methods of examination, including the newer methods, and the symptomatology which was still not thoroughly correlated with the facts that experimental post-mortem work and findings at the time of operation have shown to exist. Since the results of their usual examinations and the symptomatology had oftentimes apparently no real relationship to the gravity of the situation, the great necessity for immediate action could not be pointed out with absolute definite warning. He said that he would select conditions which appeared to him of much importance, would touch upon a few others and would entirely omit some which undoubtedly were of the same magnitude. There were cases met with by all which demanded quick action and that in some instances the usual diagnostic methods be used with discrimination and not stretched out over too long a time, but that they be limited yet correctly done. In chronic surgical diseases of the kidney no haste need be undertaken, but a most thorough and prolonged examination during the period of preparation for operation should be carried out. In a general way the urgent cases requiring immmediate operation were those in which the condition in or around the kidney threatened that organ with destruction or if no relief by operative interference was given that the general condition became so involved that the termination in most cases was fatal. It seemed more desirable to make a classification of these cases according to general conditions than to use any pathological or etiological classification. Hemorrhage, no matter whether produced by injury or in the course of nephritis, tuberculosis, stone, or neoplasm, gave rise occasionally for immediate intervention. The same could be stated of anuria, and here again the usual chronic conditions above mentioned might be the cause, but it was to the different types of acute nephritis attention would be directed. For present purposes the old classification of acute and chronic nephritis seemed most satisfactory. At present he would deal only with acute conditions. These were: 1. The acute parenchymatous type which was produced by all the well-known infectious diseases. 2. The acute suppurative type, which was exemplified so well by the colon bacillus infection. 3. The acute toxic type, which was produced by many drugs and toxins. What the significance of the passage of bacteria really was had not been positively established, but, in the speaker's opinion, it was a distinct sign of the involvement of the kidney. For instance, if the *Bacillus tuberculosis* was found in the urine, it did not necessarily indicate that the kidney was involved in a tuberculous process, but that a nephritis might be present permitting its passage. All agreed, however, that if the kidney had any cause for decreased resistance it readily permitted germs to be the cause of disease. Decapsulation probably relieved intrarenal tension, but it was improbable that it relieved intrapelvic tension or edema of the kidney as thoroughly as an incision through the organ into the pelvis. The possibility of the existence of a physiological albuminuria was still debatable, but Dr. Schmidt was inclined to believe that albuminuria never existed unless nephritis was present. It was an absolute fact that urinary findings might be completely negative even in extreme cases. On the other hand, if the immediate vicinity of the pelvis was involved and breaking down into the same, the urinary findings were very apparent. The fact should be emphasized that a negative urinary finding did not show the absence of a small abscess in the renal or perirenal tissue, and, furthermore, clinically it had been demonstrated that the renal function in these cases was not always impaired. It might be that the greater the destruction the greater the probability of loss of renal function. It had been shown by v. Noorden that the presence of albumin, red blood corpuscles, and hyaline casts was not sufficient to establish a diagnosis of nephritis, and by Cohn that traumatism could cause these elements to appear in the urine. With definite facts of this kind it must be admitted that some of the urinary findings in the class of cases under consideration were not of the importance that they were in certain and well-known processes. Furthermore even the functional and urinary tests, including cryoscopy of the blood, had been known to fail. In this group of infected kidneys cases were met with where there was suppression of one side only in the early stages, and anuria of both kidneys set in if the condition was permitted to persist. Clinically, it had been shown that certain conditions located on one side produced certain substances which undoubtedly, after gaining access to the circulation, had the power of destroying the opposite kidney. In infected cases it was not necessary for the germ itself to gain access to the second kidney. The symptomatology of all acute kidney disease varied with the intensity of the infection and often the duration of a few hours, certainly days, was of the greatest importance. With increasing diminution of urinary secretions in cases of septic involvement of the kidneys, why wait for anuria? When marked suppression had set in it was desirable to urge operative interference. It might be urged that such cases would recover without operation, but experience had shown that this was doubtful. When anuria had persisted for more than forty-eight hours the mortality was extremely high. In cases of this kind produced by stone, there would be scarcely any one to question the advisability of operative procedure. When produced by septic involvement, the subject was not so clear in the minds of all. In acute purulent infective nephritis were included all those cases (except those belonging to the acute infectious diseases) where there were bacteria in the circulating blood which for some reason or other produced infiltration of the kidney parenchyma. All these processes were similar; etiologically all were also metastatic and hematogenous infections, and why the process should differ in individual cases had not yet been determined. There was, as a rule, the usual general train of symptoms present, varying, however, to a marked degree. Local symptoms might be absent or one might find extreme sensitiveness. There was always present the characteristic resistance over the erector muscle on the corresponding involved side; occasionally there had been noted a localized inflammatory edema. In the diagnosis, naturally all the newer methods should be employed, the *x*-ray, ureteral catheterization, functional tests, the separately collected urines should be examined bacteriologically, chemically, microscopically, and possibly guinea-pig inoculation should be employed. In the differential diagnosis pyelonephritis had to be taken into consideration. It could be stated definitely that this condition was most often urogenic in nature and, therefore, ascending in character, and more frequently bilateral in contradistinction to those cases under discussion. As a rule uremic symptoms were absent and edema of the extremities was always absent. The author did not dwell on those conditions in which operative interference was generally acknowledged to be indicated. He concluded as follows: (1) That it was impossible for a one-sided acute infectious nephritis to occur; that if such an acute condition persisted for any length of time certain agents were produced in the course of the destruction of the kidney which destroyed the kidney cells. These bodies of nephrotoxic character, after gaining access to the circulation, were not only at once the source of the greatest danger in destroying the kidney cells of the involved side, but equally important to the opposite side, producing similar destruction of the otherwise healthy kidney. (2) That if the process was not too far advanced there was at least only the destruction of a certain amount of kidney tissue. With the hope in view that the operative procedure would stop the further progress of the destruction of its kidney and of its opposite, there was also the hope that by the operation the consequences to the system in general might be avoided. (3) That under the circumstances the correct course to pursue was to undertake operative measures, particularly where all known conservative treatment had been of no avail. (4) That these procedures might vary as to the indication. In the severe hemorrhages the operative procedure would be guided by the condition and this also held true in cases of anuria. (5) That in groups one and three, after being used all medical means for at least a short period of time, operative interference was desirable and decapsulation in these cases was the operation of choice. (6) That if operation should be decided upon in cases of acute infectious nephritis, especially in colon infection, the kidney should be exposed. If the involvement had not progressed too far nephrotomy was the operation of choice; otherwise a nephrectomy should be performed.

Dr. George E. Brewer said they were all as yet unfamiliar with the indications for operation in certain renal conditions, especially those which demanded immediate operative intervention. In his discussion he said he would limit himself to a consideration of the acute hematogenous infections of the kidney. There was no question in his mind that there was abundant proof that microorganisms in the blood might pass through the healthy kidney without producing structural changes. But,

on the other hand, they might produce changes from sloughing, swelling, infiltrations, and even destruction of the organ. What changes occurred depended entirely upon the virulence of the microorganisms and the resistance of the kidney tissues. There was no doubt that any kidney that had been subjected to disease, or injury, or anything that caused hyperemia was a kidney that was vulnerable to these organisms. As they attempted to pass through they might find a lodgment and form an abscess, or abscesses which broke down and formed larger abscesses in the capsule or perirenal tissues. There were two general classes to be considered, the ordinary acute form and the hyperacute form. In the first class, the patient was moderately ill and presented the textbook appearance of pyelonephritis or suppuration of the kidney with which they were all familiar. But there was another type so virulent that the patients died before such changes as enumerated occurred. In this type, the process was so virulent and the symptoms so intense that even renal symptoms were not present. In the symptomatology of this virulent type there was present a beginning chill with a sharp rise of temperature to 104°, 105°, or 106° F. and in one case he had met with to 107° F. Associated with this sudden rise of temperature there was an intense prostration and pain on the affected side; this pain was often referred to the anterior abdominal wall, which, of course, was very misleading. An examination of the urine would show no particular change. Why? Because the function of the kidney had been entirely suspended. The urine from the opposite kidney would show no evidence of any change. But upon centrifuging the urine almost invariably there would be found a few blood cells and often a trace of albumin. In these cases prompt surgical intervention was the only recourse. In the majority of the hyperacute cases there was a colon bacillus infection, but there was no rapid destruction of the kidney; this was an acute infection, with symptoms somewhat similar to the above, but relieved by a rapid and radical method—nephrectomy. In the staphylococcus or pneumococcus infection, the infection was so rapid that unless the kidney was promptly removed the patient would die. How die? Because of the pronounced toxemia from the kidney, or a toxemia resulting from metastatic abscesses in other parts of the body. These were the cases that called for imperative surgery. A careful urinary examination should be made in all these cases with centrifuging.

Dr. JOHN F. ERDMAN said that in cases of streptococcus infections of the kidney there was a possibility of mistaking them for gall-bladder trouble or infection of the liver. When hemorrhages occurred nephrectomy was indicated in many of the instances.

Dr. J. BENTLEY SQUIER said that a certain fact came to his mind; this was that in Switzerland they had two methods of operating in a certain number of groups—first, decapsulation, and, second, nephrectomy. Two years ago he published a paper in which he related the details regarding decapsulation subsequent to displacement of the kidney. Dr. Squier related the case of a woman who entered the hospital because of frequency of urination and hematuria. She was under observation for two months and was acutely ill, especially so when she came in. The condition subsided, but came on again, the hematuria being very profuse. Just what pathological condition was going on could not be determined and it was suggested that she submit to an exploratory operation, to which she consented. The kidney was exposed and a section for the pathologist was made. The kidney was split from pole to pole. There was no evident lesion of the kidney that called for its removal. The kidney was sutured back in place, decapsulation having been performed. The frequency in urination and tenesmus disappeared and for eighteen months she was perfectly comfortable. Then hematuria again appeared and was very profuse, undermining her health. The kidney was again exposed and was found to be imbedded in a dense adherent capsule. Nephrectomy was performed. On section the condition was found to be a typical case of essential hematuria with chronic arteriosclerosis. What had occurred in this case? The tension had been relieved by the decapsulation. Adhesions had then formed and bound the organ so tightly that it acted as though possessed of a fresh capsule. The decapsulation operation was merely palliative and resulted well until the adhesions and fibrosis formed. A second case was very similar and decapsulation was also done. There was a unilateral bleeding. The patient was relieved for two years when there was a recurrence of the symptoms. The report of these cases did not prove anything conclusive, but he believed that with more experience with decapsulation they would learn it to be a palliative operation and not by any means a curative one.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held November 18, 1913.

DR. LINSLEY R. WILLIAMS, IN THE CHAIR.

The Relation of and the Lesions Produced by the Members of the Streptococcus Group, with Special Reference to Endocarditis and Rheumatism.—Dr. E. C. ROSENOW of Chicago presented this communication. He gave a demonstration of specimens and showed on the screen many photomicrographs. After expressing his appreciation of being able to attend the meeting he said that some believed, as the result of much study and investigation, in the entire specificity of the streptococcus group, while others believed that there were certain degrees or modifications as a rule. So far as he knew, for instance, there was no absolute proof that pneumococci could be converted into hemolytic cocci. After working for one entire year he found that streptococci could be transformed into pneumococci and *vice versa*. Dr. Rosenow's part of the evening was devoted to a lantern slide demonstration.

Dr. AUGUSTUS WADSWORTH said that six years ago, in a paper read before the New York Academy of Medicine, he had reviewed previous studies of malignant endocarditis and emphasized the bacterial nature of many forms of endocarditis and their relation to the malignant forms of the disease. In the discussion the late Dr. Edward G. Janeway said that he had only seen one case of malignant endocarditis which recovered. This was both interesting and instructive in the light of their recent conceptions of endocarditis. All of this was due to the study of the different streptococci found in these cases, although attempts to clarify these different streptococci had never been satisfactory. Intermediate strains had always been found. Dr. Wadsworth was, therefore, especially interested in Dr. Rosenow's real achievement, the changing at will of pneumocci into streptococci and of streptococci into pneumococci. Dr. Wadsworth was also particularly interested in the lesions Dr. Rosenow had obtained experimentally with the different types of streptococci and pneumococci. In his own work he had studied chiefly the pneumococcus. In pneumococcus infection of the rabbit he had frequently seen lesions which were the counterpart of those presented in Dr. Rosenow's specimens of "experimental rheumatic myositis" in the rabbit. The records of Dr. Wadsworth's experiments showed that these were pyemic foci obtained only under certain conditions, namely, in immunized animals. With extremely virulent pneumococci in the very susceptible rabbit, hemorrhagic foci of similar distribution in the muscles were found.

Dr. N. E. BRILL said that the very important observations of Dr. Rosenow tended to modify materially our views as to the conception of the pathogenesis of streptococcic invasions of the heart valves, especially in so-called rheumatism and in the distinctive form of bacteriemia called chronic infective endocarditis, which was, in almost all instances, due to the strain of streptococcus known as either *Streptococcus mitior* or *Streptococcus viridans*. However, his views as to what he called rheumatism seemed to him to require modification. The term rheumatism was a general one and should be absolutely confined to what was known as "rheumatic fever." This specific disease had all the earmarks of a general infection of the circulating body fluids, though up to the present time no infectious agent had been discovered in the blood. It was, however, in the other conditions also termed rheumatism that a bacteriemia had frequently been demonstrated. Clinicians could differentiate three distinct types of infectious disease associated with acute non-suppurative arthritic changes, with fever and endorcardial involvement, to all of which the term rheumatism had been applied, namely, the well-defined form known as "rheumatic fever" and acute articular rheumatism, in which blood cultures had been invariably negative; secondly, a form, not at all uncommon, associated with definite attacks of tonsillitis, involvement of many points, both the large and small, but more frequently the small, accompanied by skin manifestations such as erythema, erythema multiforme, erythema nodosum, purpura and numerous petechiæ, the peliosis rheumatica of Schönlein, at times accompanied by signs of renal involvement and occasionally with lesions in the gastrointestinal tract, giving rise to abdominal pains, hematemesis and melena to which the name of erythema of the visceral group has been given by Sir William Osler. The lesion of the gastric mucosa produced experimentally by Dr. Rosenow, by the artificial injection of a certain strain of streptococcus, would appear to shed some light on this

second group, and because it was just in this group that a bacteriemia had, not infrequently, been established, first by Poynton and Paine and by Meyer, who gave the name of *Streptococcus rheumaticus* to this organism, though they believe that the organism was the infectious agent of the disease known as acute articular rheumatism. Lastly, a third group, also accompanied by fever, endocarditis and arthritis, which was the subject of discussion and which had been called subacute or chronic infective endocarditis. Dr. Brill limited his discussion therefore to this form alone. Let them call the last disease "chronic infective endocarditis" and not "sub-acute," because the most of the cases had no acute stage and lasted longer than the acute infections, varying in duration from a couple of months to as many years, even exceptionally to three, possibly four. These cases started, like all chronic diseases, insidiously, and were chronic from their incipiency, just as a small granular contracted kidney was chronic from the start. It was this form which seemed to be a definite entity and was produced by the entrance into the blood stream of the organism first described by Schottmüller and called by him the *Strcptococcus mitior*, also known as the *Streptococcus viridans*, and the attenuated streptococcus. Dr. Brill called attention to an etiological factor in this disease which had not been mentioned or generally described, and that was the common occurrence of previous and repeated attacks of tonsillitis in an extremely large proportion of these cases. He had seen a relatively great number of patients with chronic infective endocarditis and had been struck, on careful inquiry, as to the antecedent disease, with the very general confession in these patients of previous attacks of tonsillitis, recent as well as old, so that he had come to look upon an infection of the mouth, particularly of the tonsil, as the important portal of entrance to the *Streptococcus mitior*.

The symptomatology of chronic infective endocarditis might be summed up in symptoms due to the bacteriemia and those the result of the biological characters of this definite strain of organism. The former were the symptoms common to all streptococci and some other bacteriemias and therefore not characteristic of any type, viz., prostration, fever, chills, petechiæ, anemia, pains due to infarcts, pains and other symptoms due to emboli and mycotic aneurysms, joint pains and disturbances and the like. It was the specific biological character of the organism which gave rise to the pathognomonic or diagnostic features of the disease: the renal and skin emboli. Its particular biological feature was the tendency of the individual organism to tenaciously cling to each other to such an extent that shaking them in fluid cultures in a test tube would not disseminate the individual organisms; they stuck together in clumps. It was on account of this that clumps were arrested in the peripheral capillaries and in the terminal vessels of the extremities and of the kidneys. This arrest gave rise to the characteristic red, painful, tender nodes on the ends of the fingers and toes to some petechiæ, especially those with white centers, and to the characteristic malpighian tuft emboli in the kidneys, though the latter could not be determined during life. The toxic hemolytic influences of this organism gave rise to the progressive anemia, to the ordinary petechiæ, to the enlarged spleen, and to the tender sternum. In the absence of the painful tender skin nodes it might be at times almost impossible to make a clinical diagnosis without the aid of a blood culture. The latter, when positive, could alone clinch the diagnosis with certainty under these circumstances. As to the group of cases whose blood culture remained negative, they need not necessarily, on account of negative blood cultures, be bacteria free, for it occasionally occurred in them that cultures after death from the breast blood and the viscera demonstrate the existence of active organisms. On the other hand, negative blood cultures might indicate that the vegetations on the heart valves were undergoing regressive and separative changes by which the bacteria had been destroyed and were no longer fed to the blood current. He did not believe that it was always possible in such cases to make a positive diagnosis of the existence of such a condition, though he was aware that Dr. Libman insisted that he could. One might suspect the existence of the disease in the bacteria-free state, from the history. The signs which Dr. Libman regarded as characteristic in this stage, to his mind, were not conclusive, namely, the brown discoloration of the face, *café-au-loit* color and the sternal tenderness. In fact, he had repeatedly demonstrated the existence of these two signs in the course of ordinary chronic valvular disease, especially of the mitral valve, when associated with cyanosis and venous stasis. Chronic defect of this valve might give the signs of renal involvement, sometimes a large spleen and not infrequently evidence of bone marrow stimulation manifested by a polycythemia and tender sternum. Two such cases had been diagnosed by Dr. Libman as cases of healing lesion of chronic infective endocarditis, and on autopsy the heart showed not the slightest evidences of having been the seat of invasion by the *Streptococcus mitior*.

Dr. Morris Manges called attention to the extensive hemorrhages that sometimes occurred in the ventricles of the brain as shown in the specimens that were presented. Embolism was very frequent. In his experience he had never encountered, however, gangrene of the extremity or an embolus of some size. Congenital heart lesions should also be considered in the differential diagnosis of this condition. Such a lesion would predispose to the disease as would the acquired cardiac lesions. Dr. Manges referred to a case of Dr. Schmall, where the diagnosis was not made; this was one of a congenital heart lesion. That it was not so very infrequent was evidenced by the fact that it occurred three times in the 150 cases collected by Hordt. The tender nodes were very important, even if they were not as frequent as claimed by Sir William Osler, *i. e.* 70 per cent. When present in a case with fever and cardiac lesion the diagnosis of infectious endocarditis was warranted even in the absence of a blood culture. They were absolutely characteristic; in painfulness and appearance they could not fail to attract the patient's attention. In some cases they simulated the beginning of a panaritium.

Dr. W. Thalhimer said that in the past year Dr. M. A. Rothschild and he had been interested in the *Streptococcus rheumaticus* and *Streptococcus mitis** from a somewhat different point of view than that of Dr. Rosenow. They had been interested in these organisms, first, because of their possible relationship to Aschoff bodies, and, secondly, because of their similar cultural characteristics. From the reports of a number of observers, organisms had never been found in relationship to Aschoff bodies, which had also been their experience. Also in none of the cases of subacute bacterial endocarditis which they had examined so far, except the one case of Dr. Libman, of a combination of verrucous mitral endocarditis and aortic subacute endocarditis, had they found Aschoff bodies. They had never produced Aschoff bodies by intravenous injection of animals with either of the organisms above mentioned. They had produced, however, focalized myocardial lesions which were subacute and inflammatory in type, and in which organisms were not present. In addition, 53 per cent. of the animals injected intravenously with *Streptococcus mitis* had developed arthritis, and in a small series of animals injected with five different strains of streptococcus only 45 per cent. developed arthritis. Three of these strains of *Streptococcus rheumaticus* were obtained through the kindness of Dr. C. E. Winslow, of the Museum of Natural History, and the second through the kindness of Dr. Rosenow. The strains of *Streptococcus rheumaticus* had been in artificial cultivation for some time, but the strains of *Streptococcus mitis* were some of them recently isolated, and others of them, older cultures, had been under artificial cultivation for varying periods of time, one having been isolated several years previously. Consequently it would seem that their results were somewhat at variance with those of Dr. Rosenow, and had led them to the conclusion that the affinity of a strain of streptococcus, when injected into animals, for either the heart or joints, was not sufficient to determine this organism as a special type.

Dr. Paul W. Aschner said that he was especially interested in Dr. Rosenow's discoveries concerning transmutation of organisms of the pneumococcus-streptococcus group and their inter-relationship, as he had arrived at a somewhat similar conception from cultural studies. While the majority of these organisms as encountered in routine bacteriological work adhered to certain well-defined types, many observers had met with organisms varying from the type in greater or lesser degree. Some of these atypical forms partook of the characters of two types and might be regarded as transitional forms caught in the process of evolution. The organisms of the pneumococcus-streptococcus group were best divided into four classes: (1) *Streptococcus mucosus capsulatus;* (2) pneumococci; (3) non-hemolytic streptococci; (4) hemolytic streptococci. He conceived of these bateria as forming a continuous chain which might be represented in a graphic manner, showing that there were types and transitions between types; that there were saprophytic pneumococci and parasitic non-hemolytic streptococci. The non-hemolytic streptococci included such a variety of or-

*This term is synonymous with *Streptococcus viridans, Streptococcus fæcalis, and Streptococcus salivarius.*

ganisms that a type could hardly be said to exist. This class had been the cause of much confusion, for it contained bacterial forms found in the mouth, throat, and intestinal tract of normal man leading a purely saprophytic existence and formed culturally indistinguishable from these, but possessing a low grade of pathogenicity for man and animals. These had in the course of evolution acquired the property of parasitism. While they might be found in localized infections in man they were rarely found in the blood stream except in the disease known as subacute and chronic malignant, infective, or bacterial endocarditis, or endocarditis lenta. This organism was called *Streptococcus mitior seu viridans* by Schottmuller. He isolated a non-hemolytic streptococcus from the blood in a case of osteomyelitis of the mandible, the infecting organism coming no doubt from the mouth, where *S. salivarius* was found. In a case of post-abortion infection, obtained from both the uterus and the blood, the *Bacillus coli* and a non-hemolytic streptococcus. Here the infection was undoubtedly intestinal in origin. The *S. salivarius* and *S. fæcalis* were non-hemolytic streptococci. Whatever the biological and scientific importance of the transmutation of organisms, it was still a fact that when the organisms of the pneumococcus-streptococcus group were isolated from the blood there was no difficulty in distinguishing the various members culturally, as shown in the appended table. Whenever a non-hemolytic streptococcus was recovered from the blood stream by the usual blood culture technique, and other foci of infection could be ruled out, it was safe to assume that the organism was localized on the endocardium. The diagnostic value of the blood culture in clinical medicine remained unimpaired.

He had had for study cultures of the rheumatic cocci of Poynton and Paine, Beattie, and Lintz. These organisms were not freshly isolated and their characteristics might have changed, but by their methods they belonged to the class of non-hemolytic streptococci. While the *Streptococcus mitior* had only twice been found encapsulated, two of the three rheumatic cocci showed pneumococcus type capsules. None fermented inulin, and all produced large amounts of acid, as seen by the intensity of precipitation on glucose serum agar.

	Buerger Capsule Stain	Glucose Bouillon	Precipitation	Inulin	Bile Test	Blood Plates
Streptococcus mucosus capsulatus	Typical Atypical None	Clouded	0	+	Dissolved	Mucoid, Green
Pneumococcus	Typical Atypical None	Clouded	0	+	Dissolved	Green
Non-hemolytic Streptococci	Pneumococcus type Atypical None	Clouded Clumps Granular growth	+	+ +	Not dissolved	Green Gray White Colorless Slight, late, clearing
Hemolytic Streptococci	Atypical None	Granular growth	+	0	Not dissolved	Marked clearing in 24 hours

Perineal Ectopic Testicle.—R. A. Milligan reports the case of a boy aged seventeen years who sought advice on account of a lump in the perineum which at times swelled and became painful. Examination showed the scrotum to be empty. The right testicle was situated in the inguinal canal, while the left formed the lump complained of in the anterior part of the perineum.—*Proceedings of the Royal Society of Medicine.*

Functional Aphasia.—H. Mackenzie reports the case of a woman aged 35 whose husband had been admitted to the hospital with a right-sided hemiplegia and complete motor aphasia of two hours' history; since then she had worried considerably and had not slept. On April 23, on getting up, she found she could not speak at all. The author saw her on April 25, when there was complete motor aphasia. On April 27 she was better, and could talk fairly well; on April 28 she was talking normally, but in the evening was upset at home, and the aphasia again became complete. When outside the hospital she was talking quite normally. On eight or nine previous occasions, the first being two years and the last two weeks ago, she had similarly been aphasic, but never for more than a few hours at a time, the attacks always occurring after some special worry. She seemed of a very nervous disposition, but her past history did not otherwise present any special features. —*Proceedings of the Royal Society of Medicine.*

Miscellany.

Advice to the Prospective Automobile Purchaser.—H. Massac Buist presents a number of practical points that should guide the medical man in the selection and purchase of a motor car. Certain pitfalls in demonstrations should be guarded against. In the case of a demonstration car, one should know whether the carburetor has a larger jet orifice than in the vehicle as it will be supplied to the buyer; also the amount of gasoline that is being used in the demonstration car. One should observe systematically the manner in which the car is being demonstrated; whether the driver is manipulating the clutch when he is showing what can be done on the direct drive, and whether the clutch has been oiled so that it will slip somewhat. In some cases one can disregard the speedometer on the demonstration car. The writer has come across more than one that has been adjusted to register higher than is correct. When hill-climbing qualities are being displayed, one should be careful to observe how each rise is approached. There is no credit in climbing any rise without changing gear if one has to rush at it, any more than there is in demonstrating fast speed qualities on the flat if the machine has to take a long time to get into its stride. The medical man, indeed, should be particularly mindful not to succumb to the top gear or through-drive mania when he is making up his mind concerning the choice of any particular car. On the contrary, he particularly wants a machine the gears of which will be easy to change, and the motor and clutch details of which will not cause a jerk every time the gears are changed, whereby the machine is racked and tires are destroyed. The journeyings of a medical man are not confined to main routes. Accordingly many doctors are limited as to the size of car they can take by the necessity of negotiating tortuous and narrow country lanes, such as call for an ample wheel-lock and a limited over-all length of car, also, in many cases, for a wheel-track of not too great width. The car, however, should be always proportionately wide for its size and height from the ground if it is to be stable and safe on the road. Under this head mistakes of design have been made in certain light car patterns that are too narrow, and the center of gravity of which is accordingly too high. Another feature to which attention is drawn is the design of the brakes. The rubbing surfaces should be of proportionately large area, and the means of application should be easy, so that only a light touch is needed by foot or hand, with no consequent skidding or squeaking sounds; in point of fact, these are by no means as yet eliminated from certain constructors' brake systems. Means of adjustment should be accessible; on the other hand, a type of brake that is always in need of adjustment should be avoided, and one chosen that makes ample provision for wear, so that no appreciable degree of wear occurs for lengthy intervals.—*British Medical Journal,* November 8, 1913.

The Doctor and the Drama.—W. Sampson Handley notes that no actor on the English stage can give advice to youth in difficulties with such suave yet overwhelmning authority as Sir Charles Wyndham. His celebrated "It won't work" speech in the last act of "The Liars" is perhaps the best instance that can be quoted. It is the physician in him coming out, for Sir Charles, now an acknowledged head of the dramatic profession, is a qualified medical man.—*Lancet,* October 4, 1913.

A FEW PRACTICAL OBSERVATIONS THE RESULT OF 8000 EXAMINATIONS OF URINE.*

BY WILLIAM MUHLBERG, M.D.,

CINCINNATI, OHIO.

ASSISTANT MEDICAL DIRECTOR UNION CENTRAL LIFE INS. CO.

SINCE May, 1907, the Union Central Life Insurance Company has followed the plan of having all microscopical examinations of urine performed at the home laboratory of the company. Samples are required, when the amount at risk is over $10,000 or where certain facts in the insurance or personal history of the applicant indicate some urinary lesion. An average of over 1,000 samples a year, and during the past year 2,000 samples, have been examined. Two ounces of the last half of the afternoon urine are voided in the examiner's presence, who testifies to the authenticity and personally forwards the vial to the laboratory. Four grains of boric acid are used as a preservative. The microscopical examination is made of the entire sediment from 15 c.c. of the urine after centrifuging for five minutes in a Purdy centrifuge. Chemically all the tests recommended by this association are employed. Our work has brought to light some noteworthy facts and the presentation of our more important deductions may be of interest to this society.

The laboratory was originally established on account of a well-founded suspicion on the part of the medical director that very few of our examiners were capable of performing a satisfactory microscopical examination of urine—but we were greatly chagrined to learn that perhaps not more than 1 per cent. of our examiners can be relied upon to do satisfactory chemical analysis. The reason for this is twofold. The subject has not been properly taught in our medical schools, and even in our best institutions the time devoted to the subject is inadequate to instil properly the finer technical points. I know this to be true from personal experience. For several years I taught this subject at a medical school in Cincinnati, and, although I devoted more time than is customarily given to this branch, I always felt that only a minority of the class of students had really grasped the subject. Secondly, physicians have the impression that uranalysis is one of the easiest of laboratory operations. The fact is that it is perhaps one of the most difficult because we are dealing with the detection of substances, albumin, sugar, acetone, etc., that normally occur in minute traces in the urine and for which furthermore the tests are not truly specific. As a result, not only is great care required in the technique but sound judgment is needed in the interpretation of borderline cases. Were the quantitative findings a true index to the pathological condition, this would not be of great moment, but, unfortunately, in the matter of albumin at least, minute traces, verging nearly on normal amounts, are indicative of the most hopeless and insidious form of Bright's disease. In consequence of our shaken confidence in the ability of our examiners to meet our requirements in the field, the Union Central Life Insurance Company is seriously considering the plan of requiring samples of urine to be submitted by every applicant irrespective of amount, age, or previous history.

As already stated, samples are requested where certain conditions exist or have existed in the personal history of the applicant, and we have been astonished at the number of risks suffering from diabetes or nephritis that have been discovered in this way. The conditions most frequently sought after, as indicating a possible existence of these diseases, are a history of boils, carbuncles, hematuria, kidney-stone, attacks of vertigo, and recent infectious diseases such as scarlet fever, and particularly have we been impressed with the value of the question: "Do you get up at night to void your urine?" On several occasions decided traces of albumin and as much as 1 per cent. of sugar have been found in our home office analysis, where medical examiners, in whom we had reposed much confidence, had pronounced the urine normal. It is of value also in detecting cases of polyuria due to interstitial nephritis with low specific gravity and hyaline casts.

The Sample.—The medical department always insists that this be voided in the afternoon in the presence of the examiner, in two glasses, and that a portion of the second half be immediately placed in the vial which contains two tablets of two grains boric acid each, and that the mailing tube be posted by the examiner himself. The examiner is required to certify to the proper performance of this rule by signing a slip attached to the bottle which reads: "This is to certify that this is authentic . . . P.M. urine, voided in my presence by (Applicant's name) of (City) and (State). Signed by Blank, M.D." We insist on an afternoon sample. In several instances specimens of urine free from albumin, casts, or sugar in the morning, have been found to show decided traces when afternoon samples were subsequently examined. Sugar particularly is likely to be absent in the morning urine of persons suffering from mild diabetes, and the same is true to a lesser degree of albumin and casts. A second half of the sample is preferred because a considerable proportion of men suffer from chronic latent urethritis and the pus cells derived from this source are washed away with the first half and are of course of no significance. The

*Read at the twenty-fourth annual meeting of the Association of Life Insurance Medical Directors, Philadelphia, October 24 and 29, 1913.

urine must be immediately placed in the vial for two reasons—not only is preservation assured in this way but casts are more likely to be detected. We have found through experiment that if urine loaded with casts is permitted to stand a few hours, the upper half of the urine will be absolutely free from all organized sediment through the gradual precipitation and contraction of the nubecula which separates in the urine and settles to the bottom of the vessel. The supernatant urine if poured into a vial will not only be devoid of casts, but also of the normal epithelial cells. Samples received by us that contain no, or very few, epithelial cells are rejected under the suspicion that the urine was not placed immediately into the vial after voiding. The company pays postage and a fee of fifty cents for every sample sent to home office. The reason for insisting on our examiners' posting the sample is obvious. Were this done by the agent, the authenticity could not be vouched for by the examiner.

Examination for Albumin.—The tests employed by our laboratory for the detection of albumin are those recommended in the excellent paper submitted by Dr. J. B. Ogden at the eighteenth annual meeting of this society. No doubt this is the best method, but after all it has its imperfections. Practically we have found that our poorer examiners fail to detect albumin as of old, in spite of repeated instruction and insistence on the use of these tests; and in the other direction, our better examiners are inclined to find albumin where it actually does not exist in pathological amount. Checking up our own work, we have arbitrarily divided the cloudiness obtained by salt heat and acid test into four degrees. 0 represents absolutely no cloud, 4 represents a cloud which on checking up with nitric acid ring tests gives a positive trace, the intermediate figures 1, 2 and 3 represent intermediate degrees of opaqueness which are visible when the test tube is held against a dark background in a good light. Such samples do not give a reaction to Heller's nitric acid test. We believe the heat-salt and acid test if done carefully is too delicate for practical insurance examinations, and we consider the amount of albumin sufficient to call it an impairment only when there is a faint ring with Heller's test. We use the heat-salt and acid test regularly on every sample, for owing to its delicacy it places one on the lookout for definite traces of albumin which might otherwise be overlooked. Every cloud obtained with salt-heat and acid test is checked up by Heller's ring test. In the last 1,000 examinations these reactions occur in the following percentages:

0	=	49.3%
1	=	32.9%
2	=	8.1%
3	=	2.9%
4	=	6.8%

It will be seen from these figures that the reaction must be checked up quite frequently with the nitric acid ring test, which unfortunately most examiners will not do. It would be impossible to inculcate into the examiners in the field the exact degree of cloudiness acceptable for insurance work. I doubt very much whether the same interpretation is followed by any two companies—hence, in justice to the agency force, we insist on having samples sent to the home office where the examiner finds albumin, so that we may judge the matter by our own arbitrary standards combined with a careful microscopial examination. Our experience seems to indicate that albumin is found with increasing frequency in the urine of young men. No doubt the source is renal and attributable to temporary congestion of the kidney or to errors in proteid diet or in metabolism, but we have found that occasionally the albumin is derived from the prostate or Cowper's gland. It is not unusual that abstemious, unmarried young men, complain of a discharge of a clear sticky fluid from the urethra, especially after defecation. A chemical analysis of this substance discloses the interesting fact that even when highly diluted with urine there develops a typical ring with the nitric acid test, indistinguishable from that due to serum albumin. The heat and acid test with or without salt, on the other hand, is negative. Further investigations have shown this substance to be in all probability a mucin,—that is a glycoproteid rather than nucleoalbumin—although it gives some of the reactions of protamine or histones. Urine containing this secretion may or may not contain a few spermatozoa. This again shows the advantage of obtaining the second half of a specimen as it is less apt to be contaminated with this secretion.

Casts and Cylindroids.—Casts like albumin are of importance only in a quantitative sense. Examinations by our methods, show that in the last 1000 examinations hyaline casts were found as follows:—

No casts	=	72%
1 or 2 hyaline casts	=	23%
3 to 5 hyaline casts	=	2%
Over 5 hyaline casts	=	3%

The number that is obtained, however, depends upon the technique employed and the judgment of the microscopist. The amount of urine centrifuged, and the quantity of sediment examined will necessarily affect the findings. So, also, will the number vary in accordance with the criterion adopted for differentiating casts from cylindroids. We have adopted the plan of recognizing as a hyaline cast only a well-defined, slightly striated or non-striated cylinder with rounded or sharply cut ends. Marked striations, long tapering tails, or split extremities are placed in the category of cylindroids. The differentiation however is purely artificial—and must for practical purposes be more or less arbitrary. Fully 55 per cent. of the samples examined by us contain a few typical cylindroids—but as a rule there are only four to eight or ten to the entire sediment. In our opinion there is no question that the typical cylindroid like the typical cast is of renal origin. The so-called prostatic cylindroids or plugs do not resemble them either in thickness, texture, or clear contour. It is furthermore a significant fact that cylindroids are more frequently encountered in urines of lower specific gravity, indicating a possibility that they were washed out of the renal tubules before reaching their maturity as true casts. This question is of importance because every company must decide for itself how many casts to accept, and what line of demarcation to draw between casts and cylindroids. We have as a result of keeping careful record of our microscopical examinations adopted the following plan: One or two hyaline casts are acceptable, provided the urine is not of low specific gravity. Three to five hyaline casts call for two or more samples; if the same number of casts is again found, the risk is rejected. More than five hyaline casts in the sediment of 15 c.c. of urine are not accepted. Unfortunately our experience is not sufficiently extensive to enable us to investigate the mor-

tality experience of cases grouped according to the number of casts found. This study, however, will be made in the future. We are convinced from the subsequent history of the limited number of applicants showing more than five hyaline casts in the urine by our technique, that they are not good risks. Of the significance of cylindroids and mucin threads, we know practically nothing, but we have found that where they occur in excess, as they do in about 5 per cent., subsequent samples will often disclose numerous casts and traces of albumin. We have under observation at present, a patient suffering from undoubted nephritis, in whom at times the casts, which are usually very numerous, will be almost entirely replaced by typical cylindroids and a dense network of mucin threads. This experience has taught us forcibly that uniformity of results in microscopical examinations can be obtained only where the work is done according to a fixed standard—and this can be obtained only through home office laboratory examinations.

Sugar.—There is no doubt that diabetes is increasing in prevalence. This may be attributed partly to the increased nervous strain and stress of modern life and partly to the tendency towards overeating and lack of exercise. The mortality statistics issued by the Department of Commerce and Labor—Bureau of Statistics—indicate this very clearly. The death-rate from this affection has gradually crept up from the year 1900, during which year the deaths are represented on a 100 per cent. basis, to 142 per cent. during the year 1909. And this has occurred in spite of the earlier recognition, the marked results from improved therapeusis and gradual unfolding of the true pathology of this affection through the splendid researches of our pathologists and clinicians. Like arteriosclerosis, diabetes seems to be making its ravages among the better element of the population and therefore is particularly noticeable among insurance risks. We have noticed this tendency in our laboratory work. Sugar is found in a greater percentage of samples at present than six or seven years ago. Unfortunately the same criticism that was made of the tests for albumin applies to those for detection of sugar. We employ the Fehling method recommended by Dr. Ogden and in our opinion it is the best. In spite, however, of our careful instructions, we find that even our best examiners will fail to detect sugar in urine containing less than ½ per cent., and the difficulty arises from imperfect technique and the confidence that most examiners have that the operation is too simple to admit of mistakes. It must be confessed that the detection of small amounts of sugar varying from 1/10 to ¼ per cent. is not easy, especially since concentrated normal urine, sugar free, will at times show a reduction of Fehling's equivalent to ¼ per cent. of sugar. We have practically discarded the phenyl hydrazin test as a check against our Fehling's. For some reason or other—and this observation is not at all original—phenyl hydrazin will occasionally fail to precipitate the typical osazone crystals even where pathological amounts of sugar are present. In our experience, the osazone compound is probably formed but fails to crystallize and the absence of the typical crystals leaves one in doubt. Instead, we are using the fermentation test. It, too, has its shortcomings, inasmuch as the degree of acidity of the urine and the presence of sugar in the yeast itself slightly influence the findings. But we have found that it is sufficiently delicate—less than 1/10 per cent. can readily be detected thereby. Our method is as follows: An ordinary bacteriological fermentation tube is filled with urine in which a piece of Fleischman's compressed yeast, the size of a pea, has previously been macerated. This is poured into the tube and a few minutes are allowed to intervene so that bubbles formed by the maceration may be permitted to escape from the tube. Enough mercury is then introduced to flood the elbow of the tube which is then placed in the incubator for twelve to twenty-four hours. A bubble, the size of a split pea, indicates, according to our experiments, less than 1/10 per cent. of sugar and is accepted. The method is easily performed, sufficiently delicate, somewhat time-consuming, and more quantitatively accurate than the osazone test. In addition, pentoses and free glycuronic acid are not disturbing factors since they do not ferment.

Acetone.—The relationship of acetone to glycosuria is an interesting one and we believe from the insurance standpoint an important one. Without attempting to go into the pathology of this condition, or even to hazard an opinion on the technical pathological points under controversy in connection with it, it might be well to preface our remarks by sketching some of the accepted facts bearing on acetonuria. In a general way, it may be said that acetone appears in the urine whenever there is an interference with the proper combustion of carbohydrates in the body. This can be brought about either by curtailing the ingestion of starches or sugars, as occurs in starvation, fevers, etc., or by the inability of the tissues to metabolize the glucose circulating in the blood, as in diabetes. Normal persons will suffer from acetonuria if the amount of carbohydrate in the diet is reduced to 75.0 grams per diem—which represents about 30 per cent. of the average daily intake in the usual diet. A few substances like alcohol, etc., possess an antiketogenic function of partially neutralizing the acidosis. In diabetes, acetone begins to appear in the urine particularly when the patient cuts down his carbohydrate food. In the milder forms, where 100.0 grams of starch may be consumed without production of glycosuria the urine, of course, will be free of acetone. But in the medium or severe grades of diabetes, the urine will never be either sugar free or actone free at the same time. Care in the selection of the diet, and alkaline treatment and consumption of anti-ketogenetic substances may limit it somewhat, but practically, this may be disregarded. Therein lies the importance of acetone test from the insurance standpoint. We know two persons in Cincinnati, diabetics for years, who have obtained large lines of insurance since they have become cognizant of their conditions. In both instances, their physicians assure me that rigid diet rendered the urine sugar free, but acetone was always present. We have every reason to suspect that we have unearthed five or six cases of a similar nature through our search for acetone. We make a routine practice of doing this test particularly where it appears that sugar has previously been found in the applicant's urine and while the effort to frustrate one attempt to defraud, among perhaps a thousand bona fide samples, may seem like the rewinnowing of old chaff, we believe, especially in larger applications, that the results justify the extra work.

Test for Acetone.—We have found that the test ordinarily employed by physicians to detect acetone, to be of no value, unless the urine is distilled.

Neither Legal's, Chautard's nor the iodoform test will detect small quantities of acetone when performed with urine without distillation. After distilling, the iodoform test (Lieben's) is very satisfactory provided the detection is made by examining microscopically for crystals in form of hexagonal plates or small stars rather than by the odor of iodoform. We have found that 15 c.c. of urine suffice. 2 c.c. of the distillate is treated with dilute of potassium hydrate solution and Lugel's solution, permitted to stand about fifteen minutes and examined microscopically. Normally, urine will show about five or six iodoform crystals at the most to the high power microscopical field. This we have ascertained by performing the test several hundred times. As a rule, when true diabetes exists, the crystals are very numerous. This test although reliable is time-consuming and recently we have experimented with Frommer's test which may be applied to the urine direct. This test is described by Dr. Jacob Rosenbloom in the *American Medical Association Journal*, date August 10, 1912, as follows:

"About 10 c.c. of urine are treated with about 1 gram of sodium hydroxide in substance, and, without waiting for it to dissolve, ten or twelve drops of a 10 per cent. solution of salicyl aldehyde in absolute alcohol are added. The mixture is heated to 70° C. In the presence of acetone a marked purple red color develops at the zone of contact with the alkali. Frommer asserts that this test can indicate the presence of 0.000001 gram acetone in 8 c.c. of water."

We have found that unless the urine is diluted so that its specific gravity is reduced to about 1010, confusing colors occur that render interpretation difficult. When properly diluted, however, urine containing only minute or normal quantities of acetone will give after ten or fifteen minutes standing only a straw or faintly pink color. Checking the reaction against the iodoform test it has been found very reliable. The advantage of course lies in its simplicity, delicacy, and the rapidity with which it can be done when applied to urine direct.

In conclusion we wish to emphasize the importance of having samples examined at the home office laboratory by a trained expert, where uniformity of methods employed enable the medical directors to have thorough confidence in the findings as given in the report.

In presenting this paper, I take pleasure in acknowledging the collaboration of Dr. Wm. O. Pauli, who for the past three years has conducted our laboratory work.

SOLVING THE MYSTERY OF BRIGHT'S DISEASE.

A PRELIMINARY PAPER.

By JOHN AULDE, M.D.,

PHILADELPHIA, PA.

Instead of an excuse for presenting a condensed paper on Bright's disease, it will be in order to advance certain reasons, as follows: (1) Increasing frequency of the disease; (2) A novel hypothesis as to the causation; and (3) A summary of the effects of treatment in typical cases.

Prevalence of the Disorder.—This study was begun in 1898, at which time personal letters addressed to the proper officials in different cities brought eight replies, the data for ten years preceding being recorded in Tabulation I. Several months ago a letter addressed to the United States Census Bureau, Washington, D. C., brought a communication from Dr. Cressy L. Wilbur, Chief Statistician, together with the statistics embraced in Tabulation II, covering the period from 1900 to 1911, inclusive.

A casual glance at these tables shows such an enormous increase that comment is withheld for the present. To assume that this alarming condition of affairs is due to advanced methods in diagnosis would be a gratuitous insult to the medical profession—but there is a reason. To develop more fully the increasing frequency of kidney disease, as shown by the mortuary statistics, Tabulation III has been added. Thus, comparing the first period with the second, we find the increased percentage of deaths ranges from 217 in San Francisco to 539 in Cincinnati, the average for the eight cities being 370 per cent., a rate altogether out of proportion to the normal increase in population.

Causative Factors.—A critical study of such a complex problem as Bright's disease should include an inquiry into the causative factors—in order that our deductions relating to treatment shall be in line with recognized anatomic, physiological and chemical principles. The early investigations of Dr. Bright (1827) were comparatively meager in respect to pathology—the presence of albumin in the urine and usually the coincident dropsy. He recognized two types or varieties, the acute and chronic, the first being inflammatory, the latter the degenerative form of kidney disease. Precisely the same conditions obtain to-day; hence, it is no disparagement to Dr. Bright when it is stated that he merely discovered one of the defects arising from disordered metabolism. Thus, while the name Bright's disease is still retained as a generic application, it by no means covers disorders of the kidneys as completely as nephritis, the latter being found under a multiplicity of varying conditions, acute and chronic, with and without albumin or dropsy.

It would not be profitable to discuss here the character or peculiarities of the histological changes taking place in nephritis, nor the associated symptoms and complications, because this information is available in text-books and special monographs. The object of the present paper is to discover and demonstrate a fundamental basis for the evidence elicited by microscopic investigation in all cases of nephritis—in other words, to solve the mystery of Bright's disease. For example, the protoplasmic cell is now acknowledged as the physical basis of life—and it possesses or presents the peculiar characteristics, namely, nutrition (assimilation), excretion, motility, reproduction, and response to stimuli, each and every one of these life characteristics being attended with or dependent upon demonstrable chemical changes.

Following up this inquiry, it must be apparent that the potentialities of the chemical basis of life far exceed in importance the purely physical features. From the chemical viewpoint, life consists of synthesis and decomposition, hydration and dehydration—in short, life is oxidation, and, therefore, we can assert that life has also a gaseous basis, since none of these changes can take place without oxygen. To condense the argument, we may say the protoplasmic cell represents the unit in both animal and plant life, the physical as well as the chemical basis. Whatever is true or demonstrable as regards protoplasm, in respect to func-

tion and structure, therefore, is equally applicable to an organ, to selected tissue, including nerve tissue and to the body as a whole, because we cannot draw a line of demarcation showing where cellular activity is supplanted by somatic or body function.

Such being the case, it follows that both function and structure may be impaired by or through chemical changes involving the protoplasmic cell. Thus, digestion is a chemical as well as a "vital" process; the same is true of metabolism. Both are dependent upon the functional activity of cells and all function is, in turn, vitally affected by organic and inorganic chemical changes. Experimental and pathological investigations have enabled us to determine with a considerable degree of accuracy the daily intake as well as to the daily outgo of the body, so that we can estimate the percentage of deficiency when certain organs are diseased. This is notably true in the case of kidney diseases, although, unfortunately, kidney diseases are treated as if they were confined to that organ alone.

The modern conception of nephritis is rather hazy, when studied from the scientific viewpoint, because it assumes the presence of poisons which are non-existent. While it is not denied that toxins, both intrinsic and extrinsic, may set up a nephritis, there is ample proof to demonstrate that the vast majority of cases arise from certain chemical deviations in the body fluids—blood and lymph—and tissues, all of which is outlined in the accompanying diagram. An effort has been made to indicate in the order of their occurrence the causative and consecutive factors, and also the ultimate effects.

A brief explanation is in order to explain the term *"acid excess."* It is employed provisionally to designate a diminished alkalinity of the blood—in fact, acidemia might be used instead. And here, again, we run counter to the chemical function of the protoplasmic cell—it possesses the capacity of eliminating urea, carbon dioxide, phosphoric and sulphuric acids—all normal products of tissue respiration. Add to this the acids arising from muscular activity, voluntary and involuntary, together with the acids incident to impairment of the digestive capacity, such as indican and bacterial toxins, and we have a formidable array of possible chemical deviations in the body fluids and tissues. The ultimate effects of acid excess must be taken into consideration, therefore, in the treatment of all diseases, acute and chronic, functional and organic, whether infectious or non-infectious.

Although brought to my attention only a few days ago, it is gratifying to announce that the celebrated Pasteur had anticipated my findings as regards the deleterious effects of acids. When the wine-producers of France reported that their wines decomposed without apparent cause, Pasteur's investigations showed that decomposition was due to the presence of acids—which permitted or favored the growth of microorganisms. By sterilizing the wine in a vacuum, decomposition was prevented, while the palatability and bouquet were unaffected. The admission of atmospheric air, however, was fatal to the quality. The outlook was so favorable that Pasteur, in 1865, took out a patent on his process, but later released it, when it was found that fermentation could be conducted successfully without permitting the acid formation. So, in this instance, prevention was better than cure—and the writer believes the same tactics in Bright's disease will solve the mystery of its onset, since neutralization of acid excess in the human economy suffices to arrest its progress.

III.

TABLE SHOWING THE RELATIVE INCREASE OF BRIGHT'S DISEASE

First Period, 1888 to 1897; Second Period, 1900 to 1911

City	1888 to 1897 incl.		1900 to 1911 incl.		Increase, Per Cent.
	Total	Average	Total	Average	
Boston	1,459	145.9	6,350	529.2	362
New York	19,264	1926.4	76,942	6411.8	332
Philadelphia	4,751	475.1	27,168	2264.0	476
Chicago	3,813	381.3	24,344	2028.7	532
St. Louis	2,869	286.9	9,758	813.2	283
Cincinnati	833	83.3	5,389	449.1	539
New Orleans	2,879	287.9	7,794	649.5	225
San Francisco	1,971	197.1	5,136	428.0	217

With these explanatory remarks, the reader will be able to grasp the significance of the data presented to the accompanying tabulation, intended to show the causative and consecutive factors incident to the development of the malady.

IV—DEVELOPMENT OF BRIGHT'S DISEASE NEPHRITIS)

DIAGRAM SHOWING THE CAUSATIVE AND CONSECUTIVE FACTORS WITH ULTIMATE EFFECTS

Causative ..... { *Toxins* ... { Suppuration (Catarrh); Infectious diseases (Bacteria, etc.); Autoinfection (Cytotoxins) } ; *Disordered Digestion* ..... { Sloppy dietary; Nitrogenous foods; Magnesium excess }

Consecutive..*Acid Excess* ... { Diminished alkalinity of the blood and lymph; Demineralization (Calcium depletion); Impaired metabolism (Tissue-change) }

Ultimate Effects..*Magnesium Infiltration* .... { Simple replacement; Chemical transformation; United with calcium }

The ultimate effects in the form of magnesium deposits will be understood by reference to the above tabulation. For example, it must be evident to the most casual observer that a sloppy dietary will seriously impair the digestive capacity. Again, nitrogenous foods (meats), are recognized as being responsible for acidosis. While there is no literature relating to the deleterious effects of foodstuffs containing magnesium in excess, it requires but little investigation to prove that such foods seriously affect the digestive apparatus, because they obtund sensation. We have an excellent illustration of this in the employment of calcined magnesia for the relief of acute bowel troubles in children—it relieves pain by obtunding sensation.

Next in order we must study the effects of a diminished alkalinity of the blood; it leads to demineralization—and the pivot upon which demineralization turns is centered upon calcium depletion. For example, when calcium depletion takes place as a result of acid excess, there is coincident or consecutive substitution by magnesium—sulphate, phosphate, carbonate, oxide. The presence of magnesium in excess impairs metabolism; that is to say, it hinders tissue change or tissue respiration. So far, my investigations warrant the claim that magnesium infiltration or substitution occurs under three separate conditions when studied from the chemical viewpoint. In the case of children suffering from acute bowel troubles, the calcium depletion permits replacement; in the case of neuritis, neuralgia, neurasthenia, and heart disease, we have a chemical transformation, a union of magnesium with the colloid structure of the nerve, and, of course, this chemical transformation extends to the protoplasmic cell.

In studying the effects of magnesium infiltration upon the heart mechanism, I have designated this heart trouble *the magnesia heart*. On the same principle, we might refer to Bright's disease and nephritis as *the magnesia kidney*, because in every instance a diminished alkalinity of the blood, together with the highly acid urine, has led to calcium depletion with the substitution of magnesium. Proof of this is to be found in the results of treatment conducted for the purpose of promoting magnesium dissociation.

In this connection it would be interesting to study the third division of the classification adopted, magnesium united with calcium, because we so frequently find this condition present in the kidney of those who have long been under specific treatment, in which mercurials constitute the principal ingredient. Mercury depletes the lime from the bones, and there is a tendency to its accumulation in the kidney structure, so that we have various forms of calculi. Of course, it will be difficult for the general practitioner to understand this theory of magnesium infiltration, and it would be equally difficult for him to conduct treatment in a case without careful study of the physical and chemical principles advanced, but Pasteur had the same difficulty. Some years after the occurrence previously mentioned a committee of medical men and scientists was appointed by the British government to visit Pasteur's laboratory in Paris and learn something definite from personal observation as to the correctness of his deductions on the subject of germs. Every member of this committee was at that time a non-believer in the germ theory; they were not only skeptical, they were prejudiced, and regarded the proposed trip as utterly useless. However, after a thorough inspection of Pasteur's work, the committee returned to London, every man being thoroughly convinced that Pasteur's solution of fermentation was complete and unassailable. And, so it is hoped, will be the fate of the working hypothesis of magnesium infiltration.

Treatment.—The hypothesis of magnesium infiltration simplifies the medical treatment of kidney diseases in a marked degree—inasmuch as we assume a common pathology. In fact, there is no essential difference between the treatment of "magnesia kidney" and that of "magnesia heart," aside from medication conducted to counteract the effects of bacterial invasion. Hence, a summary of the treatment outlined for the "magnesia heart" ("The Chemic Problem in Nutrition") will afford a fairly complete exposition of the plan, as follows:

(1) *Restore the digestive capacity* by a suitable dietary, together with the employment of appropriate remedies for the purpose of correcting functional defects, sepsis and excessive bacterial flora. This is not a difficult problem to solve—the dietary should be limited rather than restricted; it should not be "sloppy," and unless the taste is perverted by narcotics, or the mind diverted by advertisements, we can trust the stomach to select a "balanced ration," in respect to proteins, fats, and carbohydrates.

(2) *Neutralize acid excess,* the chemical deviation, the consecutive factor which is responsible for the calcium depletion and impairment of metabolism—easily accomplished by the administration of suitable alkalies. Apparently, it is a very simple proposition, dealing with physiological chemistry, but we must not overlook, or be misled by, nature's efforts in this direction—when nitrogen in the form of ammonia is drawn from the body fluids and tissues to correct the acid excess and *make the cells work.*

(3) *Promote magnesium dissociation* by the internal employment of calcium salts, carbonate, phosphate, or sulphate—alone or combined with iodine to act as an alterative upon the organic deposits which impede, hinder, or destroy the capacity of the nerves for the uninterrupted transmission of impulses. The average daily intake of calcium for adults ranges from 10½ to 15 grains, but a sloppy dietary, or a dietary which impairs digestion and produces "acidity" will cause a daily loss of as much or more. Perhaps this will account for prolonged convalescence, for many acute ailments, for "nervousness," for insanity, because it does explain the cause of Bright's disease—calcium depletion and magnesium infiltration are the ultimate effects of acid excess.

V—INTERSTITIAL NEPHRITIS (BRIGHT'S DISEASE)—URANALYSES*
TABULATION SHOWING RESULTS OF TREATMENT ON THE HYPOTHESIS OF MAGNESIUM INFILTRATION

Date, 1913	Reaction	Specific Gravity	UREA		Albumin	Sugar	Indican	Remarks
			Per Cent.	Ounces				
February 24..	Alkaline	1.026	2.3	11.5	Trace	None	Little	Over 5,000 granular and hyaline casts to the ounce.
March 14..	Acid	1.033	3.1	15.5	Trace	None	Little	Casts—2,000 to the ounce. Considerable pus—vaginal (?)
April 4..	Acid	1.034	3.8	19.0	Trace	None	Not much	Many waxy and hyaline casts—some granular—2,500 to the ounce.
May 7..	Acid	1.026	3.0	15.0	Trace	None	Not much	Total in 24 hours, 80 ounces, making urea output 1,200 grains daily. Over 500 casts to the ounce.
May 29..	Faintly alkaine	1.024	1.9	9.5	None	None	Little	No casts—no albumin.
August 1..	Acid	1.020	2.7	13.5	Trace	None	Not much	Not over 100 hyaline casts to the ounce.
September 8..	Acid	1.024	2.3	11.5	Trace	None	Not much	Over 100 casts to the ounce—hyaline; some with epithelia; others, coarse, granular matter.
October 9..	Alkaline	1.026	2.3	11.5	Trace	None	Not much	No casts; sediment mainly mucus.

*Examinations made by Paul H. Langner, Ph.G., Clinical Chemist, Philadelphia, Pa.

In the treatment of nephritis we have *three reliable landmarks,* not only in regulating medication, but also in determining progress—also valuable prognostic aids. For example, the subjective symptoms are notably significant—if the patient *feels* better from time to time, the outlook is favorable. However, we can check up the objective symptoms, such as the condition of the digestive apparatus, acton of the heart and character of the pulse, and if deemed necessary, the blood pressure—and last, but not least, the salivary and cutaneous reactions, and the reflexes, the knee-jerk for example. Finally, we have the examination of the urine, showing diminished loss of albumin, increased output of urea, while the casts rapidly decrease in number—and in typical cases disappear altogether.

The above tabulation shows in the most graphic manner the clinical evidence in favor of the hypothesis advanced. The patient is a female, age fifty, married, no children, and had been under medical treatment for three years. There were present all the usual symptoms—nervousness, cardiac embarrassment, insomnia, neuritis; in short, general debility, while the urinary test showed over 5,000 hyaline and granular casts to the ounce, with but a trace of albumin, and alkaline reaction. Edema of the extremities was but slight. Notwithstanding the unpromising outlook within two weeks the urea output had increased 50 per cent., while the casts were reduced to 2,000 per ounce—and within three months had entirely disappeared. The reappearance of casts and albumin should not be charged against the plan of treatment. Rather, it is offered as a crucial test, since this patient has been in almost constant attendance upon her mother, slowly dying from a malignant disorder. And besides, we must bear in mind that it is rare to find normally acting kidneys at the age of fifty years.

1305 ARCH STREET.

THE TREATMENT OF PNEUMONIA BY BACTERIAL VACCINES.*

BY HENRY A. CRAIG, M.D.,

NEW BRIGHTON, N. Y.

PATHOLOGIST, BACTERIOLOGIST AND ADJUNCT ATTENDING PHYSICIAN, S. R. SMITH INFIRMARY, S. I.; BACTERIOLOGIST, ST. VINCENT'S HOSPITAL, S. I.

PNEUMONIA pathologically is a septicemia. It is a systemic disease and not merely an inflammation of the lungs. The infecting organism, the pneumococcus, multiplies in the circulating blood. All the symptoms of a pneumonia, even the dyspnea, may be present in a pneumococcus infection without any lesions in the lung. They are due to the endotoxins set free from the pneumococci acting upon the nerve centers, heart, etc. When mice are experimentally inoculated with the pneumococcus, they develop an intense fatal septicemia with dyspnea, etc., but consolidation of the lungs does not occur. The human lung is still solid when the crisis occurs but the dyspnea stops because the pneumococci have disappeared from the circulating blood and the endotoxins have been neutralized by the antibodies manufactured by the body. The battle between the body and the pneumococci is at an end, the battlefield being cleared up later.

The most frequent first symptom of lobar pneumonia is a rigor. *X*-ray pictures have shown that the rigor occurs before any consolidation of the lungs. The rigor is an indication that the pneumococci have developed in the blood of the patient, having entered generally through the upper respiratory tract, to a sufficient point of saturation to cause a reaction on the part of the body. The pneumococci cause actual injury to the cells of the body, so that the body must rally her forces to her defense or be destroyed. Who can say how often a few pneumococci, which are so very common in our respiratory tract at this season, do actually get into our blood and are killed by the phagocytes before they reach a sufficient concentration to cause any definite reaction on the part of the body.

Pneumonia does not develop, because the body is able to cope with the invading pneumococci without making any great fuss about it, *i.e.* without being forced back to her last line of defense, the production of the lesions in the lungs.

Pneumonia is a battle between the body and the pneumococcus which has invaded the blood of the victim. The body, being the challenged member of the duel, can choose the weapons and the site of the battle. Therefore it chooses the lungs which are an ideal site, for all the blood must time and again pass through the lungs. The pathological changes that now occur, congestion followed by consolidation, indicate nature's attempt to localize the infection in the lungs. The bacteria are filtered out of the blood current and held enmeshed in the fibrin precipitated from the blood serum, so that the ever vigilant leucocytes can crowd out among the imprisoned pneumococci and devour them. This is much more to the advantage of the leucocytes than in the swiftly moving blood current. The leuco-

*Read before the Richmond County Medical Society, October 8, 1913, as part of a symposium on the management and treatment of pneumonia.

cytes are the soldiers in the fight, a great standing army of forty or fifty thousand million in the average person and able to be doubled or quadrupled at a short notice. But the soldiers must have weapons. If some bacteria and washed leucocytes are mixed, nothing happens; but add some normal blood serum, which contains a substance called opsonin, and under the microscope the leucocytes can actually be seen eating up the bacteria. Opsonins are necessary to so prepare the bacteria that the leucocytes can devour them. The blood serum constantly contains to combat the various bacteria more or less of opsonins, either inherited or acquired as the result of previous infections, perhaps very mild ones that have passed unnoticed. But these are not sufficient in case of such an invasion as a pneumonia and the body must hasten and manufacture more or the defense will fail. This is, no doubt, what occurs in some fatal cases in which the leucocyte count is high and the opsonic index low, showing a large number of soldiers but these imperfectly armed. Then after the production of sufficient opsonins, proper phagocytosis, etc., the body must, in addition, manufacture antibodies to neutralize the endotoxins set free by the disintegration of the pneumococci or again the defense will fail. These antibodies seem to be inoperative until they reach a certain degree of concentration. This is what happens when the crisis occurs; the endotoxins are suddenly neutralized and all the symptoms rapidly disappear. These opsonins, antibodies, etc., are manufactured chiefly by the fibrous tissues of the body under the stimulation of toxins, vaccines, etc. This is our cue in the treatment of pneumonia by the various biological products—vaccines, sera, leucocytic extract, etc. We are attempting to assist nature along her own chosen line of defense.

Antipneumococcus serum is not like diphtheria and tetanus antitoxin for it is not antitoxic. The difficulty is that the pneumococcus does not produce a soluble extracellular toxin as do the latter, which can be injected into some animal and cause the production of antitoxin, which being recovered from the animal can be used therapeutically to produce a passive immunity to the disease. This is an ideal procedure. Our present pneumococcus serum is bactericidal not antitoxic, but it should assist the body in killing off the pneumococci. It has the advantage that it can directly attack the pneumococci and not simply stimulate the body to do so as a vaccine does. The perfect serum would be one both bactericidal and antitoxic. In desperate cases it should be tried as it promises more then than does a vaccine which would not have time to work.

Reports as to the treatment of pneumonia with leucocytic extract are very encouraging. It acts chiefly by increasing phagocytosis. The disadvantages are the expense of the treatment, the large doses necessary, and the pain produced by the inoculations. The great advantage is that it is suitable for any infection and always ready for use without requiring any bacteriological skill as does vaccine treatment.

Vaccine treatment is based upon the fact that the injection of a proper vaccine causes the production of an active immunity to the corresponding infection. It stimulates the body to increased production of opsonins and antibodies and therefore is a proper scientific treatment, for it is a direct imitation of nature's methods. Recovery from a pneumonia requires the destruction of the invading pneumococci and the neutralization or elimination of the endotoxins set free by the disintegration of the pneumococci. This is just what a vaccine assists the body to do. Some observers state that vaccine treatment has no place in the treatment of a systemic infection and should be used only in case of localized infections. They argue that in a general infection the body is already overwhelmed with the bacteria and their toxins, and how can the injection of a little more of the dead bacteria help out the situation? Naturally the results are not as good as in cases of localized staphylococcus infections, where the treatment is practically specific, for we have a worse situation to deal with. The object of treatment by bacterial vaccines is to stimulate the increased production of opsonins and antibodies and, as stated above, it is the fibrous tissues of the body that are particularly active in doing this. There are no other means that can do this as well as the injection of a proper dose of a proper vaccine. Particularly as it is injected into the subcutaneous fibrous tissues, which is very active in this respect. Also these tissues, not being actually engaged in the contest, are in a better condition to respond and flood the blood serum with the necessary opsonins and antibodies. The site of the lesion, the lungs in this case, are more or less overwhelmed by the toxins and therefore not as well able to produce the opsonins and antibodies as a distant part of the body. It brings new tissues into the fight as reinforcements. The fact remains that the increase of opsonins, antibodies, agglutinins, etc., after the injection of a vaccine, can actually be measured. And these measurements afford an exact record of the measure of resistance of the patient to the disease. In addition, the injection of a vaccine increases the production of leucocytes, thus adding reinforcements to nature's forces. This can but do good by increasing the soldiers available for the fight. A lack of leucocytosis is a very bad prognostic sign in pneumonia.

An autogenous vaccine, that is one made from the patient's own particular infection, is naturally better than a stock vaccine, for there are many varieties of the pneumococcus and the opsonins are specific even to the subdivisions of an organism. A polyvalent stock vaccine gets about this difficulty to a certain extent but imperfectly, as the dose of the right variety, if present, would be too indefinite. It is to be remembered that the pneumococcus is a close relative of the streptococcus and in many cases is associated with it. Many of the cultures show both and sometimes it is not easy to distinguish between them. Therefore in treating pneumonia with stock vaccines it is advisable to give both.

The keynote of the treatment of pneumonia by vaccines is early administration. It is not a method suited for late desperate cases. If given early the body is stimulated to produce an excess of opsonins and antibodies, the leucocytes are probably already adequate or the vaccine will help make them so and the pneumococci can be killed before they reach such tremendous numbers that in their destruction such amounts of endotoxins are set free as to greatly injure the heart, kidneys, nervous tissues, etc., before they are neutralized or excreted.

The early administration of a proper vaccine can hardly fail to be productive of good in a large percentage of the cases. The writer has had a number of cases where the vaccine was given within a few hours of the initial chill and, though the diagnosis was beyound question, the whole process was

over in 48 or 72 hours. Many other observers have reported similar occurrences. The patient, in such cases, has a pneumonic infection as shown by positive blood cultures, alveolar sputum alive with pneumococci, etc., but a real pneumonia does not have time to develop to the stage of consolidation; for the body is able to kill the invading pneumococci without being forced back to her last line of defense —the production of a pneumonic process in the lung, which, in so many cases, fails of its purpose, the victim being destroyed in the attempt. The other biological products should act in the same way, as do strictly medical measures at times. Many physicians no doubt have had cases in which they have felt certain that they had aborted a pneumonic infection but hardly dared call it a pneumonia as consolidation did not have time to occur, the lesions in the lung merely reaching the stage of congestion. I maintain that we should make this occur more often than it does by every means at our disposal, not the least of which is the proper use of a vaccine. Our early eliminative procedures and supportive measures tend to help nature to accomplish this purpose but they do not succeed often enough. If someone could discover a specific chemical substance for the pneumococcus of the nature of salvarsan, the early administration of this would abor our pneumonic infections before a pneumonia developed.

The best method of procedure, though all observers do not agree to this, is to administer a polyvalent stock vaccine of the pneumococcus and streptococcus, of each thirty million, at as early a date as possible. Make sputum smears and cultures, blood cultures in early cases, lung puncture in late ones, and proceed to the preparation of an autogenous vaccine. If there is no definite response in 24 or 48 hours, repeat or preferably give an autogenous vaccine. If there is no response in 36 or 48 hours, double the dose. If there is a response, as evidenced by improved clinical symptoms and signs, increased well-being of the patient, etc., defer reinoculation three days or until the first symptoms of retrogression in the general condition or the physical signs occur. Maintain the dosage or increase it every two or three days until the patient is entirely well. Generally about three doses are necessary.

As to results, they are certainly an improvement on all other methods of treatment. For we should use all other means that we have found of benefit in conjunction with the vaccine treatment. Vaccine treatment, properly carried out, is capable only of good. Hundreds of cases have been reported with an average mortality of 5 to 10 per cent. The mortality from the old routine treatment is still 16 to 20 per cent. and in alcoholic cases, nearly 50 per cent. in some epidemics. In twenty consecutive cases, seen by the writer in private practice, there was but one death. In hospital practice, as a rule, the cases are not seen early enough and a pneumonia is well developed before we can see them. Still last winter at Smith Infirmary, in the service of Dr. Mord, where we used it in every case, we had many remarkable cases and many recoveries where the prognosis seemed very bad. Figures are of little value unless they consist of a great many cases and the writer can not quote enough of his own cases to sound very convincing. But I feel assured that in considerably over a hundred cases so treated, I have observed that the disease runs a shorter course, the patients are less toxic, there is less fever, and generally no delirium occurs except in alcoholic cases. Convalescence also is shortened and the danger of complications is lessened. Best of all, more of the patients get well.

One should remember the advice of Wright, the originator of the method of treatment, to give citric acid in severe cases of infection. A certain amount of increased viscosity of the blood is a good thing but, as in many other cases, nature sometimes overdoes a thing. In the bad cases of pneumonia, the viscosity of the blood becomes too great, resulting in impeded circulation, lymph stasis, etc. Hence in these cases, large doses of citric acid are necessary to diminish the viscosity of the blood and lymph. Twenty to thirty grains may be given every two to three hours.

In conjunction with the vaccine treatment, emphasis should be made upon the importance of supporting the patient by proper nourishment, judicious stimulation, good nursing, etc. Of assisting elimination of the toxins by the bowels, kidneys, skin, etc., of keeping up the blood pressure, of sparing the heart from needless strain, and carefully tiding it over the period of greatest stress. For the immunity produced by vaccines is an active immunity. They simply stimulate the body to manufacture the necessary opsonins and antibodies, so that the body must be kept in as good condition as possible to do it.

46 Franklin Avenue.

THE DETERMINATION OF CHANGES IN THE PAIN SENSATION.

By GUSTAV F. BOEHME, JR., B.S., M.D.,

NEUROLOGIST AND SURGEON TO THE WEST SIDE GERMAN HOSPITAL AND DISPENSARY; CLINICAL ASSISTANT IN NEUROLOGY, VANDERBILT CLINIC; CLINICAL ASSISTANT, NEUROLOGICAL INSTITUTE, ETC.

Pain is defined as "suffering," "a disagreeable feeling," as "distress." How inadequate these synonyms, these groups of words! Who can in terms express or describe it? Subjectively any one of the above phrases will to some extent cover the significance of the feeling as expressed by any one who has a subjective phenomenon which he describes as painful. Here, however, we are dealing with a cutaneous manifestation, a condition induced by the action of certain physical stimuli on the skin of the individual and either recognized as an entity by the observer, or denied as such, and declared as part and parcel of common sensation.

We would, however, consider the subject as divided into two and attempt to separate the pain sensation as such, from a group of painful (disagreeable, distressing) sensations, and point out certain fallacies in the determination of the pain sensation, and to advocate a specific and constant method of its determination. For simplicity of study the following classification will be of assistance.

A. *Painful Conditions* (where painful means unpleasant, distressing, disagreeable): (1) Increased tactile sensations becoming painful. (2) Increased thermal sensations becoming painful. (3) Increased pressure sensations becoming painful. (4) Increased electrical sensations becoming painful. (5) Increased chemical sensations becoming painful. (6) Muscular and arthritic painful conditions. (7) Visceral painful conditions. (8) Painful conditions in bone and periosteum. (9) Painful conditions in the nerves.

B. *The True Pain Sense* (cutaneous sensibility of pain), which does not correspond in any sense, except painfulness, as meaning distressing, etc., with "painful conditions."

The question now arises whether the "painful" (unpleasant, disagreeable) sensations are identical with, or a separate entity from the cutaneous pain sense as known by the neurologists. We would hold distinctly that this is not the case, and that both should be separated distinctly.

Of the painful conditions mentioned, the first three, painful tactile, thermal, and pressure sensations will here, for brevity, be considered together, but under no condition must it be understood that these three sensations are the same or even transmutable into each other. In some conditions it is of assistance to employ the words of our patients. In all three conditions they will exclaim "it hurts," not "it pains" or "it feels sharp or dull." In one they say it doesn't hurt exactly, but it feels unpleasant; in the second they most frequently and constantly exclaim, "it burns, it freezes," making a distinct separation of the sensation produced from that of pain; in the last they declare that "it squeezes terribly," that "it presses so that it hurts." No declaration here of pain, of sharpness, of dullness; no reference in any way to the sensation we attempt to obtain when we prick our patient with a pin or pinch his skin (which method of eliciting pain is to be discussed later). If then our patient's minds act unconsciously in this manner, and separate each of these sensations, why should we declare them to be one? And yet some one will declare that it is the ocular or aural knowledge of what is being done which assists them in making the differentiation. This is not so. Let a rapidly rotating brush strike a patient's skin without his seeing it: does he declare the unpleasant tactile sensation to be a "pain" in the sense of a disagreeable sensation or as a distinct pain sense disturbance? Invariably the former is the case. Apply the ethyl chloride spray to the back of a patient—does he complain of the pain as such or of a painful sensation which he describes as "freezing"? Let the Paquelin cautery run along the most painful sciatic nerve area; is it pain that the patient objects to, or the sense of burning? Apply a tourniquet around the arm of the salvarsan patient too firmly, and he complains, not of pain, but of a painful sensation of tightness; he tells you that it binds. Certainly in none of these conditions can the identity of the pain sense and painful (distressing, unpleasant, etc.) sensations be affirmed. Pain is a subjective condition, and who, better than the individual suffering therefrom, can distinguish between its varieties (that is if we use the term loosely as it is commonly applied).

And how frequently in examining a patient do we ask him to differentiate its varieties. "Is it a sensation of tightness?" we ask. "Does it feel like something pressing here or there?" we inquire. "A feeling of pins and needles?" perhaps we ask. We are here distinguishing, not between pains, but between distressing, disagreeable, or so to say, "painful" degrees of other senses than the pain sense. If this be true, why employ the terms so loosely? Far better would it be to differentiate and to classify these sensations under headings such as are here suggested.

The unpleasant feelings produced by electricity present a more complex problem. As yet we know not its nature, nor the nature of its action. Certain it is, that the electric current stimulates both sensory as well as motor nerves and muscle tissues. Has the current a selective activity for the pain sense? We do not know. It would seem, though, that its stimulating effect is general on all the superficial nerve-endings, and, as such, the painful, distressing, unpleasant feeling would be an admixture of all; and to say that the electric brush is a test for the pain sense as such would seem manifestly unfair. Besides this, the fact must be considered that the current, especially the faradic, causes contraction in the muscles, and a part of the painful sensation produced may well be attributed either to pressure on the nerves within the muscles (deep muscular sense overestimated), or to the accumulation around the nerve-endings within the muscle of chemical products excrementitious in character, from the frequent contractions. This is a field of conjecture, and unless it be cleared definitely, electric painful sensations should not be regarded as pain sensations.

The field of increased painful chemical sensations had best be viewed from two aspects. The substances of irritative effect may be classified as endogenous and exogenous, and the effect of each must be noted.

The exogenous chemicals are those which if applied to the skin produce painful sensations. Here again we know only that the peripheral nerve-endings are stimulated by the substance employed. The sensation is most frequently described as smarting, "it seems to eat in" is a common description. Are there nerve-endings especially for chemical products? It is certain that the tongue contains papillæ with a specific selective activity for chemicals in solution. Yet we do not feel disposed to this view as far as cutaneous sensation is concerned, but are inclined to believe that the painful sensation produced is a combination of the irritative effects of the chemical, of dehydration, tissue destruction, etc., on all of the terminal filaments and special end-organs in the skin. This then is not the true pain sense, but rather a mixed "painful" sensation.

Endogenous substances are such substances as are produced in the body of the individual in disease or health, and in this instance act specifically on the nervous mechanism. Of such bodies one must consider the products produced in infectious diseases (beriberi, typhoid fever, diphtheria, syphilis, leprosy, etc.) in protozoan processes (malaria, etc.), in metabolic disturbances (gout, rheumatism, diabetes, etc.), in intestinal and other autointoxications, and organic poisons inhaled, ingested, or absorbed (lead, arsenic, mercury, phosphorus, etc.). In all of these one hears of neuritic processes which are described as painful. Let us investigate some of these and note whether they are painful sensations or disturbances of the "pain sense."

In the infectious fevers, typhoid, leprosy, beriberi, etc., the pain sense as such is definitely involved and as such both the subjective symptoms as well as the objective signs are present. In all, the motor power may be, and frequently is, involved, as well as the other cutaneous sensibilities, so that in testing one must specifically isolate the disturbance of the pain sense from the painful disturbances of the other senses.

In all the endogenous poisonings with sensory symptoms, one or all of the cutaneous senses may be affected, and as our investigations should lead to a definite separation of these senses a proper method must be observed.

Of the muscular and arthritic, of the bone and periosteal, of the visceral painful sensations, it is hardly within the scope of this paper to enter the field of discussion. Have these organs a specific

pain sense or are the sensations due to disease processes, etc., merely distressing (painful) and exaggerated and unpleasant muscle, bone, etc., sensations, if these be present. For fear of a misunderstanding at this point we do not desire this to be interpreted as a transmutation of these sensations into "pain sensation." The patient, for example, does not describe a rheumatic (used advisedly) joint as paining in the sense of pain sensation but rather as "anguishing," "distressing," as "indescribable." And this is true for the other inflammations, each has its own distressing, painful condition, taken only in this sense and not as disturbance of the true pain sense. Frequently, too, (Head) visceral distressing conditions are reflected to the skin areas as pain, and in these conditions undoubtedly the pain sense in the skin over the segmental areas affected is involved, as can be proven by the proper tests for that sensation. Yet even here how different is the painful sensation which the patient describes spontaneously, from the objective disturbance in the local "pain sense."

There yet remains the painful condition along the nerves. Certainly the fibers conveying the "pain sense" may be acted upon anywhere in the course of the nerve by toxic products, trauma, pressure, etc. It remains to be proved that these fibers can be stimulated along the course of the nerve to produce a disturbance in the pain sense or merely "painful sensations." Both conditions are possible. One frequently sees a neuritis with a distinct disturbance in the "pain sense" (numbness, hyperalgia), with few or no "painful" or "distressing" symptoms; on the other hand, however, the reverse is often true: the patient may complain bitterly of distress along the course of the nerve with no disturbance in cutaneous pain sense. In the nerves themselves there seems, therefore, to be a definite separation between the general disagreeable, so-called "painful sensations" and the "pain sense."

The question now arises, can such a definite pain sense be proved? Two diseases help distinctly to demonstrate its existence. While these are mentioned here it is not forgotten that the reader is cognizant of both, and he will therefore bear with a repetition of common knowledge.

In locomotor ataxia the tactile and deep muscular senses are lost, but the pain sense remains. Pathologically the loss of tactile and muscular sensations means a destruction of definite fibrils, means a sclerosis of the posterior columns and a sparing of other definite fibers which convey the pain and temperature sensations.

In syringomyelia the tactile and deep muscular senses remain (intact) and the posterior columns are uninvolved, but pain and temperature sensations are dulled, are gone, and specifically as such. Pathologically the nerve fibers in the anterior commissure are destroyed. There is then a definite disease entity, a definite destruction of pathways conveying pain and temperature sensations.

We have so far attempted to show a distinction between pain sense and "painful" (distressing, unpleasant, disagreeable) sensations and must now turn to a survey of the field of true "pain sensation."

Definitions are unsatisfactory, their purpose is elemental. So are synonyms for this condition. We have attempted so far to show what "pain sensation" is not; it is now necessary to demonstrate its physical cause, its manifestation and its method of elicitation.

If a sharp pin point be applied to the skin with its axis at right angles to the skin a normal individual will, as a general rule, state that he has a "sharp feeling," that something "pricks" him. This sensation is entirely different from the former sensations which are called painful or distressing. To this sensation (for we must adopt a standard) we would apply the name "pain sensation." Perchance this will seem a marked narrowing of our previous concepts of this sensation, yet, as will be shown later, it is the only fair and constant means of its elicitation and of judging its intensity.

Numerous are the methods suggested by various authorities. Dana suggests "pricking the skin with needles or the sharp points of the esthesiometer, or the use of the faradic current or the wire brush," and speaks of special instruments for pinching the skin. Raecke and Bing test with light and deep needle pricks and by pinching. Strümpell advocates a number of methods, *e.g.* pin-pricks (superficial and deep), firm pinchings, and strong heat stimuli; or the pin may be pushed through a fold of skin. P. Schuster advocates all of the above-mentioned methods, and mentions the fact that the pain sense varies in different individuals and in different parts of the body of the same subject.

It is this looseness of method, this failure to adopt some standard, which should be eliminated, and when we speak of variations in the pain sense we should have the same common picture. Certain it is that the majority of observers think of the pin-prick when variations of the pain sense are mentioned as the means of its study.

Yet even here inconstancy exists. The pin is stuck into the skin lightly and deeply, the pin or needle is inclined at any angle to the skin, folds of skin are transfixed or moved to and fro by the pinpoint. One uses an ordinary pin, another a fine steel one with a porcelain head. There seems no unanimity of method.

To come to a proper method, therefore, we must investigate the pain sense as such in the skin. In the first place we must recognize the fact that all areas in the skin do not have "pain-sense" endings, and these areas of absent pain sense are separated only by millimeters from those possessing it. This can be proved by taking an ordinary pin and applying it as described above to the skin; some spots will immediately feel the prick, the sharp sensation of the point, in others it can be pressed deeply down and, while slightly uncomfortable, in no way will the sensation felt be the same.

Dr. Hastings some years ago demonstrated this fact, and put it to practical use in giving intramuscular injections of vaccines. He directed the point of the needle perpendicularly to the skin, and also sought for the painless points before injecting. I have always followed this method in hypodermic medication, in cocaine and quinine, and urea local anesthesia, and find that in no instance does the patient complain of the initial needle prick, which certainly is not the case if the needle be directed into the skin at random.

It is now necessary to review the methods advocated and to discard such of them as are erroneous. The method of pinching the skin will first be considered. In no way does this elicit a pure sensation. Here are commingled painful tactile and pressure sensations, and perhaps (although this is a mooted point) the true pain sense. How hard should one pinch? How large a fold of skin should one pinch up? How many pain-sense areas are included in

such a fold? And how erroneous, when all these factors are considered, must such a quantitative judgment of the variations of the pain sense be. Instruments of precision (?) have been invented to test the pain sense in this way. What have they tested? Who can say? Only the degree of unpleasantness, if anything. We are therefore disposed to discard this method of testing painful (unpleasant) sensations, for certainly it does not help in determining the "pain sense."

Electrical and heat stimuli are also advocated. These must be removed from consideration at once. Is a "painful" heat sensation a disturbance of the pain sense? Perhaps both sensations are conveyed by the same fibers, but are the end-organs the same? We doubt it. I have on numerous occasions mapped out on normal individuals the so-called cold and hot areas of the skin, and find they do not agree with the pain-sense areas. As for electrical stimuli we have already attempted to show that we do not know what senses are stimulated. If this be so, can an electrical "painful sensation" be utilized as a fair measure of the "pain sense"?

There still remains the method which is most frequently employed in clinical work. It consists of picking up a fold of skin and attempting to push a pin through it. Here again we deal with a polysensation. But this is not all. One can easily demonstrate in a normal individual that a pin can be run almost painlessly through a fold of skin. In the first place the pain sense seems not to be stimulated as much by this lateral attack as by one at right angles to the skin. Secondly let one find a field which is painless on the skin by the method advocated, and in close proximity to it find a similar area (not too far distant); then if he run the pin into the first spot and out of the other no pain is produced, and no stimulation of the true pain sense. There is another source of error in this method. If the pin is inserted into the skin parallel to the long axis of the limb (in other words in the general direction of the nerves) the pain sensation will be far more acute than in a transverse pinprick (across the nerve fibers). This method then presents three sources of error, and when the finer distinctions in the variations of the pain sense are sought for it certainly does not give a constant result.

We have now attempted to show the fallacies in each method so far advocated and must, after destructive criticism, supplant these tests by a constant one. And this we feel prepared to do.

Pain sense should be tested for as follows:

(1) Pin-pricks. These should be made perpendicularly to the skin; at first superficial, then deeper. The pin employed should preferably be a steel one with a fine sharp point and a small porcelain or glass head.

(2) Areas in close proximity should be tested, so as to separate pain areas from areas having no pain sensation.

(3) If with superficial light pin-pricks no pain is elicited, press deeper; try, however, to be in an area of pain sensibility.

These maneuvers give a constant "pain sense," one which the patient recognizes as such, and one which the observer can measure. If under such circumstances we speak of diminished "superficial pain sense," "absent pain sense," etc., we will have a standard, and we will not wonder whether the "pain sense" or a "painful" variation of some other sense is meant.

There remains one point which will only be suggested at this time. When we call a sensation dull, *e.g.* that produced by the head of the pin, are we dealing with pain sensibility or tactile sensation as opposed to the pain sensation produced by the pinpoint? This seems to be the case, but we feel that our observations to date have not yet cleared this point, and as after all sharp, sharper, sharpest, are the best measures of the pain sense over different areas, it need hardly play an important part.

I have attempted here to point out certain fallacies. I have tried to establish a definite "pain sense" as (distinguished) from painful (distressing, unpleasant, disagreeable) variations of other sensations and essayed to bring forward an old method for its study, but employed in a constant way. It was with some trepidation that I entered the field, apparently so unimportant and so clear, yet it was a subject which even in my early days of psychological study seemed far from clear. Further study will either affirm or refute my viewpoint; painful sensations to me are not identical with pain sensation. The haphazard methods of testing either are confusing, and at least here there is room for much improvement. The method advocated may be proved at fault, but it is my hope that at least a constant may be determined upon.

THE PROGENY OF THE TUBERCLE BACILLUS.*

By STEPHEN J. MAHER,

NEW HAVEN, CONN.

CHAIRMAN, CONNECTICUT STATE TUBERCULOSIS COMMISSION

Old tubercle bacilli alive in a moist, somewhat unfavorable environment, swell or elongate and become markedly granular, lose more or less of their acid-fast resistance, and fuse together into a poorly acid-fast granular or homogeneous matrix. Subcultures from this matrix on various media not quite suitable for tubercle bacilli develop poorly acid-fast or non-acid-fast bacilli or cocci, which have no longer the power of causing tuberculosis in injected animals, but have the power of increasing the virulence of simultaneously injected tubercle bacilli.

1. From this matrix of fused old tubercle bacilli can be developed bacterial forms similar to Much's coccal granules, Foulerton's streptothrical forms, Dixon's branching forms, and Ferran's rod forms. From this matrix it is possible to grow coccal and bacillary forms that vary in morphology, in acid resistance, and in chromogenic power, according to the variance in the age and vegetative energy of the tubercle bacilli that composed the matrix, and according to the variance in the technique to which the matrix is subjected.

All of these derivatives of tubercle bacilli are very tender. They need constant watching. Many of the first sub-cultures die without apparent reason. They are very sensitive to environment. After they have grown for a few generations at 37°, or at room temperature, they will not grow well at any other. In sub-cultures they all grow best on glycerinized media.

2. All non-acid-fest coccal and bacillary derivatives of the tubercle bacillus are, strange to say, gram-negative. Old tubercle bacilli, fusing into a

*Read at the Eleventh International Conference on Tuberculosis, Berlin, October 23, 1913.

matrix, gradually lose their gram-positiveness, and finally only a very few resistant granular rods remain in the gram-negative fields. The coccal granules enclosed in the still intact tubercle bacilli are, however, more markedly gram-positive than their enclosing bacillary capsule. Taken in connection with the clinical fact that so frequently in epidemics of cerebrospinal meningitis, many cases of pure tuberculous meningitis, and even some cases of mixed tuberculous and cerebrospinal meningitis occur, does not this observation give color to the suspicion that the meningococcus is a child of the tubercle bacillus?

3. One of the most striking and suggestive methods of developing the non-acid-fast or partly-acid-fast bacterial forms from tubercle bacilli is to grow the tubercle bacilli on glycerin-broth in air-tight flasks for two or three months at 37°, and at the end of that time to remove the seals, substitute sterile cotton plugs, and put the flasks at 22° or thereabouts. If the scum is so dense as to shut off the air from the supporting medium, it is desirable to break up the bacillary crusts by gentle shaking of the flask on a few successive days.

I have been working with six different strains of human tubercle bacilli—three from pulmonary tuberculosis, one from bone tuberculosis, one from scrotal tuberculosis, and one from glandular tuberculosis. From all of these strains, by the procedure here described, I have been able repeatedly to secure the coccal and bacillary non-acid-fast, gram-negative forms, that did not curdle milk, that usually crackled in the flame, and were identical in every way with the forms found in pure tuberculous sputum, and in the pus from tuberculous glands.

4. From none of these six strains of human tubercle bacilli have I been able to grow any of the fine large rosaries of streptococci that are so abundant in certain cases of apparently pure tuberculous sputum. But in the first cultures of coccal and bacillary derivatives of tubercle bacilli the water of condensation in the glycerin-agar tubes invariably contains some of the new organisms in chains. And when the coccal derivatives are grown in glycerin-broth or sugar-broth the tendency to grow in chains is very marked. In cultivating in liquid media the older, partly decapsulated bacillary derivatives, it is difficult to keep these granular rods from elongating into streptococcal filaments.

From tuberculous pus, which on microscopic examination showed only long granular tubercle bacilli, I have repeatedly grown pure cultures of a beautiful streptococcus, which at first contained in every chain one or more acid-fast granules, evidently akin to the granules in the tubercle bacilli of the pus. On sub-cultures these chains were entirely non-acid-fast. When injected into tuberculous guinea pigs, these streptococci caused marked focal reactions, and in two series of experiments pursued during the past year seemed to have some beneficial influence over guinea-pig tuberculosis.

On the other hand, in cases of non-tuberculous, so-called idiopathic asthma in which the sputum is almost a pure culture of stretpococci, the most marvellous improvement in symptoms can be frequently brought about by the administration—preferably by mouth—of a few doses of tuberculin.

5. You have probably noticed that so far I have said nothing of the yeast cells that are found in tuberculous sputum and pus, and you are tempted to ask me whether I consider that these yeast cells have any relationship to the tubercle bacillus. I prefer not to go into that question very deeply to-day. It is the most interesting question connected with the whole problem. Here and now I will merely say that I have not been able to grow any yeast forms from the matrices of old cultures of tubercle bacilli, in spite of the fact that very often these matrices, stained with either Ziehl-Nelson or Gram stains, contained very alluring promises of yeast formation. But the relationship of the yeast cells and large streptococci found in tuberculous pus to the disintegrating nuclei of the tuberculous pus cells is something that I am very sure of, and that I hope to be able to prove to your satisfaction in another year.

In view of these findings, I would to-day answer as follows the question concerning mixed infection that I raised* at the Conference in Brussels three years ago:

Mixed infection in tuberculous areas is caused, not by the invading of these areas by bacteria from the outside, but by the development in these areas of the bacterial progeny of the struggling tubercle bacillus.

APPENDICAL INFECTION, WITH ABSCESS FORMATION; SHOULD THE APPENDIX BE REMOVED AT PRIMARY OPERATION?

By GEORGE S. FOSTER, M.D.,

MANCHESTER, N. H.

SURGEON AND PATHOLOGIST TO THE HOSPITAL NOTRE DAME DE LOURDES.

This disease, its complications and definite mode of treatment, is one that is before surgeons of to-day in a truly emphatic light. In weighing the matter for judgment, by those who are conscientious, the treatment of the appendix with supervening abscess formation must surely be left to the decision of the skilled operator.

This question is one that cannot be answered without unlimited consideration and careful forethought. Just how the appendicitis might have been caused, what variety or varieties of organisms we are dealing with, the locality, position, and pathological condition of the appendix, to what extent the surrounding peritoneum has become involved, the duration of the illness, general condition of the patient, and numerous other questions must at once come to the mind of the surgeon.

Appendical abscess is the end-result of an acute attack primarily, or of an acute exacerbation of a chronic condition. It is comparatively rapid and progressive in formation. Therefore we know that the condition is not of the so-called cold variety. We are dealing with something which builds itself hurriedly and continues to spread in like manner, unless fortunately forestalled by nature.

When we consider that we are encountering that floor upon which the abscess must form, namely the peritoneum, we surely are meeting a delicate membrane. Histologically the peritoneum is constructed of a single layer of flattened epithelioid cells, which develop from the mesothelium lining the primitive body cavity (cœlom). Between these cells is poured out, from the lymph and blood stream, the natural lubricant of the peritoneum. In considering the resisting power of the peritoneum one must take the parietal and visceral layers as one.

*Medical Record, Nov. 12, 1910: "The Relation of the Acid-Fast Tubercle Bacillus to Other Forms of Bacterial Life."

The visceral layers, on the whole, have greater resisting powers than the parietal peritoneum, because the underlying organ or organs must act in part as an interference to ready, continual spreading of the sepsis. Again, we are aware that the pelvic peritoneum can withstand more contamination than that lining the abdomen proper.

The appendix, when in its normal position, is on the border line, having more sensitive surroundings below.

That an abscess may form from abnormal conditions in the appendix, we must have either the bursting of a primary abscess within the appendix itself, gangrene, or perforations without primary abscess. The latter might come from necrosis by enterolith irritation or other foreign body within the lumen of the appendix.

After this brief introduction leading up to the point under consideration, I will now quote the words of some authorities engaged in this line of work. In writing to them for opinions I asked this question: "In a case of appendicitis with abscess formation, should any attempt be made to remove the appendix at the first operation?"

Through their courtesy I will give abstracts from the answers:

Dr. William J. Mayo.—I think the appendix can usually be removed at the time of the opening of the appendical abscess by the experienced operator. It will occasionally happen to the most experienced that the removal of the appendix at the time of the primary operation will not be considered advisable on account of certain complications, and the inexperienced surgeon had better be content with opening and draining the abscess, unless the appendix lies free in the abscess cavity. Careful search should be made for fecoliths which have sloughed from the appendix into the abscess cavity. After all, it is a matter of personal equation, and no surgeon should go further than he can go safely.

Dr. J. B. Murphy.—The appendix should be removed only when it is very accessible, and the evidence of virulence mild.

Dr. Albert J. Ochsner.—In answer to your inquiry, I would say that in appendicitis with abscess we follow this rule: If we can remove the appendix without danger of infecting the surrounding peritoneum we always remove it at the primary operation, but if there is the slightest doubt in our mind we simply drain and remove the appendix later, at least six weeks or longer after the primary operation.

Dr. John B. Deaver.—The abscess being strictly circumscribed without accompanying peritonitis, the appendix not being visible or palpable, the abscess in my judgment should be evacuated, drained, and allowed to heal, taking out the appendix subsequently.

The late Dr. Maurice H. Richardson.—When the abscess of acute appendicitis can be drained without soiling that part of the peritoneal cavity thus far uninfected, I deem it the safest treatment simply to drain, without searching for the appendix. When the abscess cannot be drained without at the same time infecting unaffected peritoneal surfaces, then the chief harm is done, and it adds little, if any, risk to seek for and to remove the appendix.

The late Dr. Joseph Price.—In all acute cases the appendix should be removed. The non-removal results in general infection and retroperitoneal infection. Nothing but disastrous results follow imperfect work. Removal of the offending gangrenous appendix is what the operation is done for. It is good, complete, early surgery that gives a nil mortality.

Dr. W. S. Rodman.—After emptying the pus, a limited search is made for the appendix. I do not, however, break down adhesions and make an extensive search for it. I presume that I remove the appendix in about 25 per cent. of abscess cases. In the remaining cases it is removed at a subsequent operation. I am sure that this is the conservative way of dealing with pus cases. I have had nearly two hundred of circumscribed abscess treated in this way. All have recovered. I have the most positive convictions on this subject and cannot bring myself to believe that it is wise to remove the appendix in a majority, much less all, cases at the first operation.

Dr. B. F. Lund.—In short, I think it is better to get out the appendix at the first operation, when the abscess is opened, unless it presents so great technical difficulties as to endanger the patient's life. When the search for the appendix at the first operation is so difficult as to make it dangerous to the patient, it is much safer simply to open the abscess and wait until later for the removal of the appendix.

From the above quotations it will be noted that among those who have had unlimited experience with innumerable cases there still remains doubt at times as to which method to employ.

In dealing with appendicitis complicated by abscess formation we must consider that we are bound to try and master more than one situation. Primarily the appendix infection is at fault, while secondly the peritoneum and adjacent viscera must be protected from becoming too extensively involved. We must surely all agree that if the abscess be well walled off, the appendix deep and bound to the floor, it would be much safer simply to incise and drain, leaving the appendix unmolested. Trauma is one of the great evils to be avoided in abdominal surgery; the resisting power of the peritoneum is lowered by too great pressure, tension, and manipulation.

On the other hand, when the abscess is just below or within the abdominal wall, providing (as is often the case under these circumstances) few if any adhesions have formed and the appendix is easily accessible, we are doing nothing but justice to the patient in removing the latter.

As M. H. Richardson once said (personal communication): "Old cases, that is those of a week or longer standing, are more apt to have a well circumscribed cavity where drainage can be more satisfactory and the surrounding peritoneum left uncontaminated. In more recent conditions, one to three or four days, the abscess walls, if formed at all, are not so great a defense." Here it would seem that simple drainage with the least amount of manipulation would save tearing these feeble adhesions, allowing them to become thicker, and at secondary operation the appendix could be removed. In this way all enteroliths and sloughs could come away on the drain, extra pus could not collect, and the patient's opsonic resisting power would not be disturbed.

It seems reasonable to assume that the peritonitis could thus be kept well localized, and if light drainage, not abrupt packing, be introduced, no pressure necrosis would result.

Contamination of clean peritoneum is the thing to avoid. If we can prevent this we are most surely giving our subject the benefit of the doubt, and this the patient demands at all times.

From the theory of the opsonic index we learn that during the uprise and stage of maintained high tide of immunity we must not disturb the index by greater toxemia. When we consider that the average case is in one of these opsonic stages we cannot safely set aside the rule. If we recontaminate that portion of the peritoneum which is already soiled, and at the same time soil clean surfaces, we produce nothing short of an unwarranted spreading infection.

By this secondary traumatic infection we surely upset the already well established association between opsonis and complements accompanied by their agglutinating and digestive properties. In short, if we can leave opsonic and complement association undisturbed, produce a limited field within which phagocytosis can take place, and retain a localized involvement of the peritoneum, we have reached the height of our aim.

In the writer's opinion, with the one exception previously noted, such a high standard can always be reached by simply opening the abscess, using the muscle-splitting incision, setting free all pus that will come out with very light pressure, and then introduce a light cigarette drain and wait for nature to adopt her conservative course. Removal of the appendix could be done at a secondary operation, providing it had not already sloughed and come away on the drain.

967 Elm Street.

THE ACTION OF ACETIC ACID ON SYPHILITIC BLOOD STAINS.

By FRANK SORGATZ, M.D.,

ASSISTANT PROFESSOR OF MEDICINE, UNIVERSITY OF OKLAHOMA,

AND

REX BOLEND, B.S., M.D.,

INSTRUCTOR IN MEDICINE, UNIVERSITY OF OKLAHOMA,

OKLAHOMA CITY, OKLA.

In a previous paper* we have referred to a series of experiments, concluding with a reaction which shows an increased resistance on the part of the red blood cells of syphilitics to antihuman amboceptor. To review briefly, this consists merely in placing in a test tube fixed quantities of luetic cells, antihuman amboceptor, and complement and comparing the resulting hemolysis with normal cells treated in like manner. It will be seen that in order to produce hemolysis in the former an amboceptor of greatly increased activity is necessary. For example, normal cells being hemolyzed by a 1/1,000 dilution, luetic cells may require 1/500 or even 1/200 to bring about the same result.

These experiments, it may be said in passing, were occasioned by certain well-known discrepancies in the Wassermann and Noguchi reaction and also by the Weil test, in which cobra venom is used as a hemolytic agent.

The constant results of these tests have suggested the use of other substances known to be destructive to red cells. The well known action of acetic acid recommended its use, as well as the use of other acids. However, for reasons hereinafter given, acetic acid has been the basis of the experiments which have culminated in the following test.

The purpose of this test is to demonstrate what we believe to be a relative increase of resistance of the red blood cells of luetic individuals to hemolytic agents, as compared with normal cells. For this purpose we use drops of suspected blood received on filter paper, controlled by normal specimens obtained at the same time and treated in an identical manner.

The apparatus used consists of a number of specially constructed test tubes, a rack for holding the same, filter paper of a uniform quality, a needle, pipette, thumb forceps, and scissors. The test tubes are made of ¼ or ⅜ inch glass tubing, tapered at the lower end and two and one-half inches long. The rack should have a capacity of twelve tubes in two rows, so arranged that each two successive tubes may be compared. For convenience the holes are numbered from 1 to 12, Numbers 1, 3, 5, 7, 9, and 11 being on one side and numbers 2, 4, 6, 8, 10, and 12 on the other. The most satisfactory filter paper we have found to be the Talquist hemoglobin papers, which may be obtained from any dealer. Any needle may be used for puncturing the skin, but a straight Hagedorn held in an artery forceps and used as a plexor is most convenient. The scissors and thumb forceps are used to cut and handle the specimens, as they should not be touched with the fingers.

The reagents used are pure methyl alcohol for fixing the specimens and acetic acid for demonstrating the hemolysis. The latter must be pure glacial acetic acid freshly solidified by cold and diluted with freshly distilled water. The dilutions being six in number, namely, 1/5,000, 1/7,500, 1/10,000, 1/12,500, 1/15,000 and 1/20,000, respectively. These solutions deteriorate with great rapidity and must be made every day. For convenience, the glacial acetic acid should be kept in the refrigator and a small quantity removed each day for making the dilutions. One cubic centimeter, it will be noted, is sufficient for a large number of tests.

Preparation of Blood.—The blood is obtained preferably from the finger, as the flow can be more readily controlled. It is received on filter paper in drops not more than three mm. in diameter. It is well to obtain a large number of drops and choose for the test the most desirable. Blood is obtained at the same time and in the same manner from the normal individual who acts as control. It is well to suggest that the papers should be marked at once to avoid confusion. The specimens are allowed to dry at room temperature. Twenty or thirty minutes is usually sufficient. However, if the atmosphere is humid it is well to allow a longer time. After drying, the specimens are fixed by saturating the filter paper with methyl alcohol, after which they are permitted to dry as before. Drying, in either case, must be thorough, but should on no account be hastened by the application of artificial heat. A rise of temperature above 60° C. is fatal to the test.

Technique.—The droplets are cut from the filter paper in such a manner as to show the drop in the center of a small square or oblong of the paper. This must be small enough to enter the test tube readily. Six such specimens are obtained from each paper and dropped into the test tubes by means of the forceps. The fingers must not touch the squares and the test tubes, needless to say, must be clean and dry. The suspected specimens are placed in tubes 1, 3, 5, 7, 9, and 11 and the normal in 2, 4, 6, 8, 10, and 12. The dilutions are now placed in the tubes by means of the pipette, beginning with the highest dilution, 1/20,000, which is placed in tubes 11 and 12, a sufficient amount being used to immerse the papers and an equal number of drops in each tube.

*U. S. Medical Journal, Vol. V., No. 6. "New Methods of Diagnosis in Gonorrhea and Syphilis."

The 1/15,000 dilution is then placed in tubes 9 and 10, 1/12,500 in tubes 7 and 8 and so on, the original number of drops being adhered to and the pipette washed in distilled water and thoroughly shaken out before the next dilution is used. The tubes are then slightly agitated to dispose of air bubbles and the rack is placed in a good light to observe the reaction. It will be seen that the action of successive dilutions on the normal and suspected specimens may thus be observed in adjacent tubes.

Result of the Test.—The drops of normal blood will begin to disappear almost at once in the stronger dilutions, while the suspected specimens, if positive, will retain their color in a degree corresponding to the activity of the luetic condition. Strongly positive specimens will not be acted upon by even the 1/5,000 dilution, while weakly positive ones will resist the 1/15,000 and perhaps the 1/12,500 dilutions, and so on through the various gradations. The reaction should be kept under constant observation for twenty to thirty minutes and the rack should not be agitated as the discoloration of the solutions by the hemoglobin is likely to cloud the appearance of the papers.

This difference in resistance may be very conveniently and specifically stated by dividing the titre of acetic acid with normal cells, *e.g.* 20,000, by the dilution necessary to produce hemolysis in a given specimen, thus giving what we have termed the Hemolytic Index. For example, if a dilution of 1/10,000 is required the fraction would be 20,000/10,000 and the index would be 2. If the dilution required should be stronger, say 1/7,500, the fraction would be 20,000/7,500 and the hemolytic index 2.66 plus, and so on. We have seen some specimens in which the index thus obtained was 4. and 5.

Discrepancies.—It must not be forgotten that discrepancies often occur in this as well as in many other tests. However, they may nearly all be explained as follows:

1. Acid of unknown or uncerain titre, that is, acid not freshly frozen or solutions not freshly made. Acetic acid is extremely volatile and the solutions must be made with the utmost adherence to the above technique. While this volatility may at first glance seem to be a serious hindrance to the use of acetic acid, further investigation shows it to be a strong argument in favor of it. Knowing that all acids deteriorate in greater or lesser degree, one whose volatility is marked and unquestioned and which can be easily standardized would be preferable to an unknown or doubtful acid.

2. Unclean or wet test tubes will, of course, cloud any reaction, and should be guarded against.

3. Impure water will likewise cause confusion.

4. Inexact technique, such as obtaining the control at a different time from the suspect; handling the squares with the fingers; in fact any deviation from the above regime will invalidate the results.

5. Syphilis existing in the control of course nullifies any results. This may be avoided by previous examination and, if necessary, mercurial medication. We are presupposing a willingness on the part of the experimenter to use his own blood as control.

6. Severe anemia in either patient or control will lower the hemolytic index. If the cause can be removed, as in the case of malaria, the efficacy of the test is not hindered. A blood examination should precede all suspected cases.

7. Climatic conditions will affect the absolute but not the comparative results. The hemolysis takes place more readily as the temperature rises and the titre of the acid varies within certain limits at different times of the year and different states of the atmosphere. Variations in altitude and barometrical conditions might also affect the results. On this account it is necessary to use the above-mentioned exact and elaborate controls.

The reason why this reaction occurs cannot at present be given, any more than can the Wassermann or Noguchi be explained. We are of the opinion that the blood serum of luetics confers a relative immunity to hemolytic agents upon either homogeneous or hetrogeneous cells, but it will require long and painstaking effort to prove this finally. Such a theory explains this reaction and Weil's reaction, as well as the so-called complement-fixation tests for syphilis. And based on such a theory, we would expect identical results from all three, with perhaps a little more delicacy in the use of the two former, owing to the employment of homogeneous cells.

This we have found to be the case. At present we have records of one hundred and six examinations of both normal and luetic specimens, controlled in each case by a carefully performed Noguchi and the results have been practically identical, *i.e.* strongly positive in late primary and early secondary cases; the percentage of positive reactions gradually decreasing as time goes on, being abolished entirely by specific medication, and reappearing after suspension of treatment.

It is in this connection that we wish to refer to a possible superiority of this test over the so-called complement-fixation tests. In actively treated cases the tests all become negative very promptly. Now if treatment be discontinued and tests made simultaneously at intervals of one or two weeks, it will be noted that the blood of the patient, as demonstrated by the filter papers, shows a gradually increasing hemolytic index, until finally after 6 or 8 weeks the Noguchi or Wassermann becomes again positive. We cannot say that it appears earlier in the course of the disease than the complement-fixation tests, as recent cases constitute but a small percentage of the series in which this test has been used. We are of the opinion, however, that a constant difference is theoretically present, owing to the fact, as before stated, that homogeneous instead of heterogeneous cells are used.

In recommending this test we would call attention to its simplicity as compared with the tests in vogue, but caution against any deviation from the technique as herein set forth. It, moreover, should not be depended upon in the absence of ample clinical evidence of syphilis or a careful Noguchi or Wassermann test. We have no intention of discarding absolute and retaining merely confirmatory findings. Our work has resulted only in the disclosure of a few facts which may serve in some way to illuminate our path and as such are respectfully submitted.

The Localization of Arsenic in the Viscera after the Injection of Salvarsan.—Jeanselme, Vernes, Bertrand, and Bloch find that arsenic is deposited chiefly in the spleen, the liver, the nervous system, and the lungs, after the administration of salvarsan. No reason can be assigned for this elective affinity. Arsenic is deposited in the kidney only when the excretory capacity of this organ is impaired.—*La Presse Médicale.*

THE MEDICAL INSPECTION OF IMMIGRANTS AT ELLIS ISLAND

By E. H. MULLAN, M.D.,

PASSED ASSISTANT SURGEON, U. S. PUBLIC HEALTH SERVICE
ELLIS ISLAND, NEW YORK.

The medical examination of arriving immigrants is of interest to those engaged in various professions. This is attested by the numerous visits to the Medical Department at Ellis Island, which have been made in recent months by physicians, psychologists, school teachers and others from all parts of the United States.

During recent months certain pupils attending the summer schools of various universities, as well as those attending the nearby school of eugenics have made prolonged inspections of the Public Health Service at Ellis Island. These people have shown much concern in the medical work which is being accomplished by the Public Health Service in weeding out the physical and mental unfit among the hordes that pass through our great gateway. It may also be of interest to the readers of this journal to know what activity is now in progress in this particular field of public health work.

The arriving immigrants are brought to Ellis Island by barges from the various steamship docks of New York harbor, either on the day of their arrival or on the following day. The first thing that the immigrant has to undergo at Ellis Island is the medcial inspection, which is conducted by the Public Health Service.

When the immigrant makes an exit from the human machine of the Public Health Service without receiving a chalk mark he has successfully passed the medical inspection, and then ascends the large winding stairway to the upper hall, where a second examination is conducted by officers of the Immigration Service.

At this examination conducted by the immigration service the experienced officials size up the immigrant and members of his family. They interrogate him in regard to his birthplace, occupation, skill, financial condition, destination, the existence of relations and friends in the United States, and so forth. Should there be no certificate of physical or mental disability against the aliens in question, the inspector carefully weighs all the other data in the case. He then concludes as to whether the aliens under examination are a good risk for the United States, or whether they are likely to be a burden to others. If the inspector considers them a good risk he quickly stamps their ship cards "Landed," and off they go by boat and by rail to their future home.

If, on the other hand, the inspector considers the aliens as doubtful cases, or should they possess mandatory mental certificates, they are referred to the Board of Special Inquiry, where the case is further deliberated upon by three inspectors. Should this board reach the conclusion that the alien is one who is likely to become a public charge, he is forthwith excluded. A decision of exclusion is immediately reached whenever the alien possesses a mandatory medical certificate, and the alien is deported in the first outgoing ship of the line which brought him over.

Immigrants certified for organic disease by the medical officers may possess considerable means, they may have well-to-do brothers and sisters in the United States, who are able and anxious to look out for those who are now seeking admission to our shores. These relatives will declare before the board their intent, and will declare with security if necessary, that their afflicted loved ones will never become a public charge. In many cases of this kind there is only one course of procedure open to the board, and the immigrant in question is accordingly landed.

Upon entering the reservation of the Public Health Service at Ellis Island the ship card of the alien is stamped (Public Health Service, such and such a date.) This stamping of the card will show to the immigration authorities that the immigrant has passed through the medical department. After the cards have been stamped at the entrance of the medical department the aliens are guided by an attendant into three different lines, which are separated one from another by iron railings. In each inspection line the alien passes two medical officers, one officer standing at the first curve of the line, while the other, 20 feet beyond, is at the extreme end of the line. At this point all three lines merge into a common exit which leads to the upper hall of the Immigration Service.

It is the function of the first medical officer to look for all defects both mental and physical in the passing immigrant. As the immigrant approaches the officer gives him a quick glance. Experience enables him in that one glance to take in six details, namely: The scalp, face, neck, hands, gait, and general conditon, both mental and physical. Should any of these details not come into view the alien is halted and the officer satisfies himself that no suspicious sign or symptom exists regarding that particular detail. For instance, if the immigrant is wearing a high collar the officer opens the collar or unbuttons the upper shirt button and sees whether a goiter, tumor, or other abnormality exists. A face showing harelip, partial or complete, is always stopped in order to see if a cleft palate, a certificable condition, is present.

It often happens that the alien's hand cannot be distinctly seen; it may be covered by his hat, it may be hidden beneath his coat, or it may be deeply imbedded in blankets, shawls, or other luggage. Of all the physical details in the medical inspection of immigrants it is perhaps most important to watch the hands. In many cases where the hands cannot be plainly seen at a glance further searching has revealed a deformed forearm, mutilated or paralyzed hand, loss of fingers, or favus nails.

Likewise, if the alien approaches the officer with hat on he must be halted, hat removed, and scalp observed in order to exclude the presence of favus, ringworm, or other skin disease of this region. Pompadours are always a suspicious sign. Beneath such long growths of hair are frequently seen areas of favus. The slightest bit of lameness will show itself in an unevenness of gait or a bobbing-up-and-down motion.

After constantly observing the passing of thousands of immigrants, the experienced eye of an examiner will quickly detect the slightest irregularity in gait. Where the alien carries luggage on his shoulder or back it may be necessary to make him drop his parcels and to walk five or ten feet in order to exclude suspicious gait or spinal curvature. All children over two years of age are taken from their mother's arms and are made to walk. As a matter of routine hats and caps of all children are removed, their scalps are inspected and in many cases palpated. If care is not exercised in this detail ring-

worm and other scalp conditions are apt to escape the attention of the examiner.

Immigrants that are thin and of uncertain physical make up are stopped while the officer comes to a conclusion as to the advisability of detaining them for further physical examination. A correct judgment is often arrived at in these cases by the officer placing his hands between the back and chest of the alien, so as to obtain an idea of thoracic thickness, and also by feeling the alien's arm. Very often a thin and haggard face will show on palpation a thick thorax and large muscular arm.

Many inattentive and stupid looking aliens are questioned by the medical officer in the various languages as to their age, destination and nationality. Often simple questions in addition and multiplication are propounded. The officers are familiar with several sentences and the numerals in many languages. This small knowledge of the alien's language and these brief questions enable the officer to bring to view the alertness, attention, accuracy, mathematical power, and emotional reaction of the alien.

Not infrequently positive signs of mental disease are obtained by bringing the alien to a standstill and giving him these brief mental tests.

Should the immigrant appear stupid and inattentive to such an extent that mental defect is suspected an X is made with chalk on his coat at the anterior aspect of his right shoulder. Should definite signs of mental disease be observed a circle X would be used instead of the plain X. In like manner a chalk mark is placed on the anterior aspect of the right shoulder in all cases where physical deformity or disease is suspected.

In this connection Sc would indicate scalp; P, physical and lungs; H, heart; K, hernia; L, lameness; F, face; Ft. feet; E, eyes; C, conjunctivitis; CT, trachoma; S, senility; G, goiter; N, neck; B, back. The words hand, skin, temperature, and measles, which are often used, are written out in full.

The alien after passing the scrutiny of the first medical officer passes on to the end of the line, where he is quickly inspected again by the second examiner. This examiner is known in service parlance as "the eye man." He stands at the end of the line with his back to the window and faces the approaching alien. This position affords good light, which is so essential for eye examinations. The approaching alien is scrutinized by the eye man immediately in front of whom the alien comes to a standstill. The officer will frequently ask a question or two so as to ascertain the condition of the immigrant's mentality. He may pick up a symptom, mental or physical, that has been overlooked by the first examiner.

He then looks carefully at the eyeball in order to detect signs of defect and disease of that organ and then quickly everts the upper lids in search of conjunctivitis and trachoma. Corneal opacities, nystagmus, squint, bulging eyes, the wearing of eye glasses, clumsiness, and other signs on the part of the alien, will be sufficient cause for him to be chalk marked with "Vision." He will be then taken out of the line by an attendant and his vision will be carefully examined. If the alien passes through this line without receiving a chalk mark, he has successfully passed the medical inspection and off he goes to the upper hall, there to undergo another examination by officers of the Immigration Service, who take every means to see that he is not an anarchist, bigamist, pauper, criminal, or otherwise unfit.

Roughly speaking 15 per cent. of the immigrants are chalkmarked by the medical officers, and it is these chalked individuals who must undergo a second and more thorough examination in the examination rooms of the Public Health Service. Those aliens marked X and circle X are placed in the mental room. All other marked aliens are placed in the two physical rooms, one for men and the other for women.

In the physical room the men are divested of their clothing and are thoroughly examined with the aid of stethoscope, thermometer, and Snelling testtypes. The height and weight in certain cases are taken. When the examination is complete, an O K card or appropriate medical certificate, setting forth the physical condition, and signed by three medical officers, is issued to the alien. Serious conditions, such as poor physical development, valvular heart disease, hernia, varicose veins, senility, arteriosclerosis, chronic skin diseases, organic diseases of the nervous system, defective vision, deformities, etc., are certified as conditions which affect the ability to earn a living. Minor conditions, such as slight deformities, visual defects, and harmless skin diseases are simply certified by two medical officers upon a plain certificate.

The Board of Special Inquiry (three immigration officials) gives careful consideration to all cases which are certified as affecting ability to earn a living, and the merits of these cases are thrashed out from every point of view. In the physical examination room if cases of trachoma, favus, ringworm, syphilis, gonorrhea, or tuberculosis are found they are given appropriate blue cards and are sent either to the General or Contagious Disease Hospital, where they are observed, treated, and certified by officers of the Public Health Service. Febrile cases are quickly examined and disposed of in like manner. After twenty or thirty aliens have been examined and disposed of, the big doors of the empty room are again opened to receive another batch of immigrants. This process of filling the room with immigrants, examining them, and disposing of them is repeated over and over again throughout the entire day.

In the mental examination room, the weeding out or sifting process begins when the X-marked immigrants have accumulated to the extent of twenty or twenty-five in number. In this room one, two, or three medical officers question the various aliens who are marked X. They propound simple questions in addition, subtraction, multiplication, and counting backward. They also apply one or two performance tests. After a quick sizing up of the case, the officer decides whether to hold the alien for still further mental examination or to liberate him. If the officer decides on the latter plan, he presents the alien with an O K card. The alien now makes his exit, picks up his luggage and soon finds his way to the moving stream of immigrants who are journeying to the upper hall. If, on the other hand, the officer decides to hold the alien for further mental examination, he writes a brief history of the case on a large yellow card. The alien, with card in hand, is now sent to the hospital for a night's rest, bath, good meal, etc., in order to be put in good condition for a thorough neurological examination on the following day.

Some of these cases have to be observed days and repeated examinations made before certification is accomplished.

In the weeding-out process which occurs in the mental room the circle X cases are gone into carefully with the aid of an interpreter. These cases have shown, either on the line or in this room, some positive signs of mental disease. Roughly speaking, out of every 100 X cases, 10 aliens are held for further examination and observation. Out of the 10 that are so held, 2, 3, or 4 are certified as insane, imbecile, or feeble-minded.

All cases so certified, as well as all aliens afflicted with loathsome and dangerous contagious diseases, are excluded and are returned by the same ship to the land from which they came.

While a description of the medical inspection proper is perhaps long, the actual carrying out of it is short. The one momentary glance at an alien by an experienced officer enables the latter to detect serious irregularities in any one of the six inspection details above recited in 50 per cent. of those who pass through the inspection line.

Six medical officers of the Ellis Island staff are detailed to the Boarding Division. It is the duty of these officers to board at Quarantine the various incoming steamers from foreign lands and inspect the cabin passengers. These passengers are certified on board for physical defects and many of them are sent to Ellis Island to undergo further examination and certification.

During the past fiscal year ending June 30, 1913, 1,044,457 aliens were inspected and 22,733 were certified for physical and mental diseases. It is interesting to note that 661 aliens were certified for insanity, epilepsy, imbecility, and feeblemindedness.

Relatives will not allow their loved-ones who are sick with physical or mental ills to emigrate. For this reason the cases of active tuberculosis and acute mental disease are comparatively rare.

Like any other field of work, immigration is a speciality. It is a speciality that comprises knowledge taken from many sources, medical and otherwise. Some knowledge in eye diseases, skin diseases, nervous diseases, physical diagnosis, information concerning racial conditions, languages, geography, and knowledge of shipping, all go to make up an efficient medical inspector of immigrants. The very fact that an officer is doing immigration work presupposes that he has some training in mental diseases and mental defects. Many of our officers have had experience in hospitals for the insane varying from six months to three years before entering the service, others have been specially trained, after entering the service, in the psychopathic department at Ellis Island as well as at other psychiatric institutions. Other requisites that go to make up an efficient officer in this line of work are a strong physique and speed. Careful, accurate, and scientific diagnosticians who are not active and who do not possess the element of speed in their make-up are useless at Ellis Island where thousands have to be inspected, sifted, and gotten rid of every day.

To be most efficient, an officer at times must do his work according to fixed rules, according to certain routine methods. This is especially true on the line and in the weeding-out process, where hundreds have to be handled. Individualism under such circumstances is productive of fatigue and its complement, inefficiency.

When an officer comes to the question of a definite diagnosis and various matters are put up to him for his decision and action, he can then show his individuality. In all cases where judgment is necessary, it must be quick and accurate.

The medical work at Ellis Island is laborious, the constant standing on one's feet, the careful inspecting of details in hundreds of passing immigrants, the moving from room to room and the arriving at decisions and diagnoses in hundreds of cases is productive of mental and physical fatigue. In some cases the hard work and strain have been the direct cause of physical and mental breakdowns.

This work is hazardous in that officers and attendants are constantly exposed to contagious diseases. During the past year, among several cases of sickness that have occurred, two officers on line inspection duty have contracted scarlet fever in the performance of their duty. In the contagious disease hospital three physicians, four nurses, and one attendant have contracted diphtheria.

Throughout this country there are many and various views in regard to immigration matters. In the Public Health Service immigration is not a joke, but a stern reality.

EYESTRAIN.

By L. EDWIN BARNES, M.D.,

CHICAGO.

The purpose of this paper is to call the attention of the general practitioner to the serious conditions caused by the insidious undermining of the nervous system by what is termed eyestrain. The two most common errors of refraction causing this condition are hyperopia and astigmatism. Myopia, on account of the relaxed condition of the accommodation is not so great a factor.

The causes of hyperopia are either the lessened convexity of the refracting surfaces of the eye, viz., cornea and lens; changes in the media, the transparency of the cornea, the contents of the anterior and posterior chambers, the lens, and the vitreous humors; or the absence of the lens. More often it is due to a shortening of the anteroposterior diameter of the eyeball, which may be hereditary or caused by arrested development.

The effort to correct these errors produces abnormal development of the ciliary muscle, particularly of the circular fibers, which in time become greatly in excess of the radial fibers. This constant effort leads to tonic spasms, which condition is difficult to overcome. This is one cause for improperly fitted glasses, because it necessitates a mydriatic to paralyze temporarily the muscles of accommodation. This is not always necessary as proven by the punctumeter. By this instrument the range of accomodation is measured and if found correct for the patient's age no mydriatic is necessary. I use this first in all examinations, as it facilitates the examination.

Returning to the action of hypermetropia, it causes parallel rays of light to focus, not on the retina as they should but behind it, thus making a blurred image. The mechanism of the eye in overcoming this defect causes the ciliary muscle to contract, thus making the anterior surface of the lens more convex; this renders the rays of light more convergent and brings them to a focus on the retina. This is nature's way to correct the defect up to a certain point, but the result of the constant strain on the ciliary muscle causes an immense consumption of nervous energy, upsetting the nervous equilibrium. In astigmatism the curvature of the cornea is the most frequent causative factor; the

curvature of one principal meridian may be correct while the other is markedly defective. The cause in this condition may be hereditary, it may be a congenital malformation of the cornea from anatomical defects in the bones of the face and skull. Almost every person is slightly astigmatic. Conjunctivitis and other affections or injuries are said to be contributing factors. Astigmatism causes distortion of images and marked visual disturbances. The resulting continuous and unequal accommodative effort must produce eyestrain and consume much nervous energy. An astigmatic person may be able to improve his vision only at the expense of his health. Uncorrected astigmatism, particularly in delicate and nervous patients, results in the worst forms of reflex asthenopic symptoms.

Dr. Hobart A. Hare in his latest (fourteenth) edition of "Practical Therapeutics" on page 723 states that "eyestrain in the broadest acceptation of the term is the name applied to those symptoms which may be caused by the presence of refractive error, or imbalance of the ocular muscles. While all varieties of ametropia (imperfect refractive powers of the eye) may cause eyestrain, hypermetropia and astigmatism are most potent in this respect. Fully 75 per cent. of functional headaches are caused by refractive errors; and these headaches may vary from moderate frontal distress to violent explosions of pain and may be situated in any portion of the cranium. Moreover, they may be entirely unassociated with any pain in the eyes or apparent disturbance of vision, and are frequently *caused by low degrees of refractive error;* in fact they are more frequently caused by them than by the higher defects. In addition to headaches, eyestrain may cause (1) pain in the back, especially between the shoulder blades and at the root of the neck, (2) precordial pain, (3) vertigo, (4) drowsiness, (5) insomnia, (6) habit chorea, (7) choreiform movements, (8) convulsive seizures, (9) melancholia, (10) neurasthenia, (11) palpitation of the heart, (12) syncope, (13) night terrors, (14) stomachic disturbances, (15) constipation, (16) flatulent dyspepsia, and (17) a variety of general or so-called reflex neuroses. The existence of any of these symptoms or affections should direct the attention of the physician to the condition of the eyes, and any refractive error or muscular imbalance should be corrected. Certain cases of so-called spinal curvature in young persons are due to the influence of ametropia."

The writer has had two cases of nervous dyspepsia within the last month, one treated ineffectually for three months, no improvement, with digestive ferments. One had a low degree of myopia—25° myopic astigmatism and 2° exophoria, or outward deviation of the visual axes. The other had a low degree of refractive error, but a large amount of latent hypermetropia (2.5°) as manifest by the punctumeter, and confirmed later by a second examination following mydriasis. Both of these patients have been symptomatically cured since wearing their corrections.

The latest and most remarkable case I have had is a neurasthenic. She has had everything but smallpox according to her history; most of her complaints have been referred to the pelvic region. On examining her eyes by the punctumeter I found she had 2° latent hypermetropia, but would not accept over + 1.50D. manifest. She returned the next noon after using atropine instillations, when she revealed + 3.50D, which was the correct reading as stated by the punctumeter of Hardy.

This patient has been remarkably benefited by the glasses, so much so that she has consulted her physician only twice in three months. Was it her eyes? I am firmly convinced they were important factors in the case.

I could report many similar cases, but these are sufficient to direct the attention of the general practitioner to the seriousness of the low refractive errors and other disorders of the eye, which are far greater factors than they appear upon first consideration of the subject.

The more apparent or high errors are noticed and treated earlier than the inconspicuous ones, hence the insidious strain is neglected.

6935 Stewart Avenue.

Phagocytic Power of Eosinophile Leucocytes.—Manceaux has recently reported at the Société de Biologie that he has observed the eosinophile leucocytes of a pleuritic exudate engulf and digest red blood cells. The phagocytic power of eosinophile leucocytes has already been demonstrated by Weinberg *in vitro.—La Presse Médicale.*

Complete Congenital Absence of Both Radii.—W. M. Robson and N. B. Odgers, report the case of a boy aged six years, who has had "club" hands since birth. Both hands are kept in the extreme varus position, but, since an operation three years ago, can be straightened with a splint. An *x*-ray photograph shows complete absence of both radii.—*Proceedings of the Royal Society of Medicine.*

Treatment of Exophthalmic Goiter by X-Rays.—W Ironside Bruce presents an analysis of eighteen cases of exophthalmic goiter which had been treated at Charing Cross Hospital since 1905. Six of the eighteen did not appear for re-examination, and one had died, in which case only three exposures had been given when diphtheria supervened. The remaining twelve were examined three months ago, and they had been divided into three categories: (1) cured; (2) greatly improved; (3) improved. Four were cured; the exophthalmos and goiter had gone, and no symptoms remained. Five—of which one had been operated upon—were greatly improved. Three had improved, and one of these also had been operated upon, two still remaining under treatment. The exophthalmos disappeared in four cases, was slight in three, and marked in five, two being still under treatment. The skin was normal in seven cases, and there was slight telangiectasis in four, and marked telangiectasis in one. These latter were the author's earliest cases, and the number of exposures given was much greater than had been since found to suffice. All the patients expressed themselves as much better, and they stated that their weight had increased. In none of the patients was there any sign of myxedema; and that was of interest, since in a case the author recorded some years ago, in which he thought myxedema had developed, the patient got very fat at the latter end of the treatment, which lasted two years, and the hair over her forehead began to fall. Three months ago her appearance was normal, no sign of myxedema being noted. All the author's cases were treated with the *x*-ray tube at a distance of 18 to 12 inches from the skin, the surrounding part being screened off by a 4-inch thickness of felt. They had attended either two or three times a week for periods varying up to two years. The effect of the treatment was wonderfully good. But the author had always tried to have in mind the fact that cases of exophthalmic goiter had been known to recover without any treatment whatever, so that one must somewhat discount the value of the *x*-ray treatment on that account.—*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, December 27, 1913.

REPORT OF THE SURGEON-GENERAL OF THE ARMY.

THE annual report of the Surgeon-General of the Army has been issued recently and it is encouraging to note that for the calendar year 1912 the health and sanitary conditions of the army were satisfactory. As is pointed out in the report, the constantly noneffective rate, which is a statement of the average number of men in each 1,000 incapacitated for duty by disease or injury each day during the year, is the true measure of the loss in efficiency of the Army from disease and injury. Judged by this criterion, the Army has never been so healthy, as the rate for 1912 was by far the lowest since the time such records have been kept. For disease alone the rate for 1912 was exactly the same as that for 1895 and only slightly higher than that for 1896, the lowest on record. The fact, too, must be taken into consideration that since the acquisition by the United States of tropical countries the risks from disease have been much greater to our soldiers. Thus, taking the rate for disease in the Army in 1912 in the United States only, 22.57 per 1,000, it will be found considerably lower than the corresponding lowest Army rate, 25.23 for 1896. In the Philippine Islands, on the other hand, the noneffective rate for American troops, both for disease and injury, was higher in 1912 than in 1911. That a cold climate is better suited to the white man than a tropical one, is demonstrated by the healthiness of the troops in Alaska and by the comparative unhealthiness of those in the Philippine Islands.

The Army Tropical Board in reply to a letter from the commanding general of the Department of the Philippines, asking for the opinion of the board in regard to the effects of continued tropical service, and relative to the character of residence best calculated to preserve the health of the occupant, formulated certain conclusions to the effect that life in tropical lands is inimical to the health of a white man and even under the most favorable conditions weakens his resisting powers against disease, and that it is essential to the relative well-being of soldiers that in tropical climates they should be housed in cool quarters and that every effort should be made to enable them to withstand climatic influences in the best way possible.

The rates for certain special diseases were very gratifying and particularly was this the case in regard to the results following the compulsory immunization of the Army by the typhoid prophylactic. In 1912 but eighteen cases of this disease occurred in that part of the Army stationed in the United States. Of these eighteen cases only six had received the prophylactic, while five of them occurred in recruits who were infected prior to enlistment and were in the incubation stage when enlisted. The results of immunization against typhoid fever among the native troops were as satisfactory as among the white troops. Perhaps the most encouraging part of the report is that which refers to venereal diseases. It seems that as a result of the propaganda of education in the Army, of compulsory prophylaxis with physical examinations, and the stoppage of pay by act of Congress of men incapacitated for duty by these diseases, some control has apparently, at last, been secured over the occurrence of venereal diseases. Tuberculosis shows signs of diminishing in the Army, but while the admission rate for malarial fevers in the Army in the United States is diminishing, in the Philippine Islands it is higher than it has been in any year since 1896. Alcoholism in the Army has decreased in a satisfactory manner in the United States and in the Philippine Islands.

The Surgeon-General calls attention to one particular in which the Medical Department of the Army is lacking—the great deficiency in number of the Hospital Corps. The Surgeon-General suggests that the Secretary of War should recommend to Congress the reorganization of the Hospital Corps. He believes that this recommendation will be granted and the recruiting of suitable men for this relatively unattractive service will be thereby greatly facilitated. The report gives evidence of an excellent condition of affairs in the Army from the health and sanitary standpoints, an outcome which devolves great credit on the medical department.

ROCKY MOUNTAIN FEVER AND SHEEP GRAZING.

As a result of the discovery that Rocky Mountain spotted fever is transmitted by the bite of the wood tick various measures have been suggested for the eradication of the ticks. Dr. L. D. Fricks, surgeon U. S. Public Health Service, writing on the subject in Public Health Reports, August 8, 1913, discusses the question of exterminating or controlling ticks by sheep grazing. Experiments in this direction were initiated in the beginning of May, and Fricks summarizes the results as follows: (1) Over 87 per cent. of 295 ticks placed in the wool of unshorn sheep were recovered dead. (2) The majority of the ticks recovered from sheep grazing naturally over tick-infested territory were found dead. (3) Many of the engorged females recovered appeared not to have been fertilized. (4) Comparatively few ticks, either dead or alive, were found on the sheep after they had been sheared.

H. P. Wood of the Bureau of Entomology of the Department of Agriculture publishes the experiments undertaken on sheep in Bulletin No. 45 (November 22, 1913) of that department. The experi-

ments proved that lambs or sheared sheep will breed a considerable number of ticks and kill but few. Therefore, the only possibility of employing sheep in the work of tick eradication would be the using of wethers or other sheep with heavy wool. As it does not appear practicable to attempt to use wethers alone in Bitter Root Valley, the use of sheep is possible only as one means of reducing the numbers of the ticks, and even this plan is open to objections. However, while the experiments seem to show that the grazing of sheep in itself would be a negligible quantity in controlling the spread of ticks, Wood points out that in a tick-infested country, favorable to the herding of sheep, these animals might be employed for this purpose. Then if these sheep were dipped once in seven days much good might be accomplished.

NON-TUBERCULOUS APEX CATARRH.

An article which appeared on this subject by Litzner (*Münchener medizinische Wochenschrift*, Nov. 4) suggests a question of priority which deserves mention, because the name of an American physician is involved. The late H. S. Straight, for many years professor of diseases of the nose and throat in the Western Reserve University, Cleveland, O., insisted upon the existence of a non-tuberculous apex catarrh, and was always ready to demonstrate such cases to sceptical brother practitioners. It is doubtful, however, if he ever made a single convert. Possessing a character for industry, zeal, initiative and combativeness, he never permitted himself to weaken in his propaganda. He became almost famous because of his "heresy," and his colleagues looked upon him with amusement; for them his "apex catarrh" was either an imaginary state or initial apical tuberculosis.

The article by Litzner on non-tuberculous apical catarrh might have been written by Straight himself, save that the German includes under this term very severe cases, as well as mild ones. The German author claims that this condition is known to sanatorium men, and that its recognition is owing to the great amount of time devoted by these physicians to physical diagnosis.

If Litzner is correct, and if the term comes into general use, the priority of Dr. Straight's claim must be agitated, although he himself never spoke of priority at all. He never claimed to have made a great discovery, and wrote but little on the subject. It appears, however, that Dr. Straight was not only a superior diagnostician, but that his refusal to allow persistent ridicule to influence his views gives him a high status as a pioneer in affections of the chest. Let us hope that Straight's posthumous claim will be fairly discussed, and if it be sound that some step, however small, will be taken to secure for him the honor which will be his just due.

Insanitary Finger Bowls.

According to the *Mid-West Hotel Reporter* there has been since the Duluth Convention of Hotel Proprietors a somewhat heated controversy with regard to the finger bowl considered from the sanitary aspect. The storm, however, seems to have gathered and broken around the heads of those concerned with the moving of the resolution, without those who raised the tempest having a correct comprehension of the aim of the resolution. The object of the resolution was not the abolition of the finger bowl but its regulation, a very different matter. Finger bowls, if not an absolute necessity, are at least an esthetic and cleanly adjunct of civilization, and it is fitting and decorous, and, it may be added, sanitary, that they should be clean and contain clean water. Waiters, no doubt, are apt to be careless and therefore those in authority in hotels and restaurants should see to it that the finger bowls should be of a material easily cleaned and moreover should be kept clean.

Wood Alcohol as a Cause of Blindness.

Cases are more or less frequently cropping up in which persons have lost their lives or sight from the effects of wood alcohol. Recently in New York a varnisher engaged in varnishing the inside of large storage beer vats was rendered totally blind as the result of inhaling the fumes of a varnish of which a prominent component part was wood alcohol. Accidents of a similar nature have occurred also in other breweries through the employment of a varnish containing wood alcohol. As is pointed out by the New York Committee on Prevention of Blindness with reference to such fatalities and casualties, there is no excuse for the continued use of wood alcohol in varnish, since denatured alcohol is cheaper and absolutely safe for all industrial purposes. The employment of wood alcohol in liquors is a crime, and its use in varnish, although not so obviously a crime, in most instances perhaps being the outcome of ignorance, is nevertheless a custom which should be prohibited by law.

Vagotomy *vs.* Rhizotomy for the Gastric Crises of Tabes.

Rhizotomy for gastric crises has now become a typical operation, with a relatively low mortality when done by special surgeons, but it is asserted that the results are negative in at least 40 per cent. of the cases. In the Section for Surgery of the recent session of the German Naturalists and Physicians (*Berliner medizinische Wochenschrift*, November 17) Exner discusses his rival operation of vagotomy for the crises. He has done the operation nineteen times at a late stage in gastroenterostomy. His results are no better or worse than those obtained by Foerster's method. There should be special indications for each method, but as yet they cannot be formulated.

News of the Week.

Proposed Health Centers.—The Hospital Investigating Committee of the Board of Estimate of New York has submitted a plan for the conservation of the health of the city. After calling attention to the immense amount of preventable sickness in New York and the fact that only about 10 per cent. of cases of illness are treated in the hospitals, the report says: "The city has assumed responsibility for caring for sickness when it reaches a stage needing hospital treatment and, within certain limits, for the prevention of contagious diseases. Any

theory of social obligation which warrants the city in obligation which warrants the city in undertaking the care and prevention of sickness would warrant it going still further, if its finances would permit. Undoubtedly a larger percentage of disease could be prevented than is now prevented, if a more thorough system of home visitation existed for the purpose of informing all citizens of means and methods of maintaining sanitary and healthful conditions. The methods of doing such work, its cost, and the results to be obtained, cannot be determined without experimentation. The city ought to try an experiment in a small district, and in a limited way, to determine, if possible, whether or not such work could advantageously be performed by the city as a regular part of the work of the Health Department and the hospitals. It should undertake this experiment also to determine whether or not a large portion of sickness can be cared for at home more cheaply than in expensive hospitals." The committee recommends that the work suggested be undertaken by physicians, nurses, and inspectors of the Health Department and of Bellevue Hospital in co-operation; that the first health center be located in the Bellevue ambulance district and that all functions now performed by the different bureaus of the Health Department pertaining to this district be centralized in a health center building, including a tuberculosis clinic, a child hygiene clinic, and associated with this a milk depot, a dental clinic for children; inspectors of contagious diseases, visiting nurses, inspectors and nurses in charge of inspection of school children and the supervision of midwives. The committee estimates that the additional cost to the city of the establishment of such a health center would be only $5,820 a year.

City Death Rate.—For the week ending December 13, the death rate in New York City was 13.04 as against 13.44 for the corresponding week of 1912, the total number of deaths being 1,343 and 1,333 respectively. The death rate of the first fifty weeks of the year was 13.75, while for the same period of last year it was 14.07, making a decrease of .32 of a point. The third quarterly report of the Department of Health for 1913 shows that during the three months ending September 30, there were reported 16,818 deaths, giving a rate of 12.43 per thousand, against an average of 19,937 deaths for the same quarter during the preceding five years. The mortalities from the principal causes of death during this period were as follows: Tuberculosis, 1,868; cancer, 1,033; organic heart disease, 1,979; typhoid fever, 115. During the same period the number of births increased from 34,406 in 1912, to 34,556 in 1913; while the number of marriages during the quarter increased from 11,627 in 1912 to 12,741 in 1913.

"The Psychoanalytic Review" is the name of a new quarterly, devoted, as announced on the title-page, "to an understanding of human conduct." It is edited and published by Drs. William A. White and Smith Ely Jelliffe—a guarantee that it will be readable and instructive, whether one accepts all the doctrines therein expounded or not. This initial number contains articles on "The Theory of Psychoanalysis" by C. G. Jung of Zurich, "Psychoanalysis of Self-mutilation" by L. E. Emerson, "Blindness as a Wish" by T. H. Ames, and the first instalment of a series of lessons on "The Technique of Psychoanalysis" by S. E. Jelliffe. C. R. Payne contributes a critical digest of "The Paranoia Problem," and there is a translation by Wm. A. White of the first part of Franz Riklin's "Wish-fulfillment and Symbolism in Fairy Tales." This first number (November, 1913) is a handsome volume of 120 pages, well printed on soft opaque paper. The Freudian school of psychology is to be congratulated on being represented by so excellent a periodical.

Health Exhibit Opened.—The Department of Health of New York on December 17 opened a permanent exhibit showing the activities of the department in the Exhibition Hall of the Department building, 140 Centre street. The exhibit has its origin in the budget display which was made a year ago. At the opening short addresses were made by Dr. Stephen Smith, Commissioner of Health from 1868 to 1875; Dr. Abraham Jacobi; Prof. Charles F. Chandler, Commissioner of Health from 1873 to 1883; Dr. Hermann M. Biggs, and Prof. T. Mitchell Prudden.

Long Island College Hospital.—Beginning with the session of 1914-15, the Long Island College Hospital, Brooklyn, N. Y., will require one year of college work for admission to the freshman class. In order that students may advantageously prepare themselves for entrance, the college has established a Medical Preparatory course devoted to the subjects of physics, chemistry, biology (both didactic and laboratory work), elementary physiology, French, and German. As many of the high school students in the neighborhood of New York are graduated in February, a spring and summer course will also be given, beginning on February 3, and continuing for thirty-two weeks, the completion of which together with a Medical Student Certificate from the Regents, will entitle the holder to admission to the freshman class of the Long Island College Hospital.

Albany College Buildings.—The Building Committee of the Faculty of the Albany Medical College recently received revised plans for the new college buildings which it is proposed to erect on the county grounds near Delaware avenue, Albany. The plans were placed on exhibition in the Education Building for general inspection before a decision was reached.

Fewer Medical Students.—The Federal Bureau of Education has compiled a report indicating a gradual decrease in the number of medical schools and medical students in the United States. During 1913, as compared with 1912, the schools were decreased by 14, the students by 1,200, and the graduates in medicine by 500. The number of women students, however, showed a considerable increase. Of a total of 18,451 students in 1912, 712 were women, while of 17,238 in 1913, 835 were women.

Dr. Abr. L. Wolbarst will hold a Genito-urinary Clinic on Thursday evenings at 8.30, from January to May inclusive, at the West Side German Dispensary and Hospital (New York School of Clinical Medicine). These clinics will be free to physicians.

Smallpox on Ship and Train.—The U. S. S. Ohio, which reached Cuban waters recently after a Mediterranean voyage, reported eleven cases of smallpox among her crew, with twelve men sick and under observation. One man died from the disease on the way across. The patients will be transferred to the Isolation Hospital at Guantanamo, and the battleship, after fumigation and vaccination of the crew, will proceed to Charleston, S. C., for a period in quarantine.

After the discovery that a passenger on the Pittsburgh Express, which reached Philadelphia on the morning of December 14, was suffering from

smallpox, thirty-nine men who had been in the smoking-car were forced to submit to vaccination.

Medical Society Elections.—Jefferson County (Ala.) Medical Society: Annual meeting at Birmingham on December 1. Officers elected: *President,* Dr. J. M. Mason; *Vice-President,* Dr. Ben Ferguson; *Secretary-Treasurer,* Dr. H. P. Shugerman.

Madison County (Ala.) Medical Society: Annual meeting at Huntsville on December 1. Officers elected: *President,* Dr. C. E. Blanton, New Market; *Vice-President,* Dr. H. H. Thomas, Huntsville; *Secretary-Treasurer,* Dr. Edgar Rand, Huntsville.

Hale County (Ala.) Medical Society: Annual meeting at Greensboro on December 2. Officers elected: *President,* Dr. Jacob Huggins, Newbern; *Vice-President,* Dr. R. F. Monctte, Greensboro; *Secretary-Treasurer,* Dr. C. A. Poellnitz, Greensboro.

Calhoun County (Ala.) Medical Society: Annual meeting at Anniston on December 2. Officers elected: *President,* Dr. J. C. Moore; *Vice-President,* Dr. A. N. Steele; *Secretary,* Dr. J. W. Landham; *Treasurer,* Dr. E. C. Anderson.

Obituary Notes.—Dr. Alexander S. Cornell of Copemish, Mich., a graduate of Detroit College of Medicine in 1894, died on December 2 as the result of being run over by his own automobile.

Dr. Jerome Dwelly of Fall River, Mass., a graduate of the Harvard Medical School, Boston, in 1847, first city physician of Fall River, serving through the cholera epidemic in 1854, for fourteen years a medical examiner, and for nearly thirty years an examining surgeon for pensons, for over twenty years a member of the school committee of Fall River, and a member of the Massachusetts Medical Society and the Bristol South District Medical Association, and former president of the latter, died at his home on December 3, aged 90 years.

Dr. W. Henry Wishard of Indianapolis, Ind., a graduate of the Indiana Medical College, La Porte, in 1849, a volunteer surgeon in the United States Army during the Civil War, and a member of the Indiana State Medical Association and the Marion County Medical Society, died at his home on December 9, aged 97 years.

Dr. Nathaniel Heath Street of Newbern, N. C., a graduate of the University of Virginia, Department of Medicine, Charlottesville, in 1881, and a member of the Medical Society of the State of North Carolina and the Craven County Medical Society, died suddenly on December 1, aged 56 years.

Dr. Zachur Prall Boyle of Philadelphia, a graduate of the University of Pennsylvania, Department of Medicine, in 1881, for many years and until recently chief surgeon of the Philadelphia & Reading Railway Company, died on December 6, at the age of 55 years, as the result of injuries received in a fall.

Dr. R. C. Young, formerly of Ridgeton, Ont., a graduate of McGill University, Medical Faculty, Montreal, in 1873, and twice mayor of Ridgetown, died at his home in Detroit, Mich., on November 25, aged 62 years.

Dr. Norman Eugene Farewell of Brooklyn, N. Y., a graduate of Trinity Medical College, Toronto, in 1897, and assistant surgeon at the Brooklyn Eye and Ear Hospital, died at his home, from pneumonia, on December 11, aged 37 years.

OUR LONDON LETTER.

(From Our Regular Correspondent)

UNION OF PANEL DOCTORS—THE CRISIS OF THE BRITISH MEDICAL ASSOCIATION—NEURASTHENIA—SYMPTOMS OF FATIGUE—DREADNOUGHT CLINICAL SCHOOL—WISBEACH INQUEST—OBITUARY.

London, December 5, 1913

The project of uniting the numerous associations of non-panel practitioners which have sprung up in the country gives promise of success. On Saturday a meeting was held representing above a thousand members of these societies and they resolved to federate under the name of the "National Medical Union" with the object of protecting the interests of those not on the panel. It was agreed that the subscription should be one guinea a year and the opinion seemed very prevalent that 10,000 members would soon join the new organization. Mr. Wm. Coates of Manchester presided at the meeting and was appointed chairman of committee; Mr. G. A. Wright and Professor Russell of Edinburgh being elected presidents. Other members chosen for temporary officials were: Dr. J. Playfair, V. P.; Dr. B. O'Connor, V.P.; Dr. Greenyer of Brighton, V.P.; Dr. Brienley of Manchester and Dr. Oppenheimer, Treasurers; Dr. Carswell and Dorrell, Secretaries. In the course of the discussion acute differences of opinion were elicited on some points connected with the establishment and administration of the new body. This was specially marked in reference to the terms of membership. The representatives from Manchester and Edinburgh held that no one connected with the Insurance Act, directly or indirectly (*e.g.,* in partnership with one on the panel), should be eligible and this apparently was the view of the majority. On the other hand, some London speakers thought it might be desirable for members of the union to serve on insurance committees and local medical committees under the act. A motion in this sense was made and rejected. It may be, as some influential persons present seemed to think, that the formation of the union will be an important event in the history of the profession in this country. Time will show.

Yesterday a "special representative meeting" of the British Medical Association called to consider the report of the council recommending an increase of the annual subscription to £2.2.0 was held in London and on a roll call vote the proposal was carried by 131 to 42; two members did not vote. The majority required is two-thirds and in a large meeting that would seem sufficient to prevent hasty change, but the number shown to be present indicates the little interest taken in the proceedings by the thousands of members. The proposal excited a certain interest in advance, was freely discussed at a number of the branch meetings and many members declared that this meeting would prove a great crisis in the association. In some districts there was a little canvassing and in some electioneering circulars were distributed. On the whole the usual apathy of the profession has let the question drift and the council's recommendation pass. Dr. J. A. Macdonald, chairman of the council, moved the adoption of its report and declared that their work could not be effectively carried on without more money. It had been said that many members would resign if the motion were carried and he felt that

contingency must be faced, but he hoped that there would not be many resignations and if there were the association might be better without them. The last remark seems rather unfortunate for a chairman. Dr. Haslip led the opposition on the ground that London was dead against it. He thought it one of the worst business schemes. It really meant letting the minority do as they liked at the expense of the immense majority as could easily be proved by a postal vote. Dr. Gillett of Oxford said that in his division out of fifty members at a meeting all but two were against the change. He held it better to be strong in numbers with a small balance than the opposite. Dr. W. J. Smith was for retrenchment and condemned the proposals for new departments and branches as premature. Dr. Meade said he was instructed by the York division against increase. Dr. Henry said a fight was ahead and they should wait for that. Dr. Button said the finances were badly managed and they should put a business management over them. Dr. Beaton said the request for money was always very inopportune, this way only just over a farthing a day. Dr. Goodbody said in Marylebone they only got 30 to 35 at a meeting out of 665. They took a postal vote and got 373 replies, 146 for and 201 against, 25 per cent. threatening to resign on account of the way the money was spent. Dr. Lawson said if the insurance expenses had been £10,000 they gained a million and a half for the profession. Retrenchment would lead to bankruptcy. Two or 3,000 came in to save their bread and butter; on each who paid 25 shillings they spent over £3. Let them go if they only stayed to get more than they gave. So the council has scored another triumph by the vote at this meeting to which so few took the trouble to go. Possibly with continued threatenings the apathy of the majority will still prevail.

Medical chats last month reeked with "that blessed word "neurasthenia." Everyone asked every one's opinion about it. The discussion about it at the Medical Society of London extended over a couple of meetings and no less than eighteen speakers who professed to know much about it expressed their more or less discordant notions concerning it. Some attempted to define it, but its nature proved too illusive, for one hardly likes to say they did not know what they were talking about; though it is certain they were not all describing the same thing. Personally, when pestered with the continual inquiry as to what I thought it consisted in I contented myself with referring my questioner to the etymology of the word and asking him if he could justify the combination of its components by passages from the classics in which either was used. The ruse was fairly successful, but I must not try it on you, for you may expect to hear something of the debate itself, though you will not spare space for the briefest abstract of the eighteen speeches. Suppose, then, I send you a few remarks of the opener of the debate, Dr. J. S. Risien Russell, as to the value of whose paper subsequent speakers were more agreed than on anything else. Dr. Russell then held there are different types of neurasthenia requiring, or course, corresponding difference of treatment. He spoke of three main groups—cerebral, spinal, cerebrospinal. He thought children might be affected and even some might be born with a tendency to the disorder, inheriting, so to say, the neuropathic taint just as others are supposed to do the tuberculous. The temperament, even the nationality of the neuropath, deserved consideration as much as the indications of exhaustion, irritability on undue tension of the nervous system. The best treatment was rest in a home for such patients—not where all diseases were admitted. After the "rest cure" treatment should be continued as it might be indicated. Hopefulness must be encouraged in every way for these patients were all given to despondency, though often open to suggestion—psychical influences were accordingly important; so a cheerful demeanor and positive assurance by the attendant that the case was certainly curable often did more than drugs which were assigned to quite a secondary place. Thus much for the opening of the debate. Passing over the speeches let me add a word or two from the summing up of the president, Sir David Ferrier, who had patiently listened to all. He said the divergent views were largely due to the fact that they were not all talking upon the same subject. This word neurasthenia was a limbo to which they relegated all sorts of nervous disorders. It was important to recognize that all the symptoms could appear in a person in a healthy condition. Normally fatigue was not exactly unpleasant, but if in spite of the effort to continue was pushed to exhaustion, then neurasthenia might supervene. In the subject of the affection fatigue came on before it should and that seemed to set up the neurasthenic state. For physical exhaustion rest was the natural cure. For the neurasthenia the morale must be improved. To accomplish this psychotherapy was the ideal treatment.

Prof. Wm. Stirling of Manchester, in the course of his Lady Priestley Memorial Lecture at the National Health Society, discussed the symptoms of fatigue. The subjective ones were known to everyone, but some of the objective deserved mention as indicating the condition of the muscular and nervous systems. Some parts were under the control of the nervous system, *e.g.* the fine movements of the fingers in writing, those of facial expression and movements of the head. On extending the free hand the thumb was apt to drop; the whole hand might drop from loss of tone in the muscles involved. The head often took an unsymmetrical position, or inclined forward, and the trunk might so bend. The muscles were limp and flaccid from loss of tone and rest was necessary to regain it. For the brain, in addition to sleep when it could be obtained, naturally a change to some exciting but useful occupation was a true rest to many persons. For others something approaching manual labor in the open air was best. Change of scene also was generally beneficial.

Surgeon-General May, Director Medical Department of the Navy, presided at the annual dinner of the Dreadnought Clinical School, surrounded by a number of distinguished members of the profession. He said the many eminent men present proved the value of post-graduate schools, though recently founded because medical science cannot stand still. Sir Archibald Geikie, P.R.S., contrasted medicine to-day and 300 years ago, and said medical men had not only advanced their own profession but gone out of their way to advance other branches of science. One man whose name was not often mentioned, he looked upon as one of the greatest this country had produced—he was Wm. Gilbert, founder of the science of magnetism, of whom medical men should be proud. Sir T. Barlow said this school had laid its foundations deep and wide on science. Sir J. Crichton-Browne said if the

money spent on mischievous quack medicines could be given to the school of clinical medicine mankind could reap incalculable benefit. The Insurance Act, he thought, must be amended and he hoped its objectionable features would be removed in the coming amendment.

The coroner's inquiry as to the death of the panel doctor who was found dead in bed while under a charge of slander concluded on Wednesday when the official analyst said he had found in the parts he examined 2.67 grains of morphine and 6.7 grains of veronal, which would correspond with 5 grains of morphine sulphate for the whole body. The jury returned a verdict of died from poison, self-administered, while temporarily insane, following mental depression.

Col. J. H. Newman, late of the Indian Medical Service, has died in his 69th year. He had the medal for Abyssinian expedition in 1868 and served in the Afghan war in 1878-9. Subsequently he filled various positions, becoming colonel in 1895 and retiring in 1900.

OUR LETTER FROM THE PHILIPPINES.

MEETING OF THE MANILA MEDICAL SOCIETY—POLYNEURITIS IN FOWLS FED ON UNHULLED RICE—CHOLERA AND CHOLERA CARRIERS — APPARENT CURE OF LEPROSY—NUMBER OF PHYSICIANS IN THE PHILIPPINES—PERSONAL.

Manila, P. I., November 15, 1913.

The regular monthly meeting of the Manila Medical Society took place at 8.30 p. m., November 3, at the College of Medicine and Surgery. The only paper read was that by Dr. Gibson, the Associate Professor of Physiology of the College of Medicine and Surgery, entitled "Polyneuritis in Fowls Fed Upon Palay (Unhulled Rice)." Dr. Gibson stated that a chicken was fed exclusively on unhulled rice, and at the end of a month showed no clinical evidence of polyneuritis, but upon sections being made of the sciatic nerve there was evidence of degeneration. Another chicken was fed on palay for a period of two months, and at the end of that time there was no clinical evidence of polyneuritis, but there was more marked evidence of degeneration of the sciatic nerve than in the preceding chicken. The third chicken, which was fed for a period of ninety days on palay, showed no clinical evidence of polyneuritis, but showed more advanced degeneration of the sciatic nerve than either of the preceding cases. The author was of the opinion that if unpolished rice is fed continuously to a chicken that eventually polyneuritis will result. He mentioned that polished rice caused distinct clinical polyneuritis as a rule soon after the twenty-third day.

The cholera situation in Manila and vicinity continues to remain about the same. For the week ending November 8 there were twenty-three cases and seventeen deaths, and for the week ending November 15 there were eight cases and eight deaths in the city of Manila. In addition to the foregoing, the disease has spread to Pilar in Bataan Province, Santa Cruz in Cavite Province, to some of the suburbs of Manila, and to Pasig in Rizal Province. In each of these places the first cases were promptly discovered, and after the sanitary measures were put into effect no further cases occurred except at Pasig. In that town the instructions for managing the outbreak were not strictly carried out, with the result that the disease spread to many of the barrios in Pasig, and there have already been twenty-two cases and ten deaths. One of these cases was an American soldier stationed at Fort McKinley, who, while upon a drunken debauch, exposed himself to the disease in the barrio of Butin of the town of Pasig. The diagnosis was bacteriologically confirmed by the army surgeons at the Fort McKinley hospital.

Cholera carriers still continue to be found among the contacts of the majority of the cases. The measures employed in this outbreak have probably been more successful in preventing the spread of the disease than any that have been carried out heretofore. By making the measures less rigorous much of the opposition from the ignorant masses, which has been so troublesome in former cholera campaigns, has been avoided, with the result that it usually has been possible to find the first cases in most instances. Briefly, the measures consist in the prompt transfer of the sick to the cholera hospital. Stool specimens are taken from all of the contacts, and those that prove to be cholera vibrio carriers are also removed to the San Lazaro Hospital detention quarters. There is no quarantine imposed at any time. The toilets and the receptacles, linen and other articles with which the sick came into contact are rigidly disinfected. Much stress is laid upon hand disinfection for all contacts of the case. In the provinces where hospital facilities are not available the sick person is quarantined in his house, and the dejecta of all sick as well as the contacts is directly deposited in a disinfecting solution. A large bowl of disinfectant is placed outside the house, and each person upon leaving the house is required to wash his hands in the solution. Experience so far indicates that the infections are contact infections, and that there is no general food or water infection.

Last week two additional lepers were discharged on probation from the San Lazaro Leper Hospital after they had apparently been cured for a period of two years. It is the intention to have these cases report once a month, in order that their condition may be observed. The cases received hypodermic injections of chaulmoogra oil in the same manner as those cases which have heretofore been reported, with the exception that no vaccine treatment was administered. The following mixture was employed: Chaulmoogra oil, 60 cc.; camphorated oil (olive), 60 cc.; resorcin, 4 grams. Mix and dissolve over a water bath by means of heat; then filter. One centimeter doses are given at weekly intervals, and these are gradually increased up to the point of tolerance. In one of the cases a dose of 20 cc. was reached, whereas in the other it was not deemed advisable to increase the dose above 5 cc. on account of the cardiac palpitation which larger doses seemed to cause.

With the exception of the case of plague that occurred in September, there have been no cases of this disease in the Philippines since May, 1913.

The Bureau of Health has just completed a statement showing the number of registered physicians in the various provinces and islands of the Philippines, and this shows that there are vast areas in which large numbers of persons reside in which there is not even one doctor. In Manila, for instance, there is a doctor for every 908 inhabitants, whereas in the Province of Antique, which comprises 1,134 square miles and has a population of 134,166, there is only one doctor. In the Island of Siquijor, which has a population of 46,000 and an area of 106 square miles, there is not a single physician. The foregoing does not necessarily mean

that there are not enough physicians in the Philippine Islands, but it is largely due to the fact that the bulk of the population has not yet been educated to employ physicians, and that the income of the average inhabitant is not yet large enough to pay for the services of a doctor.

Colonel William H. Arthur, M.C., U.S.A., Chief Surgeon, Philippines Division, while cranking his automobile had it backfire, from which he sustained a fracture of the radius near the wrist.

Surgeon E. L. Munson, of the United States Army, has been appointed Chief Health Officer of the Moro Province. He has already pushed the free dispensary system far into the interior, and is accomplishing much to establish friendly relations with the Moros, who in times past have been a constant source of trouble to the United States troops.

1. Errors of Diagnosis in Gall-Bladder Disease from a Surgical Point of View. J. H. Gibbon.
2. Condition of the Upper Region of the Abdomen in Relation to Disease of the Gall-Bladder. C. G. Stockton.
3. Acute and Chronic Suppuration of the Middle Ear. G. L. Toby, Jr.

1. Diagnostic Errors in Gall-Bladder Disease.—J. H. Gibbon has searched his operation records for the cases in which he expected to find gallstones and did not, or in which he had made some other diagnosis only to find that gallstones were the cause of the patient's suffering. The latter mistakes are much less frequent than the former. The errors may, in the light of what is found at operation, be clear and it is evident when and how one went astray, but there will still remain cases which cannot be cleared up quite so easily. A history of indigestion which manifests itself soon after eating by a sense of fullness and the eructation of gas; by attacks of pain of sudden origin in the upper right quadrant passing across the abdomen and around to the back and perhaps to the right shoulder-blade, and which are relieved by vomiting; and the finding of marked localized tenderness on palpation when the patient takes a deep breath; certainly suggest gall-bladder trouble. If we have added to these severe colic requiring morphine for its relief and followed by a transient jaundice, one is quite justified in making a diagnosis of gallstones. Surgeons have learned, however, that a patient can have all of these symptoms and still not have gallstones.

2. Conditions in the Upper Abdomen in Relation to Gall-Bladder Disease.—C. G. Stockton points out that cholecystitis and allied conditions, duodenal and pyloric ulcer, appendicitis, cancer of the stomach with metastasis to the liver, cancer of the ascending colon, slowly perforating peptic ulcer with abscess, some cases of syphilis of the liver, septic endocarditis with secondary infection of the liver and biliary apparatus, affections of the pancreatic head, and, occasionally, septic right kidney represent the group of diseases which often, either in origin or in attending symptoms, are related to the right upper quadrant of the abdomen. These conditions may puzzle the diagnostician. Important among the causes of obscurity in diagnosis are: (1) The development and persistence of symptoms in an organ as results of disease in another, usually, but not necessarily, contiguous part. (2) Comparatively trivial local disease accompanied by severe and misleading symptoms, or the reverse of this. (3) The simultaneous presence of two diseases. (4) The influence of diathesis and metabolic peculiarities not only in the inauguration of symptoms, but also in masking conditions and in delaying recovery.

7. Medical Sociology in the Public Schools. Mary Sutton Macy.
8. An Epidemic of Trichinosis in Pennsylvania. J. Ballagi.

1. Pus in the Urine.—V. C. Pedersen states that pus may originate from any of the ordinary subdivisions of the urinary and genital tracts; for example, in the male from the foreskin, the anterior urethra, the posterior urethra, and the periurethral structures—notably the prostate; and in the female from the vulva, the vagina, the uterus, and the urethra corresponding with the posterior urethra in man; and in both sexes from the bladder, either or both ureters, ureteral pelves and kidneys. It therefore becomes the duty of the practicioner to know as far, and as early as possible, every detail regarding pus in the urine, which has reached any important and persistent amount.

5. The Kinetic Neuroses and Psychoses.—T. J. Orbison believes that the rational treatment of the functional neuroses is a problem of kinetics, anthropology, and psychology. The training camp method of treatment makes use of the rest treatment in suitable cases. It invariably makes use of intensive psychotherapy. It systematizes and prescribes the amount of rest, diet and exercises. During the period of treatment—at times from the very beginning—the training consists of the more or less strenuous régime that has been used by athletic trainers for the purpose of enhancing mental and physical vigor, but in such amounts as shall be suitable to the individual in hand. The training camp method is not put forward as a cure-all; it is only a rational adaptation of well known curative measures. The author's method is based upon a series of thirty cases of neurasthenia and psychasthenia, eight cases of dementia præcox, two cases of hysteria, and two cases of alcoholism.

7. Medical Sociology in the Schools.—Mary Sutton Macy notes that from the physician's point of view the laggard is a problem either in faulty hygiene or in pathology. From the teacher's point of view he is a drag on a class, a blot on the reputation of the teacher, or a problem in discipline, or all three. From the social point of view the laggard is an increased expense, a social menace, or a problem in social adjustment. The causes that produce backward children are the following: Retardation from prolonged or frequent absences, whether due to frequent illness, frequent change of home locality or school, or both; parental negligence or indifference; truancy *per se;* or other causes of irregularity in school attendance; retardation from physical inefficiencies or deficiencies, which may cover not only such conditions as blindness, partial or complete; deafness, partial or complete; adenoid vegetations and similar much discussed physical defects; but also tuberculosis, anemia, infantile paralysis, and cerebrospinal meningitis, with their sequelæ, etc.; retardation from mental inefficiency or deficiency, under which heading must be grouped not only the imbeciles, idiots, cretins, and morons who are outside State or municipal institutions for the segregation and care of such cases, but also that much larger and more important group of so called "borderline cases," which, from malnutrition or physical inefficiencies, or both, have been so far retarded as to make differentiation on first or even second examination almost impossible.

3. Etiology and Vaccine Treatment of Hodgkin's Disease.—F. Billings and E. C. Rosenow conclude on the basis of their study of twelve cases of Hodgkin's disease that the causative factor is the polymorphous diphtheroid bacillus isolated in similar cases and successfully cultivated by other observers. They report an apparently marked improvement resulting from injections of the killed organisms. The vaccines were made by growing the organisms, previously isolated from removed lymph-nodes, in aerobic and anaerobic cultures on Loeffler's blood-serum or other culture-media and incubated at least three days before use to insure sterility. Phenol (carbolic acid) 0.5 per cent. is added and the killed suspensions are chilled before use. With varying histological conditions of the lymph-nodes in the twelve cases the same bacillus was isolated in all. In only three cases was the culture obtained pure, the bacillus in the other cultures occurring with a staphylococcus which the author's findings indicate is derived from the bacillus. The lymph-nodes longest involved gave the greatest number of organisms. In all but one patient, who received a vaccine prepared from other patients, an autogenous vaccine was given subcutaneously every five to seven days in doses increased gradually from 5 to 100 million. Varying degrees of febrile reaction followed, the reaction at the point of injection being slight. In addition, roentgenotherapy was used in nine cases. Two patients, under other care, died of mediastinal pressure, and one after the third, and another following the first vaccination. Prior to the patient's death the microorganism was isolated from the lymph-nodes of the neck and groin. Of the other patients one is well, the others are improving, with a diminution of the lymph-nodes and spleen, a return of the blood-picture to normal, and gain in weight.

4. Artificial Feeding.—By H. Lowenburg. (See MEDICAL RECORD, June 28, 1913, page 1192.)

6. A New Vasoconstrictor Substance.—C. Voegtlin and D. I. Macht in the course of some investigations on Eck's fistulas in dogs were impressed by the fact that with the extirpation of the liver, after an anastomosis had been established between the vena cava and the portal vein, there occurred a train of symptoms similar to those produced by the digitalis bodies. It occurred to them that these symptoms might be due to some substance normally present in the blood which is destroyed by the liver. They therefore apparently isolated such a substance, which they found a powerful vasoconstricting agent with properties closely resembling those of the digitalis-like bodies. Using the same methods they were able to extract a similar substance from human blood serum, blood-plasma and red blood-cells. The vasoconstricting action of blood-serum has been attributed to suprarenal extract. The authors regard the crystalline substance isolated by them as a substance entirely different from suprarenal extract or any other body hitherto obtained from the blood. Neither is it identical with beta-imidazolylethylamine recently isolated by Barger and Dale from the intestinal wall, and suggested by Kaufman as being perhaps responsible for the vasoconstricting action of serum. Observations seem to point to its relation to cholesterin on the one hand and to the cortex of the suprarenal glands on the other hand.

7. Accidents in Transfusion.—R. Ottenberg and D. J. Kaliski find that accidents in transfusion due to the occurrence of hemolysis or agglutination of the donor's blood-cells by the patient's serum, or vice versa, can be absolutely excluded by careful preliminary blood-tests. The relation between test-tube hemolysis and intravascular hemolysis is close, and it seems likely that in all cases in which there is test-tube hemolysis, some intravascular hemolysis occurs. When this exceeds a certain limit hemoglobinuria results. The occurrence of agglutination (between the blood of the donor and that of the patient) need not be regarded as an absolute contraindication to the transfusion, but non-agglutinative donors should be chosen whenever possible. Phagocytosis of red blood-cells by leucocytes in the circulating blood of the patient transfused is undoubtedly connected with interagglutination of the two bloods; it occurred in the authors' series in two cases in which the serum of the patients was agglutinative toward the cells of the donors (in one of the cases the serum was also hemolytic) and it did not occur in any of the thirty-five non-agglutinative transfusions in which it was carefully looked for. These negative cases included two cases with extensive urticaria and one case with severe febrile reaction after transfusion. In the cases in which the serum of the donor was agglutinative toward the cells of the patient, no phagocytosis of red cells in the circulation was seen. In selecting donors with regard to agglutination, the agglutination of the donor's cells by the patient's serum is more important to avoid than the reverse. Febrile reactions or urticaria and other skin eruptions occur after about 10 per cent. of transfusions, irrespective of hemolysis or agglutination, and are not due to fibrin ferment or to blood-platelet destruction. These reactions, however, are never serious and the patients do well in spite of them.

1. Development of Our Knowledge of Diseases of the Heart.—T. Wardrop Griffith presents a historical survey of this development. Since the publication of his views as to the circulation of the blood by Harvey in the year 1628 knowledge of the diseases of the heart appears to have progressed along natural lines. There have been the careful recording of symptoms and painstaking observations in the post-mortem room. On the clinical side there came the assistance obtained by percussion, which, though introduced by Auenbrugger, was mainly developed by Corvisart and subsequently by Piorry; then

there came the use of the stethoscope, which was not, of course, the beginning of auscultation. On the pathological side, there came the assistance derived from histology. This was followed by the invention of the sphygmograph, an instrument very disappointing to those who expected too much from it, and which in this respect is sometimes unfairly judged, and of various instruments for the measuring of blood pressure. More and more, since the invention of the sphygmograph, experimental physiology has come to throw light on the path which clinicians ought to tread. The work of Gaskell on the reptilian heart and of others on the heart of the mammal has been pressed into the work of the clinician; and as a practical outcome of this we have the polygraph and the electrocardiograph. Something has been done by the use of the *x*-rays, and with the perfecting of the orthodiagraph more may be expected. The most valuable indication of the capacity of a heart for work is clearly what it can do; and one of the best instruments for determining this is a staircase. If there is anything wrong with the valves of the heart salvation must depend on the condition of the cardiac muscle. The capacity of the heart muscle for work depends, however, upon its five functions of rhythmicity, excitability, conductivity, contractility, and tonicity. These are the five links in the chain of cardiac integrity. If one can subject the heart to an examination as to its condition in respect of each of these functions we may be able to discriminate between forms of cardiac failure, which, though apparently identical, are really distinct; and it may be that in the future these causes may call for different forms of treatment and not call in vain.

2. Astrology in Medicine.—By C. A. Mercier. (See MEDICAL RECORD, November 29, 1913, page 905, and December 6, 1913, page 1141.)

5. The Examination of Tuberculous Pleural Fluids.—S. R. Gloyne emphasized the fact that the finding of tubercle bacilli is the only conclusive evidence of tuberculous infection. In the author's series of cases bacilli were found in 40 per cent. of the serous, and 71.43 per cent. of the purulent fluids. Ordinary film preparations are satisfactory in purulent fluids, but in serous fluids more careful measures are often necessary. In large effusions, without clot, sedimentation and centrifugation of the fluid may be sufficient. When present, the examination of clot offers the best hope of finding bacilli. In serous effusions the next best test is the lymphocyte count. Failing this, the tests in order of value are protein content (usually 4-5 per cent.) and specific gravity (about 1018). Sterility on ordinary culture media is suggestive of tubercle in purulent fluids. It is not of much value in serous exudates, since some other effusions and most transfusions are also sterile. Secondary infection was noted by the author only in one instance.

8. Eye Coloration in Relation to Diphtheria and Scarlet Fever.—A. L. Dykes refers to the observation of Biernacki who found that children with light eyes appear on the average to be more susceptible to severe diphtheria and more likely to die. Several observers have shown that there is a relation between susceptibility to disease and pigmentation. Shrubsall found that epilepsy and skin diseases are more common in the brown-eyed, while acute rheumatism more frequently attacks light-eyed people. Similar observations by McDonald demonstrate a correlation between pigmentation and susceptibility and recuperative power in the acute fevers among the school children of Glasgow. Dykes found that scarlet fever is more frequently severe and has the higher mortality in light-eyed children. This distinction was even more striking in diphtheria.

12. Chronic Polyorromenitis (Multiple Serositis).—R. G. Hann reports the case of a woman aged 41 years who presented a clinical puzzle of great difficulty. The diagnosis made was that of intrathoracic growth, but as time went on it became clear that this diagnosis must be wrong, though it was not easy to offer any other explanation of symptoms so diverse as laryngeal stridor, exophthalmos, pigmentation of the skin, and ascites. The absence of a reliable history was an additional handicap. At autopsy there were found obliteration of the right pleural cavity, a considerable amount of fluid in the left pleura, shrinkage and atelectasis of the bases of the lungs, adherent pericardium, advanced mediastinitis, a moderate degree of cirrhosis of the liver, and obliteration of the peritoneal cavity by adhesions. The consideration of the ascites introduces one of the most interesting features of multiple serositis. It has been explained variously as due to interference with the venous return from the abdomen by changes caused by perihepatitis, or by cyanotic induration of the liver; to myocardial incompetence following pericarditis, comparable to the ascites occasionally seen before general edema in failure of compensation following chronic disease of the heart; or to chronic peritonitis. The author regards the chronic peritonitis as the cause in the case reported by him, for with the peritoneum deeply involved and ascites, there was no perihepatitis. Hale White has seen two cases in which with universal perihepatitis and no chronic peritonitis there was no ascites. The chronic form of polyorromenitis has been ascribed to infection by the tubercle bacillus, but there is singularly little published evidence in favor of this theory. Acute rheumatism with its proclivity for causing effusions would seem a likely cause, and such cases have been observed.

13. Failures in Tonsil and Adenoid Operations.—W. Wilson points out that many failures from these operations result from neglect to remove the enlarged posterior end of the inferior turbinals, which are far more obstructive to respiration than are the faucial tonsils; of course, in many cases they would diminish in size after removal of the pharyngeal tonsil, but as this would occupy from two to three years, during which time the nasal obstruction would continue, the question would arise, why operate at all? A patient who undergoes an operation for nasopharyngeal obstruction deserves a perfectly functional result. It is of no use to scrape the pharynx as a routine when the entire obstruction is due to nasal stenosis. The posterior ends may be removed by snipping them away with one of the guillotines invented by Lake, but often it is impossible to get these instruments easily down both sides of the nostril. In this case a strong nasal snare may be employed: the loop should be guided over the posterior ends with a finger in the nasopharynx. Of special interest, also, is the persistence of symptoms of "throat cough" and laryngeal catarrh after operation. In many cases this will be found to be due to either a septic condition or actual hypertrophy of the lingual tonsil, which may be in contact with the epiglottis. It is possible that after complete extirpation of the faucial and pharyngeal tonsils the remaining lingual tonsil undergoes some compensatory hypertrophy.

14. Perforation of Gastric Ulcer into the Heart.—F. E. Tylecote reports a case of this condition and notes that the first case to be recorded was that by Oser in 1880. In 1894 Ludwig Pick published a monograph on perforation of the diaphragm by gastric ulcer, and of 28 cases collected by him only 10, or 35.7 per cent., involved the pericardium. Of these 10 only 4 involved the heart muscle itself. His monograph makes it clear that in these cases a perigastritis is always present, and that it is *via* the most anterior portion of that part of the diaphragm on which the heart rests that the entry is gained. Of 10 of Pick's cases in which the ulcer was on the lesser curvature, 6 perforated the pericardium, 3 the left pleura, and 1 the mediastinum. Where the ulcer was (5 cases) situ-

ated in the fundus, the left pleura was always perforated. Of 3 in the cardiac region, 2 perforated the left pleural sac and the third the pericardium. All ulcers on the posterior wall perforated the left pleura, while the one case on the anterior wall involved the heart muscle. All were chronic ulcers with thickened and indurated edges, and their bases were adherent to neighboring organs, so that they were not able to cicatrize, contract, and heal up. As one would expect—taking into account the relationship of the pylorus to the liver—in spite of the frequency of pyloric ulcer, it was only met with 3 times in Pick's 28 cases of perforation of the diaphragm.

1. Paroxysmal Dyspnea in Cardiorenal Patients.—Thomas Lewis points out that a very large proportion of heart patients who exhibit great anxiety of breathing do not exhibit a marked degree of dyspnea. Breathlessness and cyanosis are often shown in disproportionate degree. The significance of this fact has escaped attention. If a patient is urgently breathless and an equivalent cyanosis is not found, the dyspnea is not wholly due to deficient acration of the blood. The author describes a special group of cases, the most important feature of which is the breathlessness. Examination of the blood in these cases has shown by special methods evidences of a diminished alkalinity sufficient to account for the dyspnea, which alkalinity is due, not to CO_2, but to non-volatile acids. The breathlessness is of the periodic type known as Cheyne-Stokes respiration, being accompanied when severe by conspicuous restlessness during the periods of hyperpnea, and becoming exaggerated by the slightest exercise. There is no reserve, the breath cannot be held, and forced breathing is followed by no apneic period. Oxygen affords little or no relief, though it alters the type of breathing. Secondly, there is evidence that the blood is well or moderately aerated; there is no cyanosis comparable with the dyspnea. Thirdly, the dyspnea is more severe toward evening and in the night, and sleep is broken by exaggerated attacks of breathlesssness. Fourthly, the pulse rate is increased (80-100), and especially toward evening. Fifthly, the temperature is subnormal. The condition is an extremely common one, and urgent dyspnea, where there is a want of equivalent cyanosis, is the first guide; really distressed breathing in elderly subjects, accompanied or not by cyanosis, is always open to suspicion; the presence of Cheyne-Stokes breathing, and especially the characteristic nocturnal attacks, are extremely valuable indications. The periodicity of the breathing is often inconspicuous or variable; it may consist merely of slight waxing and waning in the amplitude of the breathing, there may be no true apneic periods; it may be present only at night or at the patient's first admission; it is very often overlooked. Any increase in the acidity of the blood increases the depth and rate of respiration. It is a matter of indifference if the excess of acid is volatile, as it is when CO_2 is breathed, or whether it is non-volatile. There are many notable examples of the latter. Leymann introduced small quantities of phosphoric and other acids into the circulation. The injection of acids produces hyperpnea; of alkalies, apnea. The dyspnea of violent exercise is due to accumulated lactic acid. Diabetic asthma is the result of diacetic and betaoxybutyric acids. The presence of excess of non-volatile acid stimulates the respiratory center, and hyperpnea results; the hyperpnea washes out CO_2, it increases the pressure of oxygen in the alveoli, and in this way the body attempts to accommodate itself to the altered conditions; but the accommodation is imperfect, and the reserve is decreased or abolished. Patients who suffer from the acidosis described by the author have prominent lesions in two chief organs, the heart and the kidneys. In none of his cases was either of these organs found healthy after death. One may seek the cause of the acidosis in defects of the circulation or in defects of the kidneys. That it is not due to deficient circulation is evident, for the degree of acidosis is not parallel to the circulatory defect. Is it the result of defective elimination, or does it come from an altered metabolism secondary to renal disease? To these and similar questions no certain answer can be returned; though one may suspect that, as in one renal patient urea may be retained and as in another chlorides may be retained; in a third type there may be an alteration in the elimination of acids and bases.

4. Intestinal Obstruction.—E. Deanesley presents the following maxims: Do not confuse constipation with obstruction. Always consider the possibility of obstruction when pain, vomiting, and distention exist together. If there is no rigidity and no fever in such a case, obstruction is practically certain and operation is urgently indicated. Above all, do not waste time with such futile and dangerous things as purgatives and enemata. If these rules were more generally followed the mortality of intestinal obstruction would be less appalling than it actually is.

8. Function of the Large Intestine.—J. Griffiths notes that the interest taken in the colon and its functions during the past few years has been very great. In 1901 Barclay-Smith put forward a suggestion that in consequence of the advance in the preparation of food, rendering it digestible, nothing now remains for the colon to do, and that it may be regarded as a useless appendage to our bodies. Sir Arbuthnot Lane goes further, and characterizes it as a cesspool, presumably either to be cleansed at periodic and stated intervals, as cesspools are to-day in some old-fashioned places, or to be altogether done away with, as in the modern method of sanitation. Metchnikoff regards it as having developed in order to act as a reservoir, so that primitive man might run after his prey or away from his pursuing enemies without undergoing the risk of stopping or slowing his rate of progress to evacuate his intestine. Keith, without expressing any decided opinion for or against the above hypotheses, wonders whether we cannot restore to the colon its former function. He appears to suggest that ingenuity might yet be exercised with advantage in the direction of finding an agreeable dietary which will give back its old work to this large tract of the alimentary canal, and that unless something useful be done the colon will certainly come to be regarded under our present civilization as an incumbrance to man in the performance of his daily work. The author believes that the work of the colon, apart from its use as a storage and expellor of the common refuse, is (1) to dry the contents as they leave the small intestine, and (2) to get some useful substance out of the refuse while it is mixed and churned and undergoing fermentation with, it may be, disintegration. This substance, though as yet

of unknown quality, gives to the body that which it requires for the development of that feeling which is best described as being "in the best of health and spirits"; further, it is something of all-important value to the individual. Excess of it is deleterious; lack of it is attended with pronounced changes in general nutrition, and perhaps progressive inanition, leading after a variable time to death from simple loss of vigor and strength.

10. **Traumatic Intramuscular Ossification.**—J. Morley concludes that traumatic intramuscular ossification ("myositis ossificans") is due to migration of osteoblasts into adjacent contused muscle and blood clot, after destruction of the periosteum and loss of its function as limiting membrane to the growth of bone. It is essentially the same process as callus formation. The condition may be produced experimentally in animals by reproducing the same mechanical conditions by an aseptic open operation. In a case of difficulty in diagnosis from sarcoma open exploration is advisable. Simple excision is usually, though not invariably, followed by recurrence. Conservative treatment condemns the patient to a long period of disability, which may occasionally be permanent. Excision combined with the grafting of deep fascia on to the denuded surface of bone gives the best prospect of rapid and complete recovery, and is urged for all cases not complicated by ossifying periarthritis. Osteoblasts and chondroblasts are the same cells under different conditions of nutrition.

Berliner klinische Wochenschrift.

November 24, 1913.

Operation for Aneurysm with Vascular Transplantation.—Unger sums up his paper briefly, as follows: after extirpation of a large aneurysm of the popliteal artery, the stumps of the femoral and anterior tibial arteries are united by a bridge which represents 15 cm. of the saphenous vein. This case ended successfully. The second case was one of arteriovenous aneurysm of the thigh, which was extirpated. The femoral vein was now sutured and the vena saphena used to fill the defective in the femoral artery. The result is not mentioned, but doubtless was successful. In a third case in which vascular transplantation was practiced failure occurred, because the transplant was not healthy. The author regards this work as particularly indicated in military surgery.

Influence of Splenectomy on Pernicious Anemia.—Huber extirpated the spleen of a woman with this affection and three months later demonstrated the case before a medical society. She appears to have benefited somewhat and the improvement persists. The author's reasons for performing splenectomy were as follows: there was little risk of an operative death. Again, when the spleen is extirpated a polyglobulia develops; as if under natural conditions the spleen inhibits the hematopoietic function of the bone marrow. Both hemolytic icterus and splenic anemia have been improved and even cured by splenectomy. Thus far the following have resorted to the latter for pernicious anemia: Eppinger, Mosse, Klemperer, and Hirschfeld, and perhaps others. The case corroborates the results of the predecessors in the field in the sudden changes in the blood pictures and general condition. The resource should be practiced when all others have failed. All the splenectomized cases are of too recent date to permit of conclusions being drawn. There seems to be no doubt that life can be notably prolonged, the patient being also in good condition the while. The author would always prepare for transfusion in case the latter seemed indicated after operation.

Abderhalden's Serodiagnosis in Psychiatry According to Theobald.—Toward manic-depressive insanity, chopathy, alcoholism, senile dementia, and especially dementia præcox, the reactions of the sexual glands, thyroid and brain are quite considerable. The accumulation of free cleavage products of albumin in dementia præcox is established, not only by Abderhalden's dialysis procedure, but by the antitryptic index. These products behave as heterologous in the blood. A woman with precox cannot decompose testicular matter. Two cases of severe arteriosclerosis and one of epilepsy in women reacted to testicular extract. In alcoholism, hysteria, psychopathy, and manic-depressive insanity, the author's negative results correspond to those of others. Idiots often react to cortex and sexual glands with sex specificity. In paresis, in the majority of cases, cortex was disintegrated, but sexual glands only once, and liver twice. Arteriosclerotic insanity nearly always attacked cortical substance. The same is true of senile dementia and a majority of cases of epilepsy. At present the value of the method lies in the differentiation of dementia præcox.

Deutsche medizinische Wochenschrift.

November 20, 1913.

Meningitis After Follicular Angina.—Siemerling reports the following case of this unusual sequence: a fifteen-year-old boy was taken with sore throat. Tonsils reddened and swollen, containing numerous yellow plugs. Pharynx reddened, covered with mucus. A swollen gland under the angle of the right jaw. Received a gargle of hydrogen peroxide. Fever as high as 38.2° C. Left tonsil cleared up first, followed by the other; pharynx still very red. Temperature still high. After six days of tonsilitis, the head began to ache slightly. From the first there had been slight rales and the pharyngitis did not undergo involution. To headache were added vertigo and tremor. On the tenth day of the entire illness the picture changed radically to one of meningitis. For a short time the temperature had been subnormal. The family history was now ascertained. Boy had had a cough before the sore throat had developed, but had been sound and active; in fact, an athlete. After the sudden onset of meningeal symptoms lumbar puncture was performed and the punctate not incompatible with tuberculous meningitis. The disease was of severest type, and finally recovered after all modern resources had been employed. The first diagnosis had been tuberculosis, but this was excluded as the disease progressed, as was also infantile spinal paralysis. The severity of the picture excluded mere meningismus. The condition was, therefore, held to be a severe case of meningitis serosa. Its severity would have better suited epidemic meningitis. The severe pharyngitis suggested the retronasal angia of the latter disease.

Clamping the Parametria for Hemostasis During and After Labor.—Zimmermann lauds this resource especially for postpartum hemorhage, before or after expulsion of the placenta. No essential dangers are connected with the operation, which is also much simpler than the tamponade. The clamping is also indicated in placenta prævia when the tolerance point of blood has been reached. All possibility of sepsis is avoided by this approach from the rear. The portio is pulled down beyond the vulva and the parametria are then brought down in like manner. Museaux's forceps are now applied to the parametria and the forceps which held the portio are removed. The former are left in situ twenty-four hours.

Rachitis of the Nose and Its Relationship to Bronchial Asthma.—Walb states that the nose is frequently the seat of rachitic alterations under which he classes deviation of the septum, building of spurs on the same, etc. These alterations are not all of rachitic origin, but, however engendered, cause bronchial asthma. The fact that asthma persists after their removal and that it may occur in a normal nose has led the author to believe that rachitis is a basic cause of asthma. In a number of these cases phosphorus treatment removed the asthma.

Insurance Medicine.

The Inaccuracy of American Mortality Statistics.—Whatever view one may take of the methods and manners of recording mortality statistics, it will be readily granted that their essential foundation is the correct statement of the cause of death. Dr. Horst Oertel, scientific director of the Russell Sage Institute of Pathology, New York, in a paper on this subject, says he considers it strange that notwithstanding much discussion about the improvements in the methods of recording and interpreting these statistics, the reliability of the death certificate itself is generally accepted. Unfortunately no sufficient effort is made to trace its validity, and many serious writers are apparently unconscious of the weakness of the material from which they draw conclusions. He claims that the errors and inaccuracies in the present returns of the causes of death as filed with all our Boards of Health are so great that it may be justly doubted whether deductions based on this evidence of American statistics are at all trustworthy, or, as Professor Bashford, director of the Imperial Cancer Research Laboratory, London, remarks: "The vital statistics of Ceylon are more reliable than those of New York." What are the reasons for this deplorable state of affairs and what remedies may be applied? Hoertel gives a short outline of what he regards as the reasons, and suggests some remedies.

The majority of American death certificates, even from the best representative hospitals, which have the best available records, are based usually on bedside diagnosis only, and, as is natural under our present inadequate system of hospital administration, without the additional objective proof of autopsy. This is particularly the case in the United States, where the importance of teaching pathology by autopsy has never been appreciated and has been grossly neglected. The disastrous result of this lack of knowledge is necessarily poor diagnostic and critical ability.

Most outsiders and very many physicians do not have the proper conception of the difficulty of arriving at a scientifically accurate diagnosis. Even the autopsist arrives at the truth only after prolonged microscopic study. Oertel reviewed the mortality records of one of the best known hospitals in the country and found that out of 3,170 deaths occurring during the year 1912 only 482, or 15.2 per cent., came to autopsy—a very small number compared to the average of 80 to 90 per cent. of autopsies in foreign hospitals. Of these 482, 92 were infants, and in practically all of these the autopsy disclosed important lesions not suspected, but the clinical observation had been too brief for accurate diagnoses, and they were not included in the following statistics.

The autopsy confirmed the clinical diagnosis in 87 cases out of the 390, or in 22.3 per cent. In 54 cases the diagnosis was partially correct, but other important lesions that had contributed to the diagnosed lesion were found. In the other 133 cases of the 390, or 34.1 per cent., diagnosis was either entirely wrong or not made at all. In some cases the diagnosis is recorded after autopsy has been performed, so it will be seen how uncertain and misleading statistics from such records would be. A second cause of unreliable statistics is the ignorance, carelessness, and haste of physicians, in private as well as public service, in making out death certificates. In hospitals the certificates are frequently signed by the young internes, or even substitutes, and the attending physician never passes on the certificate. Many times in private practice the physician is not to blame for many incorrect death certificates, as patients are not under observation sufficiently long enough to permit a diagnosis, or the mental and physical status of the patient precludes a correct interpretation of the case, or the important lesion may be so deeply shadowed by secondary results that it is impossible to reach a verdict during life. And it must not be assumed that obscure cases are rare; on the contrary, only the clear-cut, typical, textbook cases are very rare.

He offers the following suggestions as a solution of this unfortunate condition of affairs: (1) It must be appreciated that the only reliable death certificate is the one made by an experienced pathologist after autopsy. (2) Physicians, officials and the public should be educated as to their responsibilities in this matter. The large public hospitals should lead in this campaign and require autopsy in each case. Public sentiment, if trained, would no longer oppose autopsies on the ground that they are performed for curiosity's sake. Undertakers, for selfish reasons, take pains to prevent autopsies by impressing people that an autopsy produces mutilation.

The State Boards should include a severe practical examination in pathological anatomy and the performance of autopsies, similar in character to the examinations in force in Germany for years. (3) Every death certificate should show plainly whether a return of the cause of death is based on clinical symptoms alone, or on additional microscopic evidence during the life of the individual, or on the complete autopsy. These should be kept apart in three groups as unreliable, more likely reliable, and reliable death records. Every worker would then know what to trust, and much nonsense would remain unwritten and, it is to be hoped, unsaid.—*The American Underwriter.*

Physical Class Distinction Through Life Insurance.—In an article on Life Insurance and Eugenics, J. M. French says that life insurance is gradually building up a distinct line of cleavage, dividing a community into two classes, the one comprising those who have been accepted by a responsible insurance company as good physical risks, and the other those who have not been so accepted. This latter includes not only those who have been rejected, but also the mass who have never been subjected to the tests and have no knowledge as to their acceptance. The accepted risks are therefore on a higher physical plane, and raised much above the average.

It is one of the characteristics of all men who are worthy of the name that they reach out for something a little higher than the general average, something so difficult of attainment that not every one can reach it, something that causes them to be looked up to, something to which everyone cannot be admitted. In this way is carried on the natural process of natural selection, which results in the upbuilding of the race. The result is the formation of a voluntary aristocracy based on good physical qualifications, in which the life insurance policy acts as a certificate of admission to the society of the high grades, and a diploma of merit wherever found. Thus, life insurance is an aid to the promotion of a longer life, a better class of men and women, and the forerunner of a better race.—*American Medicine*, October, 1913.

Book Reviews.

Die Gicht. Ihr Wesen und Ihre Behandlung nach neuen Untersuchungen mit einem Anhang: Diätzettel für Gichtkranke. Von Dr. S. Cohn. Berlin-Schöneberg Spezialarzt für Gicht. Price, 2.50 marks. Berlin: Basch und Co., 1913.

The author gives practical suggestions for the diagnosis of gout, intended to make practitioners independent of the laboratory. His therapy consists of a diet containing as little sodium as possible, and colchicum in acute cases. Massage and diet regulations are given in full together with a number of case histories.

The White Linen Nurse. By Eleanor Hallowell Abbott, author of "Molly Make Believe," "The Sick-a-Bed Lady," etc., etc. With Illustrations by Herman Pfeifer. Price $1.00 net. New York: The Century Company, 1913.

Rae Malgregor is a simple country girl with a "doll" face who went into nursing because she thought "the uniforms were so cute." On the day of her graduation she suffers a nervous breakdown, which is really the protest of her spirit against the repression and deadening effect of hospital discipline. The Senior Surgeon, "gray-haired, gray-bearded, gray-suited, grayly dogmatic as a block of granite," proposes as a remedy that the hysterical girl should accompany him on a motor trip to a patient thirty miles in the country. The crippled child of the surgeon is the third occupant of the car. On the return trip they are wrecked in a meadow, but no one is seriously hurt. The nurse extricates the surgeon from under his car. While all three are gazing at the burning remains of the machine there dawns upon the surgeon the sense of his own widowed loneliness, and he bluntly proposes to the girl, asking her to undertake "general heartwork for a family of two." This is another shock to a nerve-shattered girl on a day full of stirring incidents. It is not enough to be asked to marry a man so much older than herself, whose intellectual tastes she realizes are in marked contrast to her own rustic simplicity, but she is asked to tolerate his one great weakness, namely, an annual June trip into the Canadian woods, ostensibly for hunting but really for a grand spree. His proposal is accepted, for although she is terrified to think of marrying a "June drunk," nevertheless she knows that he has "the grit to pull up absolutely straight as a die and be a *surgeon* all the other 'leven months in the year." They were accordingly married on the first day of June; the Senior Surgeon left for his Canadian carouse, and the White Linen Nurse came home alone from the church to her husband's great gloomy house. She begins the task of restoring order out of the chaos into which this had fallen. She writes, still as Rae Malgregor: "I like being married, Dr. Faber. I like it lots better than I thought I would. It's fun being the biggest person in the house." In another letter she writes: "I hope you're having a pleasant spree. Oh, I forgot to tell you that one of the wall paperers is living here at the house with us now. . . . And he's a nice young fellow." Naturally the following day the Senior Surgeon started homeward. The remainder of the narrative consists of the skillful delineation of a difficult psychological situation, the unexpected return of a jealous husband whose nerves are still tightly keyed as the result of a month's debauch; the surprising of his wife and the "young fellow," who happens to be her brother; a period of sulkiness during which the wife vainly courts the attentions of her lord, and finally the awakening of the latter with the realization of his own unworthiness and the faithful devotion of the one who spurned the opportunity to be relieved from her drudgery. The solution of the problem is a week's honeymoon. Thereafter his Junes would be hers.

The above story, unusual and unreal as it seems, forms the framework about which the author entwines a psychological study of two sharply contrasting characters. She displays a keen insight into the arduous work of the nursing and medical professions. Her style is conspicuous in its force and originality. A picturesque diction imparts vitality to simple actions. Here is a portrait of the doctor cranking his automobile: "He hurled his hundred and eighty pounds of infuriate brute-strength against the calm, chronic, mechanical stubbornness of that auto crank." Liberties are taken with the English language in such sentences as, "monotonous as a sob the waiting birch canoe slosh-sloshed against the beach." Nevertheless the book is intensely interesting. Medical men particularly can appreciate the subtlety of its humor and the depth of its pathos.

Surgery of the Vascular System. By Bertram M. Bernheim, A.B., M.D., Instructor in Surgery, The Johns Hopkins University, Baltimore, Md. With 53 illustrations in text. Price, $3.00. Philadelphia & London: J. B. Lippincott Company, 1913.

The recent developments in the surgery of the vascular system impart a special interest to this volume whose author has made ample contributions to the experimental and clinical aspects of the subject. His work was carried out under the guidance and with the cooperation of Halstead, Finney, Bloodgood and Cushing. The observatiop is made that success in this field of surgery demands years of trial, first in the laboratory and then in the clinic. There are presented the best methods employed by surgeons in vascular surgery, the anatomical, pathological and etiological aspects being omitted. The chapter headings are as follows: General technique; transfusion; end-to-end suture; lateral anastomosis; transplantation of a segment of vein or artery; arteriovenous anastomosis—reversal of the circulation; varicose veins; surgery of the heart; aneurysms, and statistical study of the treatment of aneurysms. Among the valuable contributions made by the author to the technique of transfusion may be mentioned his ball-tipped forceps which has been devised to prevent injury to the vessel wall, especially scratching of the intima, and his simple apparatus for the performance of transfusion. This consists of two hollow tubes, each four centimeters long, and bulbous at one end to form a neck for the retaining tie, and beveled to facilitate entrance into the vessel; the other ends are tubular and fitted for invagination. The special virtues of this apparatus are its simplicity, resembling in this respect the paraffined glass tubes, but having the advantages of non-breakability and dispensing with the need of paraffin; and the rapidity with which the separate tubes can be inserted into the artery of the donor and the vein of the recipient, by separate crews of operators. The various steps in this and other operations on the blood vessels are illustrated by a series of excellent drawings by James F. Didusch, under the supervision of Max Broedel.

Treatise on General and Industrial Organic Chemistry. By Dr. Ettore Molinari, Professor of Industrial Chemistry to the Society for the Encouragement of Arts and Manufactures and of Merceology at the Luigi Bocconi Commercial University, Milan. Translated from the second enlarged and revised Italian edition by Thomas H. Pope, B.S., A.C.G.I., F.I.C., School of Malting and Brewing, University of Birmingham. With 506 illustrations. Price $6.00. Philadelphia: P. Blakiston's Sons & Co., 1913.

Quite apart from the general excellence of this book there existed a very good reason for its translation from the Italian, and that is the fact that there are in English surprisingly few works covering the same field. There is no lack of satisfactory treatises devoted to a theoretical and systematic exposition of the subject of organic chemistry, but in most of them the practical aspects of the questions discussed, particularly as applied to industrial processes, receive scant consideration. Yet even for the ordinary student who is not intending to become a chemical technologist the study of the subject becomes vastly more vital and interesting if he is encouraged to familiarize himself with the practical applications of the reactions and substances he is investigating, while for the prospective industrial chemist some such book as this is of course a necessity. In addition there exists a real need for a comprehensive treatise of this sort to serve as a work of reference for those whose chemical interests usually lie in other directions. For all of these purposes the present volume is most admirably adapted. While its basis is a systematic treatise on organic chemistry the author has used this merely as a framework which he has filled in with detailed discussions of all the more important processes of chemical industry, such as the manufacture of illuminating gas and explosives, brewing, dying and dyestuffs, fermentation and the manufacture of wines and liquors, sugar production from the cane and the beet, the separation of coal tar products, etc. The descriptions of all these are sufficiently detailed to give a clear idea of the methods involved and are most abundantly illustrated with excellent drawings and photographs. A feature of much value is the large amount of statistical information in regard to each industry in different countries that is included. The translator deserves especial commendation for the skill with which he has carried out a task of unusual difficulty and produced a work which bears no evidence of its foreign origin. The book is a veritable storehouse of information and is worthy of the highest praise.

State Medical Licensing Boards.

STATE BOARD OF EXAMINATION QUESTIONS.

ALABAMA STATE BOARD OF MEDICAL EXAMINERS.

July 8, 9, 10, *and* 11, 1913.

(*Concluded from page* 1103.)

SURGERY.

1. Give the cardinal rules for treatment of wounds.
2. Give the treatment of shock and the precautions that may be taken for its prevention.
3. Name the different forms of peripheral aneurysms and give treatment for different varieties.
4. Name the varieties of fistula in ano and give treatment for same.
5. Describe the treatment of a compound fracture of the femur.
6. Give the diagnosis and tell how to reduce a backward dislocation of the head of the femur.
7. Give diagnosis and treatment of empyema or pus in the pleural cavity.
8. Give symptoms and treatment of gallstones.
9. Give diagnosis and treatment of perforation of the intestine in typhoid fever.
10. Give symptoms of suppurative pyelitis.

HYGIENE AND MEDICAL JURISPRUDENCE.

1. Define hygiene.
2. What is immunity and how developed? What is susceptibility?
3. Give the differential diagnosis between scarlet fever and measles.
4. What effect does excessive exercise have on the heart? What effect does insufficient exercise have on the heart?
5. What is the difference between parasites and saprophytes?
6. If on examination colon bacilli are found to be present in the general water supply of a community, what fact does it establish? What steps, if any, should be taken to protect the community?
7. Give the prophylaxis of uncinariasis.
8. What are the methods of self-purification of large bodies of water?
9. What are the symptoms of acute poisoning from bichloride of mercury and the antidote?
10. Found, the dead body of a newborn infant. How can it be positively determined that the child was born alive?

DISEASES OF THE EYE, EAR, NOSE AND THROAT.

1. In complete ptosis how is the eye, or its appendages, affected, and why? In complete facial paralysis how is the eye, or its appendages, affected, and why?
2. Give the differential diagnosis between acute catarrhal conjunctivitis and gonorrheal ophthalmia, and the general principles of management of each. Write two prescriptions for each.
3. Explain the normal reaction of the pupil. What is the condition of the pupil in iritis, and what the remedy? What is the condition of the pupil in glaucoma, and what the remedy?
4. State some conditions that would demand enucleation of the eyeball, and describe the operation.
5. Give the symptoms of complete obstruction of the Eustachian tube, of some standing, and explain briefly the measures to be employed for relief.
6. Give the symptoms, dangers, and management of acute purulent otitis media.
7. How would you diagnose and manage abscess of the antrum of Highmore?
8. Give the symptoms, diagnosis, and management of adenoids of the pharynx.
9. A person is eating and suddenly begins to struggle for breath and turns bluish in appearance; what would you suspect, and what would you do?
10. Give some of the indications for laryngotracheotomy and describe the operation.

ANSWERS.

SURGERY.

1. *The general rules for treatment of wounds:* Stop the bleeding; remove foreign bodies; make the part as aseptic as possible; coapt the edges; drain when necessary; dress, and secure rest to the part; bring about reaction; ease the pain.

2. *Treatment of shock:* Place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant, and give a hot saline infusion; morphine, hypodermically, may be necessary for the relief of pain. Adrenalin solution is administered into the arterial system.

In surgical operations *shock may be largely prevented* by reassuring nervous patients, keeping the patient warm, the avoidance of the excessive catharsis, and semi-starvation that often prevail before operations, the administration of strychnine and atropine before operation, the avoidance of delay and undue handling of parts during the operation, prompt checking of hemorrhage, and by using the utmost gentleness.

3. *Aneurysms* are described as: Fusiform, sacculated, and dissecting.

For *fusiform aneurysm*, constitutional treatment alone is indicated.

For *sacculated aneurysm* there are several methods of treatment: Constitutional; compression of the artery; ligature of the main artery; Matas' operation of aneurysmorrhaphy.

For *dissecting aneurysm*, there is no treatment.

4. FISTULA IN ANO.—*Classification:* There are four varieties: (1) The *complete*, which opens into the rectum internally and on the perineum externally; (2) the *external incomplete*, or *blind external*, which opens on the perineum, but not into the rectum; (3) the *internal incomplete* or *blind internal*, which opens into the rectum but not on the perineum; (4) the *horseshoe* fistula, which extends around the rectum and opens on each side. The internal opening is generally between the two sphincters, but may be above the internal sphincter and below the external sphincter. There may be several pockets or side tracts extending in different directions.

Treatment: This consists in "the conversion of the fistula into an open wound so that it may heal from the bottom. A grooved director is passed through the fistula into the rectum, and the overlying tissues severed with a bistoury. The sphincter should never be cut more than once, because of the danger of incontinence. All branching sinuses likewise should be opened, and all fibrous tissue, with undermined skin, cut away with scissors. The bleeding is then checked, and the wound packed with iodoform gauze. If the fistula is lined with mucous membrane it must be completely excised. A blind external fistula may be excised and the wound sutured. A blind internal fistula may be converted into a complete one and treated as above. The bowels are confined for the first three or four days, and the wound dressed after each defecation, being irrigated with creolin and repacked with iodoform gauze." (Stewart's *Surgery.*)

5. "In the treatment of compound fractures the main object is to render the wound aseptic and to give efficient exit to the discharges. For this purpose the patient should in all cases be anesthetized, the limb shaved, and thoroughly purified, and the wound enlarged and thoroughly washed out with some reliable antiseptic. It may be advisable to excise torn and dirty fragments of skin, muscle, and tendon, especially when dirt has been ground into them. Loose fragments of bone are removed and portions denuded of their periosteum may be taken away lest necrosis should ensue; where fragments retain any considerable connection with the soft parts they may be left without fear. When a sharp end of one of the fragments is protruding through a small opening in the skin it is first purified thoroughly before attempting its reduction and then replaced, after enlarging the wound in the skin, or a portion sawn off. Hemorrhage is dealt with in the usual way, and the fragments are placed as nearly as possible in their normal position. If the fragments can be brought accurately into position it is well to fix them by some mechanical appliance; but where the ends of the bone are much comminuted the small portions must be arranged in position as well as possible, and no attempt made to wire them. A good-sized drainage tube is inserted, and, if need be, counteropenings are made; the external wound is closed or not, according to circumstances, and dressed, and suitable splints are then applied. Under such a régime the majority of cases do well. Immovable apparatus may be used after a time, windows being left in the plaster casing to allow wounds to be dressed." (Rose and Carless' *Manual of Surgery.*)

6. In a *backward dislocation of the head of the femur* (on to the dorsum ilii), the head of the bone lies on the dorsum ilii; the acetabulum is empty; the great trochanter will be found above Nélaton's line; the leg is considerably

shortened, and is also flexed, inverted, and adducted; the toes rest on the instep of the other foot, the femur crosses the opposite thigh at its lower third.

Treatment: The patient is placed on a mattress on the floor and anesthetized. The leg and thigh are flexed in the position of adduction. This rolls the head of the bone down to the lower part of the acetabulum. The leg is then circumducted outward and brought down straight; this carries the head through the rent into the acetabulum. Failing success by this method, the body must be fixed and direct upward traction must be exercised upon the flexed thigh. As a rule these maneuvers are successful; if not, extension by pulleys must be made use of.

7. EMPYEMA. *Symptoms:* Fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis. *Diagnosis* is made by respiration, showing the fluid to be pus. *Treatment:* Aspiration, drainage, irrigation, resection of ribs (Estlander's operation), or resection of chest wall (Schede's operation).

8. GALLSTONES. *Symptoms:* "While the calculus remains free in the gall-bladder, usually there are no symptoms. Impaction of the stone in the common duct gives rise to intermittent jaundice, following sharp pain in the right hypochondriac or epigastric region, frequently radiating toward the right scapula, nausea, vomiting, sweating, depression, and often intermittent fever (Charcot's intermittent fever). When the stone is impacted in the cystic duct, jaundice is less common, but the hepatic colic is severe, and dropsy of the gall-bladder may occur. The diagnostic points are the age, sex, history of previous attack, with jaundice and intermittent fever, location of the pain, dark, amber colored urine, containing bile, and sometimes the finding of the stone in the feces."

Treatment "includes the relief of pain by morphine (gr. ¼) and atropine (gr. 1/125), hypodermically, inhalations of chloroform, hot applications, and blisters over the seat of pain, and, later, a saline purgative. During the interval the diet should be largely liquid, and drugs such as sodium phosphate, sweet oil, chloroform, piperazin, and mineral waters should be administered. Constipation should be avoided by giving fluidextract of cascara (3½) and glycerine (3½) every night. Lavage and rectal irrigation may be practised. If the attacks become more frequent and severe and medical treatment fails, surgical interference (cholecystotomy) is indicated." (*Pocket Cyclopedia.*)

9. *Perforation of the intestine in typhoid fever. Symptoms:* "When perforation occurs, violent pain develops. As a rule there are tenderness, rapid pulse, costal respiration, abdominal rigidity, vomiting, and shock. Usually there is temporary reaction from shock, the subnormal temperature giving way to a normal or to an elevated temperature. The vomiting in some cases becomes stercoraceous. There is constipation and sometimes dullness on percussing the flanks. The face is Hippocratic. The patient may die of the preliminary shock or may react and die subsequently of blood poisoning."

Treatment: "Death is practically certain without operation. Operation should be done at once, proper means being adopted to combat shock. In many cases a general anesthetic should not be given, but a local anesthetic should be employed. The incision should be made in the right iliac region and the colon should be first located and then the end of the ileum. By locating the colon we obtain a fixed point from which to begin our search for perforation, and by opening the abdomen in the right iliac region we come down at once onto the perforated gut in the vast majority of cases. When a perforation is found, it should be inverted with two layers of Halsted sutures. It is not wise to excise the ulcer. If the bowel is very badly damaged, resection can be considered, but it is usually wiser to make a temporary artificial anus. After finding a perforation and closing it, examine to see if there are others. Close every perforation, and if a point is found where the thinning of the bowel wall indicates that perforation is liable to occur, protect this point by inverting the area of ulceration by sutures. Clean the peritoneum by flushing with hot salt solution. Leave the wound open, insert strands of iodoform gauze, and establish tubular suprapubic drainage. Elevate the patient a little in bed and employ continuous proctoclysis of salt solution." (Da Costa's *Modern Surgery.*)

10. *Symptoms of suppurative pyelitis:* Chill, tenderness, and pain in kidney, fever, vomiting, headache, scanty urine containing pus, exhaustion, and uremia.

HYGIENE AND MEDICAL JURISPRUDENCE.

1. *Hygiene* is the science and art of all that concerns the preservation, promotion, and improvement of health, and the prevention of disease.

2. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic bacteria. Immunity may be either natural or acquired.

Natural immunity is this power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired: (1) By a previous attack of the disease caused by the bacteria, or (2) by the person being made artificially insusceptible. The conditions which give immunity from the pathogenic action of bacteria are: (1) A previous attack of the disease; (2) inoculation, with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

Active immunity follows an attack of a certain disease and secures immunity for that alone; or it follows inoculation of a virus weaker than necessary to cause the typical disease; or it follows inoculation by bacterial products apart from the organisms themselves.

Passive immunity is the term applied to the effect of a serum derived from an immunized animal and injected into one not immune.

Susceptibility is liability to infection; a loss or absence of immunity.

3. *Scarlet fever:* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent.

Measles: Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small dark red papules with crecentic borders, beginning on face and rapidly spreading over entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present.

4. *Excessive exercise* leads to irregular action of the heart, hypertrophy of the heart muscle, increased rate of heart beat, and disturbance of the rhythmic action of the heart.

Insufficient exercise leads to degeneration of the heart muscle, and general weakening of the heart's action.

5. A *parasite* is an organism which lives in or on another living organism.

A *saprophyte* is an organism which derives its nourishment from dead matter.

6. The presence of the colon bacilli in a water supply denotes the presence of sewage in that water and indicates the possibility and probability of an epidemic of typhoid as soon as the first typhoid case (or typhoid carrier) comes to that locality. Proper arrangements for the hygienic disposal of sewage should be made at once; and the inhabitants should be instructed as to the danger, and as to the proper disposal of sewage.

7. *Prophylaxis of uncinariasis:* Children and adults should be made to wear shoes; proper toilet facilities should be provided, and their use enforced; bathing or wading in shallow water should be forbidden; a proper water supply should be available for drinking purposes, and prompt recognition and treatment of all cases should be encouraged.

8. *Methods of self-purification of large bodies of water:* Sedimentation, precipitation, oxidation, dilution, the action of bacteria, and the action of water plants.

9. BICHLORIDE OF MERCURY. *Symptoms of acute poisoning:* "The nauseous, metallic taste is experienced during the act of swallowing. Within a few moments this is followed by an intense, burning pain in the mouth, throat, and stomach. The mouth and tongue are whitened and shriveled. There are vomitings of a white material, containing shreds of mucous membrane, and tinged with blood, and bloody stools. Salivation occurs if life be sufficiently prolonged. Death sometimes occurs early from collapse, accompanied by convulsions, or in deep coma; but in most fatal cases life is prolonged for from three to six days."

Antidote: "White of egg. The following precautions should be observed in its administration: Too much should not be given at one time, lest the precipitate be dissolved in the excess; the antidote should be followed

by an emetic, to remove the precipitate before it shall have been dissolved by the acid and chlorides of the gastric juice." (Witthaus' *Essentials of Chemistry and Toxicology.*)

10. If respiration has taken place, the lungs will float on being put into water; if respiration has not taken place, the lungs will sink. Further, the lungs before respiration are situated at the back of the thorax and do not fill the cavity; whereas, after respiration they fill the whole cavity.

DISEASES OF THE EYE, EAR, NOSE, AND THROAT.

1. *Ptosis* is due to paralysis of the third cranial nerve. The eyeball is almost immobile, the limitation of movement being upward, downward, and inward, with the upper end of the vertical meridian inclined inward, especially upon looking downward; the face is directed upward and toward the sound side, and the head inclined to the shoulder of the paralyzed side. There is slight exophthalmos on account of the paralysis of the three recti which normally draw the eyeball backward; the pupil is dilated and is immobile; accommodation is paralyzed; there is crossed diplopia—the false image is higher, and its upper end inclined toward the paralyzed side." (May's *Diseases of the Eye.*)

"In *paralysis of the facial nerve* the eyelids cannot be shut, and the cornea remains more or less exposed. When a strong effort is made to close the lids the eyeball rolls upward beneath the upper lid. Epiphora is a common result of facial palsy. Severe ulceration of the cornea may result from the exposure." (Nettleship's *Diseases of the Eye.*)

2. ACUTE CATARRHAL CONJUNCTIVITIS. *Symptoms:* "Hyperemia, profuse lacrymation, epiphora, a profuse discharge, sensation of sand in the eye, and sometimes photophobia. *Treatment:* Astringent and antiseptic washes are of value. Ascertain the underlying cause, if possible, and remove it. Anointing the lids with pure or medicated vaseline every evening is necessary. Alum, tannic acid, silver nitrate, and zinc sulphate are valuable as astringents. In intractable cases a 50 per cent. solution of boroglycerid in glycerin should be applied once daily." (*Pocket Cyclopedia.*)

GONORRHEAL OPHTHALMIA. *Symptoms:* Swelling and redness of the eyes, the presence of a discharge which soon becomes purulent, the conjunctiva of the lids becomes thickened, the eyelids are edematous, pain is severe, and there is some fever.

Management: Protect the sound eye. Wash the eye carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped onto the cornea every night and morning. The eyes must be covered with a light, cold wet compress. The patient must be isolated, and all cloths and compresses used must be burned. In adults the irrigation must be frequent, about every half hour or hour.

3. The *normal pupil* is circular, regular in outline, and the two pupils are equal in size.

The *pupil in iritis* is contracted, sluggish, and irregular.

The *pupil in glaucoma* is dilated, oval, and immobile.

Treatment of iritis: Atropine, dionine, the application of leeches to the temples, hot fomentations, absolute rest in bed, protection from the light, light diet, purgatives, abstinence from alcohol, avoidance of all use of the eyes for near work, constitutional treatment varying according to the etiology, paracentesis, and iridectomy.

Treatment of glaucoma: Myotics, such as eserine or pilocarpine; massage of the eyeball; mydriatics are contraindicated; operative treatment may include paracentesis, iridectomy, or sclerotomy.

4. The *indications for enucleation of the eye* are: "(1) Injuries of the ciliary region when the eye is completely blind, or the traumatism so extensive that the form of the eyeball cannot be preserved; (2) traumatic iridocyclitis, to prevent or cure sympathetic ophthalmia; (3) severe pain in a blind eye; (4) iridocyclitis, phthisis bulbi, and glaucoma, when accompanied by severe pain or inflammatory symptoms, and when the eye is blind or is certain to become so; (5) malignant tumors, either intraocular or epiocular, if they cannot be removed with retention of the eyeball; (6) anterior staphyloma, if the eye is blind, troublesome, and disfiguring; (7) panophthalmitis, after the suppurative stage is passed; (8) foreign bodies in the eye when they cannot be removed and cause irritation, or the eye is blind." (May's *Diseases of the Eye.*)

Enucleation of the eyeball is performed as follows: "A general anesthetic is generally given. After introduction of the speculum, the conjunctiva is divided all around the cornea, as close to its border as possible, and dissected back as far as the insertions of the recti muscles. A squint hook is passed beneath the tendon of the internal rectus, and the latter is divided with the strabismus scissors close to its insertion; then the other straight muscles are cut in the same way, together with the subconjunctival connective tissue for some distance beyond the equator. The points of the scissors must always be directed toward the eyeball and the latter stripped as clean as possible to avoid any unnecessary removal of orbital tissue. Instead of commencing with a circumcorneal division of the conjunctiva, we may begin with a tenotomy of the internal rectus and then divide the conjunctiva as we pass from tendon to tendon. The hook is passed around the globe to make sure that the attachments of the muscles have been completely divided. The eyeball is then dislocated forward by pressing the speculum backward, and thus the optic nerve is put on the stretch. A pair of enucleation scissors, closed, are passed between sclera and conjunctiva, feeling for the optic nerve; they are withdrawn, slightly opened, and the nerve is divided close to the sclera. The eyeball is held between the thumb and index finger of the left hand, and the oblique muscles, and other unsevered attachments are divided. The orbit is plugged for a few minutes to control hemorrhage, and the conjunctiva is usually closed with a single suture, which is passed through its edge at intervals and tied like the string of a pouch. The eye is bandaged and the patient kept in bed for a day." (May, *Diseases of the Eye.*)

5. The mouth is apt to be kept open; mouth-breathing is common; enlarged tonsils or adenoids or both are probably present; the patient suffers from deafness, or partial deafness. *Treatment:* Remove adenoids and enlarged tonsils; inflate with a Politizer bag or use a Eustachian catheter.

6. In *active suppurative otitis media:* "Pain (lessened when drum perforates), fever (100° to 104° F.), tinnitus, deafness (usually partial only), and purulent discharge (after perforation). *Treatment:* Dry heat allays the pain. Warmed water or warmed carbolic acid solution (1:40) may be used. Inflations, aspirations, etc., should be avoided. If the nares are filled with tough secretions, a spray of Dobell's solution may be used. If the pain continues over six hours in a child or over twelve hours in an adult without spontaneous perforation of the tympanic membrane, paracentesis of that structure should be performed. The concha and meatus should be smeared with petrolatum to avoid chapping, and the secretions should be gently mopped off as they appear. Under this treatment the ear usually returns to normal in two to three weeks." (*Pocket Cyclopedia.*)

7. "*Abscess or empyema of the antrum of Highmore* is a collection of pus within the maxillary antrum. It results from inflammation of the jaws, the teeth, or the mucous membrane of the nose. It causes pain, edematous swelling of the overlying soft parts, and crepitation on pressure upon the superior maxillary bone. Pus may escape from the nostril of the diseased side when the head is bent in the direction of the healthy side. A rhinoscopic examination discloses the fluid passing into the nares. The antrum on the side of the abscess cannot be transilluminated by an electric light in the mouth. The constitutional symptoms of suppuration usually arise. *Treatment:* Bore a gimlet-hole through the superior maxillary bone, above the canine tooth, or perforate the bone by means of a trocar. Irrigate daily with boiled water or normal salt solution. Keep the opening from contracting by inserting a small tent of iodoform gauze. In persistent cases it may be necessary to draw a tooth, break through the socket of the first or second bicuspid into the antrum, and insert a silver or hard-rubber tube, and also to perforate the antrum from the inferior meatus and keep the opening patent. In very persistent cases osteoplastic resection of a portion of the upper jaw will be demanded." (*Da Costa's Surgery.*)

8. *The symptoms of adenoids* are: Mouth-breathing, snoring, open-mouth, a vacant, dull expression of the face, modification of the voice (nasal twang), with inability to pronounce certain letters. *Effects:* Earache and other ear affections, mental deficiency, frequent attacks of coryza, nose-bleed, stunted growth, convulsions, laryngismus stridulus, and various other neuroses may also be noticed. *Diagnosis* is made by rhinoscopy, and by feeling the adenoids with the forefinger behind the palate. As the growths bleed easily, the examining finger will be found covered with blood. *Treatment* consists in thorough removal by a curette.

9. A piece of meat (or other food) is probably impacted in the pharynx or esophagus.

First of all, an attempt may be made to dislodge it by means of the fingers. If it is beyond the reach of the

fingers forceps may be used. If suffocation seems imminent laryngotomy must be done at once. If unsuccessful with the forceps, an attempt may be made to push the mass into the stomach, with a probang. If these methods fail and the impaction is in the upper part of the esophagus, esophagotomy is indicated; if in the lower part of the esophagus, gastrotomy is necessary, and the foreign body may be reached and removed by forceps or fingers introduced through the cardiac orifice of the stomach.

10. *Laryngotracheotomy* is indicated in diphtheria when intubation does not relieve and the symptoms are urgent; to remove foreign bodies from the larynx that cannot be treated by simple methods; to provide passage for air, in growths, tumors, or abscesses pressing on the larynx and interfering with the proper supply of air, and for edema of the glottis when the intubation tube cannot be introduced. "*Laryngotrachcotomy* consists in making an incision into the air-passages by dividing one or two of the upper rings of the trachea, the cricotracheal membrane, the cricoid cartilage, and the cricothyroid membrane. This operation is employed in cases where, from the age of the patient, the cricothyroid space is too small to admit of a sufficient opening, or in those in which, for any reason, the surgeon does not deem it advisable to attempt to open the trachea lower down. The incision in the skin and superficial fascia of the neck is made in the same manner as in the operation of laryngotomy, but is carried a little further downward. It may be necessary to displace the isthmus of the thyroid gland downward to expose the upper portion of the trachea, and when the trachea is exposed the incision should be made through this and the cricoid cartilage from below upward. A tracheotomy tube is introduced through the wound and secured by tapes tied around the neck." (Wharton's *Minor and Operative Surgery.*)

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Annuol Meeting, Held November 24, 1913.

DR. BROOKS H. WELLS, IN THE CHAIR.

Executive Session.—Among the various reports submitted were the following:

Report of the Counsel.—Mr. ALMUTH C. VANDIVER, Counsel for the Society, presented this report, which showed that during the period from November 22, 1912, to November 21, 1913, the persons attempting to practice medicine illegally in the city of New York had almost completely abandoned the prescription of drugs in their attempts to make a livelihood through the treatment of disease. Persons attempting to practise medicine under the guise of various forms of religious worship had been arrested, tried, and convicted. Realizing fully that the courts of this State held that the practice of any system of healing, whether designated as mechanotherapy or chiropractice, or mental suggestion, therapeutic suggestion, hypnotism or clairvoyance, had been forbidden by law in the comprehensive definition of what constituted the practice of medicine, persons seeking to earn a livelihood through treating disease by these so-called systems of healing, had employed physicians, not members of the Medical Society of the County of New York, to examine and prescribe the specialized form of treatment to be given by the violator of the law, and had offered the courts the defense that their actions were done in carrying out the directions of properly licensed physicians. The courts had unhesitatingly denounced the physicians who had allied themselves with fakirs, and had convicted the persons complained of in such cases presented. The work of the Counsel had consisted in investigating the various complaints received from many sources, and in determining, as a result of those investigations, and upon the evidence presented to him, whether or not prosecutions should be brought in the name of the Society. Many investigations had been made, which did not result in prosecutions, owing to the fact that the persons complained of were wary and did not care to take the risk of treating persons who were not carefully introduced to them. Cases were reported in detail which showed the investigation and prosecution of unlicensed practitioners of medicine, of persons claiming to practise the tenets of various forms of religion, of mechanotherapists, of chiropractors, of unlicensed osteopaths, of metaphysicians, of mind healers, of psychometrists, of hypnotists, of clairvoyants, of midwives, and of persons appealing to the superstitions of the poor and ignorant of the city. During the past year it had been especially pleasing to be consulted by many members of the Bar upon questions involving interpretation of the medical statutes of this State. Mr. Vandiver said he wished to take this opportunity to express his appreciation of the interest and attention given by the City Magistrates of the City of New York and by the Justices of the Court of Special Sessions to the cases presented by the Society for violation of the Medical Law. The Court of Special Sessions and the Magistrates had upheld the judgment of the Counsel of this Society in every case involving a test of whether or not there was a violation of the law. The cases given in detail showed that the poor foreign element of the community was benefited by the work done by this Society in maintaining and enforcing the statute requiring proper qualifications of any person attempting to heal disease. Mr. Vandiver expressed himself as convinced that the rigid investigation and prosecution carried on in behalf of the Society had caused the persons who attempted to reap financial profit from physical suffering to find places other than New York City for the pursuit of their heinous practices. The knowledge that the attempt to practise unlawfully in the City of New York would be followed by immediate arrest and conviction had a beneficial influence in preventing fakirs from entering the city. It was an established fact that the abortions committed by midwives practising in New York City to-day were much fewer in number than in years past. The Board of Health had established a system of midwife inspection. The investigators of the Society were constantly informed by the midwives that they were afraid to take the chance of performing illegal operations. While it was true that there were midwives performing operations, these operations were performed only upon persons carefully recommended to the midwife.

One of the greatest advertisers in the newspapers and periodicals of the city, a corporation known as the Edward J. Woods, Inc., which advertised the sale of certain patents for the cure of drink habit had been convicted upon the complaint of the Society and sentenced to pay a fine of $500, which was the heaviest penalty that could be imposed upon a corporation. It was hoped that a conviction of the defendant in this case would be obtained later, as his case was still pending. The case of Willis Vernon Cole, the Christian Science practitioner, who had been tried in the Supreme Court, and found guilty of practising medicine unlawfully, was still pending before the Appellate Division of the Supreme Court. The applications of Edward E. Conrad and Francis Gray Blinn, who having been convicted at the instance of the Society and later pardoned, for a restoration of the right to practise medicine, had been denied, but appeals had been made. Many persons had complained concerning the acts of registered physicians. Whenever the physician was a member of the Society the complaint was immediately referred to the Chairman of the Board of Censors. When the complaint was not of a member of the Society, note of the complaint was made and kept for future use. During the past year there had been forwarded to the Treasurer of the Society the sum of $2,200 for fines imposed for violations of the Medical Law. Some fines were imposed, but not paid, and the defendants served the alternative term in jail. There had been in all twenty-five convictions; two cases had been dismissed; one was still pending in the Magistrates' Court; four were pending in the Court of Special Sessions, and one was pending in Supreme Court.

Report of the Milk Commission.—Dr. ROWLAND G. FREEMAN said that the work of the Milk Commission had progressed successfully during the past year. The Commission had certified to the production of 11,842 quarts of milk produced on twenty-two farms, of which that from seventeen farms was bottled milk produced throughout the year, that from one farm was simply a summer supply, while the milk on four farms was sold in cans only. In addition, 2,580 quarts of inspected milk were produced on six farms; on two of these farms it was bottled and was produced throughout the year, on two farms it was produced only during the summer, while two produced milk for sale in cans. Their inspector, who had been doing this work for a number of years, had made 229 visits to the farms and had spent 118 days in work at the laboratory. She had supervised the tuberculin test of twenty-four herds and the physical examination of four herds. The Commission had charged for certification $7243.05, and for the tuberculin tests $2265. This income, which went into the Society Treasury, had exceeded the expenses of the Commission.

At the present time certified milk was sold in New York by the Sheffield Farms Slawson-Decker Company, Locust Farms Company, Clover Farms Company, Borden's Condensed Milk Company, and the Mutual Milk and Cream Company. The Borden Company, which began to produce certified milk somewhat more than a year ago, now had five farms certified. The new farms admitted for certification this year were in general superior in equipment to many of the older ones, and the results of the tuberculin tests were in some respects much more encouraging. In twenty three tests there were 2,078 cows tested; of these, 1,428 were retests; of these retests only 2.73 per cent. reacted; of new cows bought on test, 4.66 per cent. reacted; while of the new cows presumably not tested 11.94 per cent. reacted. Of the new herds seeking certification one of sixty-five cows showed only one reactor, while another herd of sixty-five cows showed forty-three reactors. The owner of this herd disposed of the forty-three cows and had acquired a new herd that was free from evidences of tuberculosis. In this case a cow with general tuberculosis had been allowed in the herd because a veterinarian had advised against the test and on physical examination had not found any tuberculosis present. Of the herds retested since October 1, two showed no reactors either on old cows or in the ones recently bought. The Milk Commission urged upon the members of this Society an increased interest in certified milk. If the members of the County Medical Society appreciated the safety of this milk and the comparative danger of the ordinary supply and would express their conviction to the patients with whom they came in contact, many times more certified milk would be sold in New York. It was only by the interest of the medical profession that such a movement as this could thrive or exist.

The Function of the Periosteum in Bone Transplantation Based on Human Transplantation and Animal Experiments.—Dr. CLARENCE MCWILLIAMS presented this communication. He reviewed his paper read before the Surgical Section of the American Medical Association at its Sixty-fourth Annual Session, held at Minneapolis, June, 1913, together with several experiments not included in that paper. He illustrated his talk with numerous lantern slide illustrations. The questions that he sought to answer were: 1. Would periosteum transplanted into the soft parts produce new bone? His answer was, "Yes, in a certain proportion of cases." 2. Was periosteum necessary for the subsequent life of grafts? His answer was that in 48 per cent. of the cases it was not necessary, but since one did not always know in what cases it was not necessary, to be sure of the subsequent living of bone grafts it was necessary to have it on the bone grafts. 3. Was contact of the graft with living bone necessary for the subsequent life of the graft, as Murphy maintained? His answer to this was that this contact was not necessary, and that Murphy's conception would have to be given up. Dr. McWilliams believed that he had very definitely and conclusively proved by his experiments that the periosteum had a very important function to perform in maintaining the nutrition of the graft and that this was largely dependent upon a sufficient blood supply.

Election of Officers.—*President,* Dr. T. Passmore Berens; *First Vice-President,* Dr. Howard Lilienthal; *Second Vice-President,* Frederic E. Sondern; *Secretary,* Dr. John Van Doren Young; *Assistant Secretary,* Dr. J. Milton Mabbott; *Treasurer,* Dr. Charles H. Richardson.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, Held November 20, 1913.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

The Fundamental Basis of Nutrition.—Dr. GRAHAM LUSK made this address. He stated that the object of his paper was to present the subject of nutrition in its broadest general aspects and to suggest the possibility of the practical application of some of the facts which years of labor through many generations of workers had brought to light. It seemed as though mankind had a right to a knowledge of the value of the foods which a bountiful Nature had provided for his use. Even among educated persons there were the grossest errors of judgment regarding the nutritive value of a hen's egg, and few of those who ate in restaurants realized that the greater quota of the nourishment which was brought to them lay not in the specific dish served but in the bread and butter which ostensibly was presented as a gift. After referring to the conceptions regarding nutrition held by Hippocrates, Galen, and Paracelsus, Dr. Lusk reviewed the work of Lavoisier and Carl Voit. Rubner, the most eminent of Voit's pupils, in almost poetic language, had said, "Mute and still, by night and by day, labor goes on in the workshops of life. Here an animal grows, there a plant, and the wonder of it all is not the less in the smallest being than in the largest." The workshops of life require fuel to maintain them, and a necessary function of nutrition was to furnish fuel to the organism that the motions of life continue. Furthermore, the workshops of life were in a constant state of partial breaking down and materials must be furnished to repair the worn-out parts. In the fuel factor and the repair factor lay the science of nutrition. It might be proved that one gram of glucose, when oxidized, yielded heat sufficient to raise one liter of water 3.755° C. Since the measure for heat was that quantity required to raise one liter of water 1° C., it followed that one gram of glucose yielded 3.755 calories of heat. Sugar yielded the same products in the bomb calorimeter and in the body and therefore the amount of heat produced was identically the same no matter where the oxidization took place. The same was true of fat. The heat value of one gram of the ordinary foodstuffs when oxidized in the body was as follows: Glucose 3.755 calories, cane sugar 4.0, starch 4.1, fat 9.3, protein 4.1. Those persons who would not believe that a knowledge of calories in nutrition was valuable must be reasoned with and they could not then but be convinced. The store of power in the food stuffs was liberated when they were oxidized in the body and became the source of the motions of life, and in the resting organism was finally eliminated as heat. If one could then measure the quantity of protein, fat, and carbohydrate oxidized in an animal in twenty-four hours one could calculate the quantity of heat which would arise from this process. If, at the same time, the animal could be placed in a calorimeter, which measured the heat actually given off during the period, the two computations should exactly agree. To Rubner belonged the glory of having demonstrated this truth. The heat given off by the body was found to be equal to the quantity of heat which would have arisen from the oxidation of just that quantity of protein, fat, and carbohydrate estimated to have been destroyed. Drs. DuBois and Warren Coleman had discovered that a typhoid patient, during a period of five hours of rest in their calorimeter, produced the same number of calories as were calculated he should produce from the materials which were oxidized in his body, and the contemplation of such a result drove home the fact that if the typhoid fever patient was to be kept from losing his own body muscle and fat, he must be given the equivalent of 422 calories in food substance during a five-hour period. Measurement of the total heat production became a measure of the intensity of the life processes. Rubner had shown that all well-nourished mammals produced the same number of calories per square meter of surface. A normal man resting in bed in the morning, having been without food for fifteen hours, would manifest a minimum level of heat production. The table presented showed the constancy of energy production under these circumstances. The basal heat production of an average man weighing 70 kilograms would be 70 calories per hour or 1,680 calories in twenty-four hours. If food were taken extra heat would be produced, but not exceeding 10 per cent. of the basal heat production, or seven calories per hour, or 168 per day, so that the maintenance requirement of this man resting in bed was 1,848 calories in the daily diet. Beyond this the amount of fuel needed depended upon the quantity of work done. If this man were sitting in a chair the heat production might rise 29 per cent. A hospital patient was liberally fed when receiving 2,168 calories. No normal man should live without exercise, so an additional energy requirement for this purpose was needed of 320 calories daily, which would bring the total number of calories required by such men as writers, draughtsmen, tailors, physicians, etc., up to 2,488 calories per day. As a matter of fact statistics showed that the inhabitants of cities took this amount of fuel daily. Men doing heavy physical labor required 3,000 calories daily in the food consumed. A boy of twelve years required 1,500 calories daily, and a baby when first born required 100 calories. In fever and hyperthyroidism where the heat rose far above the normal increased nourishment was indicated. A diet might be deficient in calcium salts and the body might suffer from calcium hunger; it might be poor in iron, as was a milk diet, and the person using such a diet might become anemic, but the important material to be treasured and protected was the body protein. There were different kinds of protein, such as milk, meat, gelatin, fish, and vegetables. These proteins had different physiological values.

The most important proteins were glycoll, alanin, leucin, prolin, phenalylanin, aspartic acid, glutamin acid, serin, tyrosin, cystin, lysin, histidin, arginin, ammonia, and tryptophan. It was apparent that proteins were specially valuable if they contained an array of units which when reunited formed body proteins. Proteins in which one or more of the necessary units were lacking could never be reconstructed into new body protein. When the units were in a very different ratio from those in body protein they were of inferior nutritive value. Such inferior proteins occurred among the plants. Plant proteins were reconstructed into beef proteins and thus beef proteins attained a higher biological value for the nutrition of man than was possessed by the vegetable proteins. The speaker cited experiments showing how necessary it was that the body have a constant replenishment of its protein store and stated that there could be no doubt as regarded the superior value of meat, fish, egg, and milk proteins over those of bread, beans, and Indian corn. The proteins of rice and potato held an intermediate position. Such facts made it possible to classify proteins into groups according to their physiological value, and as milk was now sold in three grades, in like manner the proteins of food stuffs could be labeled A, B, and C, according to their physiological value, and to group D might belong gelatin and some other proteins which could not replace the body protein that was continually wearing away. A series of experiments with wheat protein showed that gliadin, which represented nearly one-half the protein of wheat, was of inferior food quality. It required more protein in bread to protect the body from protein loss than it did when milk or meat was ingested. Other proteins, such as hordein from barley and gliadin from rye, behaved like wheat protein. The results of experiments were also adduced to show that corn proteins were not the physiological equivalent of meat protein in nutrition. Zein, the protein of Indian corn, and phaseolin, that of the kidney bean, failed completely to maintain the body weight of rats which received them and might be considered as lacking in some chemical unit. The New Haven investigators had pointed out that a single protein like casein could cause normal growth involving the production of all the various body proteins, such as hemoglobin, lastin, collagen, and even the nucleoproteins. Casein did not contain glycocoll, but this might be manufactured from it in the animal organism. Protein was usually taken in excess of that bare requirement which was measured by that quantity necessary to repair the tissue. This excess was oxidized and used as fuel just as were fat and carbohydrates. Protein had one property out of all proportion to that possessed by the other food stuffs in that it very largely increased the production of heat in the body. Individuals maintained on a low protein diet might suffer intensely from the cold. One might cause the heat production of a dog to double by giving a large quantity of meat. Glycocoll was one of the units that caused a marked increase in the heat production. In diabetes ingested glycocoll was completely converted into sugar without undergoing oxidation and hence it acted as a chemical stimulus and not in virtue of its energy content. This heat producing action of protein was effected by all kinds of protein, by those of meat, fish, eggs, milk, and such incomplete proteins as gelatin. To obtain the warming effect it was not necessary to purchase so costly an article as beef.

Dr. Lusk then compared the different dietary habits of man in different parts of the world, citing the Eskimo who consumed large quantities of meat, even as much as nine pounds daily in seasons when hunting was good; the population of India, China and Japan where the great staple was rise; and the European laborer; and found the following distribution of the various nutritive elements:

	Weight in Kgm.	Protein, Grams	Total Calories	Calories in Per Cent		
				Protein	Fat	Carbohydrate
Eskimo	65	282	2604	44	48	8
Bengali	50	52	2390	9	10	81
European	70	118	3055	16	17	67

An interesting point was that the Eskimo lived without acquiring uric acid diseases. Health and strength were not wanting in the Arctic regions where a carniverous diet was the mainstay of life. The ration of rice of the Bengali did not serve to keep him in good condition, whereas his neighbor in the hills who lived partly on his flocks was in much better condition. Rubner believed that there should always be an excess of protein constructive material in the diet so that, if after physical exhaustion there was a depletion of the glycogen reserve there might be building units in reserve to quickly repair the tissue destroyed. It was not desirable for the laboring man to take the minimum quantity of protein. Rubner pointed out that the staple diet of the robust and healthy Bavarian peasant had been milk, cheese, bread and vegetables, and this for many centuries. Such a diet, even though it contained no meat, was not a diet low in protein. Chemical analysis showed no difference as to the relative value of beef, veal, mutton, and chicken, and experiments in feeding gave no indication that one was more readily absorbed than another. The substances which were convertible into uric acid were present in all these meat foods in about the same quantity. Ultimately the question was one of flavor. Man selected what he liked best, and, taken in moderation, what he liked best he digested best. Hence, there was the demand for meat which was not necessary, and could be largely replaced by the cheaper and equally valuable protein of milk, or even the proteins of wheat and of beans taken together. It had been known for a long time that life could not be maintained on an absolutely pure mixture of salts, fats, carbohydrates, and protein. The human organism was extremely sensitive to certain substances in minute quantities. Thus, epinephrin, the active constituent of the suprarenal glands, was present in the blood in one part to 100,000,000 and this was essential to life. One might also recall the marked influence on growth exerted by the thymus gland during youth. The profound effect of small amounts of material formed in the various internal glands was a well-established fact. However, it had only recently become probable that, in order to maintain the organism in condition, a small quantity of something not hitherto recognized must be present in the food. The speaker discussed the relation of polished rice to beriberi, and recalled that Funk had sought to isolate these substances which prevented beriberi, and which he termed vitamines. From 10° kilograms of dry yeast he prepared 1.6 grams of a crystalline substance which, if given in doses of four to eight milligrams to neuritic pigeons, cured them in from two to three hours. This substance on purification yielded three materials, called Substance I, Substance II, and nicotinic acid. Substance I and nicotinic acid were of little value in curing the polyneuritis of pigeons, but when three milligrams of the one and two milligrams of the other were administered together the diseased pigeons were cured in from two to four hours. Rice polishings yielded these same two substances. It, therefore, appeared that a class of vitamines existed in the vegetable kingdom, and that these were necessary to the normal growth and nutrition of the animal tissue. If meat were eaten their direct ingestion from the plant became unnecessary. They entered into the maternal milk. Beriberi and scurvy did not exist in the United States, but only occurred when a one-sided diet deficient in vitamines existed.

Dr. Lusk then directed his attention to the problem of the high cost of living in the light of scientific knowledge of food values. He gave a table showing the increased cost of the most used foodstuffs since 1890 and also during the past year. He stated that since the efficiency of labor depended upon its energy and constant repair, it was certainly of no small account that the citizen should know how best to maintain the machine at a maximum of efficiency. He should know in times of trouble where to turn to find nourishment in the form which was best and cheapest. The manufacturer of foodstuffs would not give this information, but if, through the medium of the schools and the press, everyone knew that a man of sedentary occupation required 2,500 calories and a laboring man 3,000 calories and more, no one suffering from want would spend his money for a can of tomatoes which was little else than flavored water. It had been estimated that a family of five, father, a clerk, mother, who did housework, and three children, aged nine years, six years, and one month, respectively, required 7,750 calories daily. A study of the market value of the staple food products in New York City on January 28, 1913, showed that for an adult requiring 2,500 calories, or one-third of that required for the family, the cost would not exceed twenty cents a day at the market price of the fresh materials. When more than an average of eight cents was expended for 1,000 calories of nutriment, the diet must include luxuries. The following were the market prices of various food staples showing the great variation in price of 1,000 calories: Glucose, 1¾ cents, cornmeal, 2 cents, wheat flour, 2½, oatmeal 2 4/5, cane sugar 3 1/3, dried beans 4, salt

pork (fat) 4½, rice 5, wheat bread 5 1/3, oleomargarine 7½, potatoes 7½, butter 10, milk 10, smoked ham 10¾, cheese 11½, loin pork 12½, mutton (leg) 10¼, salt cod 19½, sirloin beef 24, turkey 40, fresh codfish steak 42. This list taken in connection with that showing the proper amount of protein for the family under discussion was of the greatest economic importance. According to this table the relative amount of protein was furnished in the following. Bread in addition to 4/5 pounds of salt cod, or 3/5 pounds smoked ham, or 4/5 pounds cheese, or 2½ pounds milk, or 1½ pounds loin pork, or 1⅔ pounds leg of mutton, or 1¼ pounds cod steak, or 1⅓ pounds sirloin steak, or 1⅓ pounds turkey. The household requirements according to this calculation would then in the poor family be from fifty to sixty cents a day; in the family of moderate circumstances, where two servants were kept, from $1.00 to $1.40, and in a wealthy family, where six servants were kept, from $1.50 to $2.10. Whatever was spent above this was for waste or in the form of flavors of high price. The high cost might also be due to carniverous indulgence approximating that of the Eskimo. When each individual could partake of nourishment in accordance with the dictates of a normal appetite there was no danger of undernutrition, but it was among the poor, that class which scientific knowledge was the last to reach, that this knowledge was of the most value. Recently Miss Dorothy Lindsay made a report concerning the diet of the working classes in Glasgow in which she concluded that one of the main contributing factors of malnutrition among the poor was bad marketing. The experience of America had shown that in the matter of school lunches for the children of the poor that it was a demonstrable economy to the State to feed the undernourished child. But the State should also teach the mother the value of bread and milk, and that weak tea could not take the place of milk in the nourishment of the child. Recently F. C. Gephart of the Russell Sage Institute of Pathology had undertaken a study into the physiological value of the various portions of food sold over the counter of the Childs restaurants in this and other cities. Four hundred samples in all had been collected and analyzed. For comparative standards the calories in bread and vintage champagne had been selected, neither of which were purchased in the restaurant.

Food Value of Portions, Including Bread and Butter When Served in Child's Restaurants.

	Cost in Cents	Calories, Total	Per Cent in Protein	Calories for Five Cents	Cost in Cents per 1000 Calories
Bread	5	933	12	933	5
Apple pie	5	337	5	337	15
Boston pork and beans	15	828	12	276	18
Ham sandwiches	5	170	20	170	30
Corn beef hash	15	507	14	170	30
Beef stew	15	461	25	154	32
Club sandwich	25	409	20	52	61
Sliced pineapple	5	36	46	36	138
Tomatoes, lettuce, mayonnaise	20	53	16	13	385
Pint of champagne	200	345	0	9	588

The extreme variability of the purchasing power of money for food stands here exposed in the limelight. It was for this reason that the government should take up this matter. The government could give information with regard to all the foodstuffs sold in packages. The manufacturer could send his sample can to the Bureau of Chemistry at Washington, declaring that to be his standard and requesting information regarding his label. He should pay for this analysis as a patentee payed for his patent. If the government, at any time, found the manufacturer selling a material on the market of a different character than the standard deposited with the government, the manufacturer should be heavily fined. Complaint had been made that in other countries scientific men sat on the boards of directors of the manufacturers of foods and patent medicines. In this country this sort of thing had been discountenanced and rightly so. The day of the sale of a man's scientific reputation and that of an institution with which he was connected had passed. The scientist had come to have sufficient altruism to believe that his services belonged to all the people and not to a set of money making individuals. It was a matter of common knowledge that physiological chemistry was as advanced in this country as anywhere else in the world and there was a great opportunity here for good work. Appeal was therefore made to the understanding of physicians and of educated people of this country to take interest in this subject to the end that enlightened activity for the welfare of mankind might follow.

SECTION ON PEDIATRICS.

Stated Meeting, Held November 13, 1913.

Dr. Henry D. Chapin in the Chair.

The Bacteriology, Diagnosis, and Treatment of Intestinal Affections in Childhood.—Dr. Ralph Vincent of London, England, read this paper by invitation. (See Report of New England Pediatric Society, Boston. December 6, 1913.)

Dr. William H. Park said he would prefer to speak only of the beautiful specimens shown and the good work done, but he felt sure that Dr. Vincent would appreciate the expression of a difference of opinion. There were two points to which he wished to direct attention. The first point was somewhat in the background in the paper, that of the danger of heating milk. In New York the Department of Health had been endeavoring to have all milk pasteurized except such as could be certified by the department. If Dr. Vincent's paper were true they would have to change this. Dr. Park said that he could not understand the conditions which Dr. Vincent had found. It seemed to him that Dr. Vincent had first been successful as a physician in the treatment of these cases and then had worked backward in the endeavor to find a bacteriological basis for his course. Milk taken from a healthy cow in a cleanly way showed very few bacteria. Ten samples of milk examined that day from certified farms showed no bacteria except in two instances. Some time ago they had examined the milk of fifty cows consecutively and in most of them there were no streptococci; when streptococci were present the cows were eliminated from the certified list. He could not believe that streptococci added anything to the value of the milk, while one encountered the danger of getting infectious streptococci. Dr. Vincent had said that when the milk was incubated for twenty-four hours the streptococci formed chains; in eight out of ten instances they grew as diplococci and not as chains. When bacilli developed the milk was past that stage where it was fit for consumption by any infant. It was only when the milk reached a stage unfit for use as food that the *Streptococcus lacticus* developed. At this stage all types of bacteria developed until a point was reached when the acid inhibited them. If milk was pasteurized in the ordinary way the bacilli always came back later; if a little raw milk was added they grew as before pasteurization. In undertaking the examination of fecal matter, Dr. Vincent had attacked one of the most difficult problems. These examinations were liable to be very confusing. The method of adding milk to the feces and incubating gave too mixed a picture to be of any definite value. To the bacteriologist the method used of identifying the organism by stain and form could scarcely be taken seriously. The colon and dysentery bacilli would look alike and grow alike. Dr. Park said that he spoke as a laboratory man and perhaps had not appreciated the clinical side of the work.

Dr. Henry Koplik said that Dr. Vincent deserved their thanks for having raised this discussion and for presenting such a painstaking and beautiful review of the work done on the bacteria of milk. Pasteur, Gafky, and Escherich had shown that milk could not be perfectly pasteurized or sterilized. Pasteurization and sterilization aimed at the destruction of the harmful bacteria, streptococci, *Bacillus lactis*, typhoid bacilli, etc., which would be immediately harmful to the infant. Pasteurized or sterilized milk for infant feeding was intended to be used within twenty-four hours and not kept for days until it might ferment. Pasteurization of milk for infant feeding was one of the greatest blessings given by science to infants. If one went back to the time of Pasteur and Escherich the rôle of the bacteria was everything; to-day they had another school, that of Czerny and Finkelstein, which held that the bacteria were not necessarily the cause of abnormal intestinal conditions, but that the food elements, the fat, proteid, and carbohydrates, had as much to do with the infection of the baby as did the bacteria. They did not yet understand the rôle that bacteria played in the intestinal diseases of childhood. They knew, however, that there were certain bacteria that made the child mortally ill; certain streptococci would have this effect, such as the typhoid bacillus, the *Streptococcus enteritidis*, and the dysentery bacillus. Whether they could differentiate these forms out of the laboratory at the bedside Dr. Koplik said he could not say. They had all tried it, but felt themselves confused. The problem had been worked out in the examination of the sputum in tuberculosis and if Dr. Vincent could solve the problem as it affected the intestinal diseases in children he would give

them a powerful weapon, but he, himself, was not yet convinced that a sure method had been found of making a differentiation of the organisms concerned in producing pathological condition in the alimentary tract in infants and thereon founding indications for the feeding and management of these cases.

Dr. Charles Gilmore Kerley said that he wished to speak of the need they felt for help in the treatment of the diseases of infancy. There was not a man here who had practiced for fifteen or twenty years who could treat his intestinal cases any better to-day than he could fifteen or twenty years ago. This had impressed him as he had listened to Dr. Vincent trying to work out a plan of treatment on a scientific basis. Dr. Vincent had been working very conscientiously for a number of years and his work was worthy of due consideration. In order to square the results that he claimed with those obtained in this country they would have to take into consideration the difference in the countries, the difference in climate, etc. In the class of cases with which Dr. Vincent had been dealing it was the intestinal contents that were involved and not the intestinal structure itself; in his cases the latter was rarely affected. In this country the autopsies showed gross lesions of the structures of the intestines, someimes extending through to the peritoneum. So far as mortality was concerned, if they took up Dr. Vincent's method of work they would not get the good results that he obtained. In London they did not know what hot weather and humidity such as occurred here meant. It was right that they should take all these things into consideration and not question the results of their colleagues in England and on the Continent; and they, on the other hand, must not think the American pediatrist exceedingly stupid if he failed to obtain the good results that they had secured. Again, as to the use of heated milk, children fed on cooked milk throve and developed normally. If one took fifty children who had been fed on cooked milk and fifty nourished on raw milk, Dr. Kerley said, he defied any one to tell from the condition of the children to which group they belonged.

Dr. L. E. La Fétra said that Dr. Kerley and he had had the privilege of seeing Dr. Vincent's work last summer at the Infants' Hospital in London. It was interesting to see the laboratory and wards in the closest communication. If any simple and practcical method could be devised for the bacterial study that would give help in regard to the line of treatment they should take advantage of it. Dr. Le Fétra said he was not familiar with the technical bacteriological side of the work sufficiently to pass judgment upon it, but the clinical results could be explained, in his opinion, by Dr. Vincent's careful observation and clinical experience as well as by his laboratory work. The dietetic part of his treatment was more important than the administration of bacterial cultures. In England the severer types of intestinal disease were seldom encountered. Dr. Kerley did not really believe that they could not treat these cases better now than they did fifteen years ago. There were so many methods of treatment now and so many forms of milk and of sugars to which they did not have access a few years ago that they were certainly in a better position to treat these conditions. They should be grateful to any one who brought aid in diagnosis or suggestions as to the treatment of the intestinal diseases of infancy.

Dr. William P. Northrup said that he did not intend to discuss the paper, but would like to express his appreciation of Dr. Vincent's effort to find an accurate method of diagnosis and to apply appropriate treatment in these cases. They should all appreciate the fruits of his labor.

Dr. Ralph Vincent of London, England, in closing the discussion, said that he wished to assure his audience that he had used the method described himself and had found it of so much assistance that he would not attempt to treat these conditions without it. The designation of his bacteriological methods as "rough and ready" by the bacteriologist did not at all disturb him. The methods were those that seemed best calculated to meet the indications. He perfectly agreed that when milk was strictly fresh there were no streptococci present in chains; in four hours they were not very common, but in eight hours they were invariably present. Dr. Park took a leap from the time of milking to twenty-four hours later and stated that at that time he found that all were diplococci. At the end of eight hours he would find the streptococci in chains. He hoped that Dr. Park would make examinations of his cultures at four, eight, and twelve hours, when he would find this true. He had examined the healthiest cows and found the streptococci and they had had the same experience at Johns Hopkins and had condemned the milk; if they did this they would have to condemn all milk. One did not find the chains when the milk was first drawn. Dr. Vincent said that he believed the natural diet of the child was raw milk. When Dr. Koplik said that it was a question of food, this was true. For, of course, if you eliminated the lactose of cow's milk the lactic acid bacilli would not grow. It had been stated that about 50 per cent. of the cases here had blood in the dejecta; that was quite unusual with them. Gross lesions of the intestines were very rare. It would be interesting to have observations made along the same lines both here and in England and to compare the results. As to the question raised by Dr. La Fétra regarding the value of the cultures, Dr. Vincent said that in many of the series of cases they gave cultures and the patient improved. About three weeks after there would occur a relapse when they would again administer cultures and the condition would be promptly controlled. The natural diet was not sufficient in all cases, the cultures of streptococcus lacticus being required in many instances in order to effect a cure.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Consumption: Its Prevention and Treatment. By E. W. Diver, M.D. Second Edition. Illustrated; cloth; 135 pages. John Bale, Sons & Danielsson, Ltd., London.

Pathology, General and Special. A Manual for Students and Practitioners. By John Stenhouse, M.A., B.Sc., M.B. Second edition, revised and enlarged, including selected list of State Board Examination Questions. Illustrated; 278 pages; cloth; price $1.00 net. Lea & Febiger, Philadelphia and New York.

The Wellcome Photographic Exposure Record and Diary—1914. Cloth; illustrated; 280 pages; price 50 cents. Burroughs Wellcome & Company, New York.

Kurzer Leitfaden der Psychiatrie. By Dr. Ph. Jolly. Paper; 240 pages; price 4 marks. A. Marcus and E. Webbers, Bonn., 1914.

Upsala Läkareforenings Forhandlinger. Paper; illustrated. A. B. Akademiska Bokhandeln, Upsala.

Der Vertrieb Pharmazeutischer und Kosmetischer Spezialitäten in Deutschland. By Ernst Rosenberg. Paper; 79 pages; price 1.75 marks. Georg Reimer, Berlin.

Medical and Surgical Report of Bellevue and Allied Hospitals in the City of New York. Vol. V, 1911-1912. Paper; illustrated; 456 pages. Edited by A. Alexander Smith, M.D., Charles E. Nammack, M.D., Van Horne Norrie, M.D., and John A. Hartwell, M.D.

The Administrative Control of Smallpox. By W. McC. Wanklyn, B.A., M.R.C.S., L.R.C.P., D.P.H. Cloth; 86 pages; price $1.10 net. Longmans, Green & Company, London, New York, Bombay, and Calcutta.

A Manual of Surgical Treatment. By Sir W. Watson Cheyne, Bart., C.B., D.Sc., LL.D., F.R.C.S., F.R.S., and F. F. Burghard, M.S., F.R.C.S. New edition, entirely revised and largely rewritten with the assistance of T. P. Legg, M.S., F.R.C.S., and Arthur Edmunds, M.S., F.R.C.S. Vol. V. Cloth; illustrated; 619 pages. Lea & Febiger, Philadelphia and New York.

The Practical Medicine Series. Vol VII. Edited by Joseph B. De Lee, A.M., M.D., with the collaboration of Herbert M. Stowe, M.D. Series 1913. Cloth; 232 pages; price $1.35. The Year Book Publishers, Chicago.

Jahresbericht der Gesellschaft fur Natur-und Heilkunde in Dresden. Paper; 168 pages. J. F. Lehmann, Munchen, 1913.

INDEX.

A

Abbe, T., the surgery of the Revolutionary War, 277.
Abderhalden reaction, in diagnosis of carcinoma, 275, 1046; in diagnosis of gastroenteric affections, 769; in diagnosis of pregnancy, 80, 99, 125, 251, 318; in organic diseases, 1043; in psychiatry, 679, 1181; in scarlatina, 1094; nature of, 1043.
Abdomen, acute, 1093; cavity of, adventitious tissues of, 733; chronic enlargement of, in children, 382; hemorrhage into, 595; operations on, relation between the blood pressure and prognosis in, 224; surgery of, 677; surgery of, local anesthesia in, 731; surgery of, use of iodine in, 732.
Abortion, contagious, in man, 945; criminal, attempted in non-pregnant, 632.
Abscess, retropharyngeal, 629.
Accident, definition of, 539; insurance and life insurance combined, 956.
Acne, facial, treatment of, 966; pustulosa, vaccine treatment of, 656.
Actinomycosis, salvarsan in, 715.
Acidosis, and diet, in diabetes, 75; as a postoperative complication, 908.
Acromegaly, an anomalous case of, 780.
Addison's disease, 213; and pregnancy, 491.
Adductor response to homolateral and contralateral stimulation, 581.
Adenoids and tonsils, removal, 487; operation for, and failure to relieve mouth breathing, 453; surgery of, failures in, 1179.
Age, middle, the mortality of, 898.
Aged, medical care of the, 997.
Air, hot, and nascent iodine in treatment of aural and nasal conditions, 29.
Alaska, health of, 571.
Albumin, Heller's test for, 1049; urinary, the origin of, 712.
Albuminuria, orthostatic, treated by exercise, 996.
Aleucocytary animals, 310.
Alimentary, disease, in infant and child, bacteriological diagnosis and treatment of, 1051, 1190; tract, detection of disturbances of, by examination of the feces, 798; toxemia, relation of thyroid to, 68.
Alcohol, date of the discovery of, 69; in relation to infectious diseases, 75; in treatment of furunculosis of external auditory canal, 906; injection into the gasserian ganglion, 907; injection of, into nerves, 136; legislation and insanity, 791; mortality in total abstainers, from, 986; prescribing, 389; wood, and blindness, 1172.
Alcoholism, premonitory auræ in, 885.
Am Ende, C., the cause of migraine, 763.
Amberg, E., high eosinophile percentage of unexplained origin, 849.
Amblyopia, following supressio mensium, 573.
Ambulation and full diet as factors in the diagnosis of gastroduodenal ulcer, 803.
Amentia, as related to sex, 753.
Amino-acids and sugars in rectal feeding, 124.
Anaphylatoxins and pathology of the eye, 401.
Anaphylaxis, 299; and immunity, 447; in diphtheria, 965.
Anastomosis, arteriovenous, for impending gangrene, 813.
Anders, J. M., the rôle of physical exercise in the open air in the prophylaxis of tuberculosis, 788.
Anemia, pernicious, splenectomy for, 1038, 1181.
Anesthesia, administration of alkaloids preceding, 583; and blood pressure, 224; corneal lesions after, 392; ether-oil rectal, 1082, 1138; in upright position with nitrous oxide gas, 545; insufflation, new apparatus for, 638; intratracheal insufflation, 584; local and spinal, in gynecology and abdominal surgery, 45; local, in abdominal surgery, 731; spinal, 952; spinal, by tropacocaine, 70; surgical, the lacrymal gland in, 79; symposium on, 38.
Aneurysm, blood pressure in, 317; of abdominal aorta rupturing through a gastric ulcer, 81; of aorta, rupturing into superior vena cava, 862; of aorta, showing results of antisyphilitic treatment, 177; traumatic, military experiences with, 585; vascular transplantation in, 1181.
Angina, Ludwig's, 433; pseudomembranous, of the nose and throat, 822; Vincent's, 537.
Angina pectoris, protective phenomena of, 953; treatment of the pains of, 215.
Anhidrosis and diabetes insipidus, 482.
Aniline dyes in surgery, 130.
Anoci-association, technique and results of, 1054.
Antisepsis in obstetrics, 32.
Antitoxin, dosage of diphtheria, 965.
Antivivisection orgy, 1130.
Anus, pruritus of, 891; atrophy of sphincter of, 397.
Aorta, aneurysm of, 177.
Aortitis syphilitica, 1105.
Aphasia, surgical, 307.
Aphthous fever, 720.
Apoplexy, traumatic delayed, 1001.
Appendicitis, acute, four days postpartum, operated on under spinal analgesia, 179; acute, simulated by tumor of omentum, 205; acute, treatment of, from viewpoint of French surgeons, 905; and diverticulitis, 620; catarrhal, 139; chronic, operations for, 721; chronic, *x*-ray study of, 765; rating in life insurance, 33; retrocecal, 620; treatment and pathology, 296; treatment and prevention, 683.
Appendix, carcinoma, 595; decidual reaction in, 954; diseases of, 446; free in abdominal cavity, 339; lesions of, *x*-ray diagnosis of, 766; meningitic symptoms caused by escape of thread worms through a perforated, 966.
Appointments with patients, 460.
Army, report of Surgeon-General of, 1171; typhoid vaccination in, 40.
Arsenic, localization of, in the viscera, after injection of salvarsan, 1166; two new derivatives of, 966.
Arteries, calcified, rigidity of, 860; hardened, and high blood pressures, 25; hypertension of, and occasional cardiac, dilatation as postoperative complications, 44.
Arteriosclerosis, and allied subjects, 725; diagnosis, 1091; new viewpoint of, 621.
Arthritis, caused by chronic focal infections, 37; chronic, 317; deformans and intestinal stasis, 684; deformans, cause of, 1093; deformans, cure of, through genito-

urinary surgery, 691; deformans, etiology, 1134; infections, 813; rheumatic, pituitary extract in, 608.
Arytenoids, symmetrical swellings on, 1094.
Astereognosis, cortical, brain of patient with, 870; cortical, from a cyst, 870.
Asthma, bronchial, and rachitis of nose, 1181; bronchial, cause of, 228; treated by aid of bronchoscope, 483.
Astrology in medicine, 995, 1041.
Ataxia, treatment, 1090.
Atherosclerosis and cholesterinuria, experimental, 724.
Atmosphere, physics of, and colds, 1014.
Aulde, J., solving the mystery of Bright's disease, 1154.
Auræ, premonitory, in alcoholism, 885.
Auricular flutter, 226; two cases of, 767.
Aurometer, the, 1044.
Auscultation of early pathological changes of lungs, 77.
Austin, C. K., the paroxystic attack of metatarsal pain, Morton's metatarsalgia, 654.
Autointoxication, intestinal, 401.
Azurophile granulations in the lymphocytes, 942.

vaccination in civil communities, 84.
Eccles, R. G., disease and genetics, 189.
Eczema, and sudden death, 990; infantile, 914; of the scalp in infants, treatment of, 230; *x*-ray treatment, 384.
Edema, cardiac, a diuretic for, 1104; cardiac, treated with alkali and salt, 169; in infants, 451.
Efflorescences, primary, the metamorphosis of, 679.
Effusion, chyliform, the significance of, 1037.
Egg, the, as an emblem of heredity, 828.
Ehrlich, on chemotherapy, 400.
Einhorn, M., further experiences with duodenal ulcer, 369; the beneficial effect of duodenal alimentation in cirrhosis of the liver, 154.
Ejaculatio præcox, treatment of, 966.
Elbow joint, injuries of, surgical management of, 36.
Elder, O. F., an easy method of administering salvarsan and neosalvarsan intravenously, 527.
Electricity, as antifat cure, 587; continuous current of, advantages, 684; in treatment of obesity, 538; induced currents, of, 683; sinusoidal current, use of, 684; static currents of, 683; storage element in the therapeutics of the constant current of, 684.
Electrocardiograph, diagnostic value of, before obstetrical and gynecological operations, 225.
Electrotherapeutics, 684; value, 427; in gynecology, 684; teaching of, 683.
Embolism, and thrombosis, 1057; paraffin, 587; paraffin, removal of dangers, 587.
Emetic, for children, 1104.
Emetine, in treatment of amebic colitis, 178; in treatment of liver abscess, 955.
Emmenagogue oils, action of, 170.
Emphysema, and allied conditions, 683; generalized, in child, 1139.
Empyema, thoracic, bilateral, treated by successive rib resections, 777.
Encephalitis, acute gonorrheal, 591; sequelæ, 536.
Endocarditis, conduct of gynecological and obstetrical operations in the presence of, 223; in children, 213; lesions produced by streptococcus group in, 1148; with special reference to its etiology, 1056.
Endometritis and membranous dysmenorrhea, 812.
Enteritis, chronic interstitial, 315; gangrenous, complicating phlegmonous cholecystitis, 1075; malted food in treatment of, 597.
Eosinophiles, high percentage of, of unexplained origin, 849.
Epididymis, tuberculosis of, 28.
Epididymitis, local applications in, 414
Epididymotomy, 399.
Epiglottis, primary carcinoma of, 544.
Epilepsy, Abderhalden reaction in, 955; and paresis in railway engineers and firemen, 489; gastric and intestinal stasis in, 352; inheritance, 323; modern treatment of, 760; new aspects of the treatment of, 185; study of, 821.
Erdmann, J. F., the colon, its malignancies, 611.
Ergot, preparation, 580.
Ergotin, intravenous injections of, in the treatment of hemoptysis, 736.
Esophagoplasty, after resection of esophagus for cancer, 1100; extrathoracic and intrathoracic, 37.
Esophagoscopy in cancer of the esophagus, 65.
Esophagus, cancer of, status of esophagoscopy in, 65; epithelioma of, 637; foreign bodies in, 505; occlusion in early life, 452; removal of plate of false teeth from, 546; resection, for carcinoma, 637.
Ethics, medical and social hygiene, 1007; professional, and prophylaxis of syphilis, 819.
Ethylhydrocuprein, in pneumonia, 448.
Eugenics, and medical ethics, 1007; and venereal diseases, in small communities, 1018; legislation and, 1036; medical profession and, 1006; practical, 1131; various aspects of, 1006.
Evans, T. R., lunar cerebrations, 211.
Examinations, and the medical student, 813; evils of, 764; medical, of all workers, 115; physical, of injured party, 113.
Examiners, medical, and health conservation, 449; demands on the, 680; educating of, 493; selection of, 81; State Board of, performs ministerial duty, 757; suggestions to, 33, 126, 218, 402, 492, 588, 680, 770, 803, 956, 1049, 1140.
Exercise, physical, in the open air in the prophylaxis of tuberculosis, 788; physical, in the prophylaxis of tuberculosis, 230.
Exophthalmic goiter, cured by ligating one superior thyroid artery, 563; new theory of, 262; pathology, 373; with scleroderma, treated with salvarsan, 689; *x*-ray treatment of, 1170.
Expert on neurasthenia, 389; testimony as to mental capacity, 389; witnesses, credibility of, 803.
Eye, coloration in relation to diphtheria and scarlet fever, 1179; congenital lesions of, 1128; operations on extrinsic muscles of, 965; paralysis of both internal rectus muscles of, 1104; strain of, 1169; traumatic bilateral paralysis of external rectus muscles of, 340.

F

Facial nerve, partial paralysis of, due to traumatism, 1030.
Family histories, study of, in life insurance, 263.
Fat, uses of, in surgery, 964.
Fatigue, symptoms of, 1175.
Fats, as ointment bases, 861.
Fauntleroy, A. M., Vienna, the postgraduate medical and surgical mecca, including practical points gleaned from Viennese clinics and from the courses given by the University of Vienna, 1020.
Feces, examination of, 798.
Fecundity, relation of colipyelitis to, 217.
Fedde, B. A., pituitary extract in labor, 906.
Feeble-mindedness, and school children, 329; the social factor in the diagnosis of, 805.
Feeding, breast, see breast; see infant feeding; rectal, amino-acids and sugars in, 124.
Femur, fracture of shaft of, infected and ununited, treatment of, 76; separation of lower epiphysis of, 169.
Ferments, of the blood, the defensive, 1043.
Fertility, unusual, 1084.
Fetus, administration of oxygen to, 112.
Fever, and syphilis, 172; aphthous, 720; in pulmonary tuberculosis, 813; treatment of, 993; urinary, causes of, 714.
Fibroid, intraligamentous, causing retention of urine, 563; uterine, *x*-ray treatment of, 85; visceral complications met with in hysterectomy for, 998.
Fibrolysin, in chronic pneumonia, 262.
Fibroma, retroperitoneal, 316.
Fibrositis, 316.
Finger-bowls, insanitary, 1172.
Fisher, M. K., the Röntgen treatment of eczema, 384.
Fliess, and his theory of the family substance, 996.
Fomites, in the transmission of disease, 64.
Food, in causation and cure of disease, 684; relation of bacterial metabolism to, 151.
Foot, congenital lipoma of sole of, 679; flat, physiological treatment of, 63; hollow, 1045.
Foreign bodies, extraction of, from children's lungs, 217; in the tissues, localization of, 823.
Formaldehyde, strange use of, 32.
Foster, G. S., appendical infection, with abscess formation; should the appendix be removed at primary operation, 1163.
Fox, F. J., the Wassermann reaction in cancer, 283.
Fractures, compound and comminuted, operative treatment, 315; ivory plates in the treatment of, 859; mechanism of production of, 36; nail extension in, 299; of long bones, external bone clamp versus internal bone plate in, 36; treatment of, 74; treatment of infected and ununited, of shaft of femur, 76.
Frambesia and syphilis, intracutaneous reaction in, 262.
Freckles, treatment, 552.
Friedman, G. A., a hitherto undescribed form of polycythemia and its possible relation to duodenal ulcer, chronic pancreatitis, and a disturbance of internal secretions (adrenalin), 701.
Friedmann treatment, in Canada, 74.
Freud, and his conception of the psychoses, 967.
Frink, H. W., the Freudian conception of the psychoses, 967.

G

Gallant, A. E., prolonged-precipitate parturition due to disengagement of the disproportionate head, 337.
Gall-bladder disease, conditions in upper abdomen in relation to, 1177; diagnostic errors in, 1177.
Gallstone surgery, 733.
Gangrene, symmetrical, and the Balkan wars, 991; impending, arteriovenous anastomosis for, 813; neurovascular, 829; of feet, study of circulation in, 37.
Garbage, municipal disposal of, a menace to public health, 87.
Gas, in the hollow viscera, balloon effect of, 765.
Gasserian ganglion operations, 958.
Gastroenterostomy, posterior, in acute perforated ulcer of the duodenum, 36; simple and rapid method of pyloric closure in, 958.
Gastrointestinal, diseases of infancy, 1097; tract, digestion of lecithin in diseases of, 79; tract, *x*-ray examination of, 41; tract *x*-ray examination of, in functional nervous disorders, 135.
Gastrojejunostomy, principles determining the use of, 959.

Gastroscopy, 41.
Gastrostomy, new method of, in epithelioma of esophagus, 637.
Geiringer, D., a direct view irrigating urethroscope for diagnosis and treatment, 434.
Genetics, disease and, 189.
Genitourinary organs, surgery of, in the treatment of arthiritis deformans, 691; the use of tuberculin in the diagnosis of obscure conditions of, 650.
Gibney, V. P., diagnosis and treatment of knee lesions in the adult, 783.
Gifts, acceptance of, from patient, 757.
Glands, ductless, effect upon development, 584; ductless, relation of, to the work of the surgeon, 963; genital, and teeth, 552.
Glaucoma, 676; operative treatment of, 819.
Glucose, detection of small amounts of, in urine, 677.
Glycosuria, and life insurance, 492; non-diabetic, 270.
Goiter, exophthalmic, see exophthalmic goiter; extracts of, and blood pressure, 378; hyperplastic and non-hyperplastic, relation of, 38; pathology, 373; question, the, 963; treatment, 1098.
Gold chloride, colloidal, test in congenital syphilis, 122.
Gout, blood serum in, 724; dietetics of, 76; 123.
Gonococcus affections, complement fixation in, 778.
Gonorrhea, causing stomatitis, 242; complications treated with sensitized vaccines, 447; diagnosis, and gonococcus vaccines, 581; new principles in the treatment of, 1001; ophthalmia due to, in Manila, 673; sensitized virus vaccination in, 999.
Goodhue, E. S., leprosy and the knife, 111.
Grafts, extensive, pig-skin used in, 822.
Graham, H. F., chronic mesenteric ileus with a report of three cases, 473.
Graves' disease, see exophthalmic goiter.
Greene, G. W., the treatment of rheumatism, 763.
Gros, E., radiography in pulmonary gangrene, 1080.
Grunewald, W. R., warning against an apparent swindler, 674.
Gums, primary tuberculosis of the, 163.
Gutman, J., experiences with the Abderhalden test in the diagnosis of pregnancy, 99.
Gynecology, and neurology, relation between, 811; diagnosis in, 596; pathology the basis of, 222.

H

Haberman, J. V., the psychoanalytic delusion, a criticism and review, 421.
Hagemann, J. A., the tonsil—a vestigeal respiratory organ, 756.

Hardening of children, 759.
Hartshorn, W. E., benign tumors of the female breast, report of a case, 987.
Hartshorn, W. M., choriocpithelioma, with report of a fatal case, 1072.
Heads, in mesial section, 61.
Health, education of the public, 961; museums, traveling, 534; public and politics, 944; public, children in relation to conservation of, 33; public, in the South, 1142; public, municipal disposal of garbage, a menace to, 87; public, negro in relation to, 1142.
Heart, affections, prognosis of from life insurance aspect, 910; and blood vessel disease, diet in, 216; and lungs, disease of, and industry, 169; as affected by the stomach, 317; block, differentiation of organic and functional, 942; disease, and gynecological operations, 225; disease and life insurance, 311; development of knowledge of, 1178; disease, diuretics in, 308; disease in childhood, 103; disease, prognosis of, 1093; disease, treatment, 455; ectopia of, 261; edema from disease of, treated with alkali and salt, 169; functional testing of, 1056; lesions of, and penumonia, 1048; needle in left ventricle, 452; symptoms, excited by examination, 357; tissue, action of strophanthin upon, 814; weakness of, in pneumonia, treated with venesection and saline infusion with suprarenal extract, 814.
Heat stroke, nature and treatment of, 125.
Hecht, D'O., the inheritance of epilepsy, 323.
Heiser, V. G., malaria in the newborn, 855.
Held, I. W., aortitis syphilitica, 1105.
Heliotherapy, as seen in Rollier's clinic, 775.
Hematuria, and its management, 731; essential, 630; renal, an unusual case of, 106.
Hemiplegia, cerebral, serological tests in, 1013; following syphilis, 767.
Hemoptysis treated by intravenous injections of ergotin, 736.
Hemorrhage, intraabdominal, 595.
Hemorrhoids, and office practice, 110.
Hemostat, as a safety blade holder, 1034.
Heredity, 407; and inheritance as they concern the physician, 999; Huntington's chorea, a study in, 134; influence of, in inducing epilepsy in children suffering from infantile palsy, 137; the egg as an emblem of, 828.
Hermann-Perutz versus Wassermann reaction, 491.
Hernia, incisional, plastic methods of closing, 733; indirect inguinal, operation for, 77; of linea alba, 1100; strangulated, in young infants, 90; vaginal, new method of repair for, 937.
Herpetic fever and the colon bacillus, 343.
Hexamethylenamine in surgery, 15.
Hill, E. C., results of treatment of syphilis with salvarsan and neosalvarsan, 984.
Hip, disease treatment, 1097; open operation for congenital dislocation of, 636.
Hippocrates, temple and school of, at Cos, 533.
Hirschsprung's disease, 413.
Hiss, P. H., Jr., clinical studies on the curative action of leucocyte extracts in infectious processes, 466.
Hodgkin's disease, etiological study of, 997; etiology and vaccine treatment of, 1178.
Holland, A. L., a new method for detecting occult blood in stomach cases, 664.
Hollingworth, L. S., the frequency of amentia as related to sex, 753.
Hookworm, in the Middle States, 821.
Horowitz, P., the Bulgarian bacillus in diabetes, 24.
Horwitt, S., syringomyelia, with pathological findings, 698.
Hospitals, administration of, 674; and dispensaries, social service in, 657; costs of, 1091; facilities of, for Americans in London, 810; Indian, 244; psychopathic, 218; State insane, failure of, 533.
Hubbard, S. D., differentiation of the erythema of scarlet fever and that of German measles, diagnosis, 197.
Hunger strike, antiquity of, 276.
Huntington's chorea, a study in heredity, 134.
Hydrocele, operation for, without wounding scrotum, 108.
Hydrocephalus, treated by cisternasinus drainage, 774.
Hygiene, educational, 344.
Hyperemia, artificial, in treatment, 524.
Hyperthyroidism, and the nervous system, 1138; injection of boiling water for, 37.
Hypoglossal nerve, paralysis of, 175.
Hypophysis, and uncinate region, lesions of, 134; extract, see pituitary extract, 175; lesions, from viewpoint of surgeon, 137; perimetric deviations accompanying lesions of the, 134; relation to polyuria, 27; tumor, 175.
Hygiene, social, movement, 1006.
Hyperidrosis, foot powder for, 230.
Hypertrichosis of the upper lip, thallium acetate in the treatment of, 230.
Hypnotics, dangers of use with morphine, 491.
Hypopituitarism, and Napoleon, 690.
Hysterectomy, complications of, 947.
Hysteria, 999; and neurasthenia, 257; aspects of, 994; with fever and ankle clonus, 353.
Hysteroepilepsy (piblokto) among the Esquimos, 873.

I.

Icterus, acute infectious, in children, 413; congenital hemolytic, 39; neonatorum, 769.
Idiocy, Mongolian, with congenital heart lesion, 318.
Ileocolitis, acute treatment, 1098.
Ileum, adenocarcinoma of, 1099.
Ileus, chronic mesenteric, 473; postoperative, 36; pseudo-, due to intestinal nerve impulse disturbances, 130.
Immigrants, medical inspection of, 1167; psychogenetic disorders in, 58.
Immigration and insanity, 488.
Immunity, and anaphylaxis, 447; mechanism, in experimental cancer, 981; natural, and nutrition, 75.
Incubation period, studies in, 455.
India, sanitary work in, 949.
Indicanuria, the feces and the sulphates of the urine, 248.
Inebriety, see alcoholism.
Infant feeding, artificial, 1098; carbohydrates in, 1145; casein in, 411; in case of a sick infant, 1097; rules in, 30.
Infant Welfare Association of New Haven, 120.
Infectious diseases, acute phagocytosis in, 1037; alcohol in relation to, 75; local specific therapy of, 398; new aspect of, 1043.
Influenza, causing otitis, 28; menin-

gitis due to, 955; relation of, to bronchitis and tuberculosis, 123.
Inhibitions and reflexes, the development of new, 850.
Injured, psychology of, declaration of, 586.
Insane, negro, Wassermann reaction among, 712.
Insanity, and immigration, 488; distribution in Massachusetts, 488; liquor legislation and, 791; of defendant, in murder case, 113; social factors in the prevention of, 1000.
Insomnia, remedies for, 584.
Instruments, presentation of, by Dr. Einhorn, 85.
Insufflation apparatus, 638.
Insurance, Act of England, bill for amending, 118; against occupation disease, 726; companies and cancer statistics, 1002; companies, educational value of cancer statistics to, 962; compulsory in Germany, 635; medicine, failure of colleges to teach, 1049; State, 534.
Intestinal stasis, 121, 557, 963, 1000; and arthritis deformans, 684; postoperative, and intraabdominal use of oil, 795; surgical aspects of, from anatomical viewpoint, 38; surgical treatment, 316.
Intestine, adhesions of, 638; adhesions and angulation of, and chronic constipation, 639; affections of, in childhood, 1051, 1190; autointoxication from, 490; doormaker of, 103; hemorrhage from, in tuberculosis, 471; instrument for short-circuiting, 103; intoxication from, 1082; large, function of, 1180; large, surgery of, 170; obstruction of, 1180; obstruction of, acute, cause of death in, 270; obstruction of, unusual cases of, 732; retrograde incarceration of, 1094; stasis in, see intestinal stasis.
Intravenous injections of theobromine sodium salicylate, 858.
Intussusception, absence of mass per rectum in, 526.
Iodine, nascent, and hot air in treatment of aural and nasal conditions, 29; use of, in abdominal surgery, 732.
Ions, medication by, 684.
Ivey, R. R., the Wassermann reaction among the negro insane of Alabama, 712.
Ivory plates in the treatment of fractures, 859.

Meding, C. B., a glimpse of Indian hospitals, 244.
Mediocrity, tyranny of, 391.
Membrane, Jackson's, see Jackson's membrane; about cecum and colon, 36; pericecal, 361; pericolic, 260.
Mendel, as student, 1038.
Meninges, hemorrhage into, during parturition, 1128.
Meningism, 31.
Meningitis, after follicular tonsillitis, 1181; carriers, 1142; cerebro-spinal, bacteriology of, 1142; cerebrospinal, in New York for fifty years, 582; cerebrospinal signs of, 1142; complicating parotitis, 453; influenzal, 955; rhinogenous, 483; tuberculous, two cured cases of, 172; tuberculous, *x*-ray study of the chest in, 775.
Meningococcus carriers, 1142.
Meningoencephalitis, congenital, 318.
Meningomyelitis, spinal decompression for, 592.
Menorrhagia, and metrorrhagia, significance of, 867; and metrorrhagia, *x*-ray treatment of, 85.
Mercury, massive injections of, in the treatment of syphilis, 966; vaginitis due to, 861.
Mesentery, cysts of, 170.
Metabolism and the circulation, 47; mixed diet and, 759.
Metacarpal bone, separation of epiphysis of, 122.
Metals, heavy, toxic effects, 355.
Metatarsal pain, paroscystic attacks of, 654.
Metrorrhagia and menorrhagia, significance of, 867; and menorrhagia, *x*-ray treatment of, 85.
Meyers, J., two cases of pancreatic lesions, 430.
Middle life, mortality of, 126.
Migraine, nature of, 430; simple and ophthalmic, the cerebrospinal fluid in, 184; treatment of, 238.
Milk, and surgical tuberculosis, 447; breast, the consumption of, 30; certified, of the County of Westchester, 869; immunized, in typhoid fever and tuberculosis, 766; machine clarification, 349; pasteurization at low temperatures, 253; public value of different grades of, 924; reaction to differentiate human from cow's, 620; relation of, to infant mortality, 1144; supplies, 168.
Miller, A. M., hemostat as a safety blade holder, 1034.
Mind, hygiene of, 108; morbidities of, of conjugal state, 104.
Misrepresentation by physician as to cure, 113.
Monstrosity, the diagnosis of a, 828.
Morbidity reports, 630.
Morphine, dangers of use with other narcotics and hypnotics, 491; poisoning, treatment, 322.
Morris, R. T., the bowel doormaker, with description of technique of operation for short-circuiting bowel, 103; the etiology of gastric ulcer, 854.
Mortality, in total abstainers, 986; infant, 236, 270; infant, and congenital syphilis, 390; infant, milk in relation to, 1144; of children from burning, 1000; of middle age, 126, 898; statistics, American, 1182; tables, Hungarian, 357.
Morton's metatarsalgia, 654.
Mothers, expectant, 437; unmarried, 575.
Mouth, sepsis from, 31, 461, 497.
Muhlberg, W., a few practical observations the result of 8000 examinations of urine, 1151.
Mullan, E. H., the medical inspection of immigrants at Ellis Island, 1167.
Mumps, blood and cerebrospinal fluid in, 216.
Muscles, extraocular, operations on, 965; traumatic ossification in, 1181.
Myasthenia gravis, 80; the pathology of, 134.
Myelitis treated with gymnastic exercises, 1081.
Myelomalacia, hemorrhagic, 146.
Myopia, 676; prevention in schools, 488.
Myotonia atrophica, cortical, 871.

N

Napoleon, and hypopituitarism, 690.
Narcosis, 769.
Nasopharynx, tumor of, 819.
Negro, in relation to public health, 1142; insane, Wassermann reaction among, 712.
Neoplasm, multiple, 594.
Neosalvarsan 246; in treatment of parasyphilis of nervous system, 131.
Nephritis, acute, in children, 822; acute, in childhood, the tuberculous nature of, 1042; acute unilateral hematogenous, 731; as a surgical problem, 37; chronic, blood examinations in, 862; chronic, potassium nitrate in, 951; classification of, 674; classification and treatment of, according to functional tests, 123; dietetic management of, 76; mercurial, renal function in, 678; nervous irritability of, 1137; nitrogenous waste products in the blood of, 674; tuberculous interstitial, 1129; urinary acidity in, 674.
Nephrolithotomy, untoward results of, 954.
Nerve, auditory, intracranial division of, 308; axis cylinder of, regeneration of, 862; injection of alcohol into, 136; intradural anasto-

mosis of, for the cure of paralysis, 800; surgery of, 999; tissues, preparation of, for photomicrography, 605; twelfth dorsal, neuralgia of, 310.
Nervous system, and syphilis, 584; ankle clonus in disease of, 597; central, treatment of syphilis of, 781; disorders of, and pelvic diseases, 488; functional disorders of, 257; hyperthyroidism and the, 1138; in pellagra, 171; parasyphilis of, neosalvarsan in treatment of, 131; surgery of, 1047; sympathetic, clinical importance of, 30; syphilis of, 811.
Neurasthenia, and emotional susceptibility, 953; and hysteria, 257; and syphilis, 262; conception of, 1175; treatment, 1092.
Neuritis, cauda equina, 872; effect of climate on, 227.
Neurology and gynecology, relation between, 811; serology in, 446.
Neuroma cutis, 354.
Neuron, degeneration of, 1045.
Neuroses, and psychoneuroses of children, 834; civic importance of some phases of the, 1055; kinetic, and psychoses, 1177; traumatic, 593.

Obsessions in medicine, 204.
Obstetrics, local and spinal anesthesia in, 45; thyroid gland in relation to, 45.
Occupation, disease, insurance against, 726.
Oculomotorius palsy from softening in each oculomotorius nucleus, 134.
Oettinger, B., a case of pseudobulbar paralysis presenting facial spastic movements simulating laughter, 737.
Ointment bases, fats as, 861.
Omentum, tumor of, with twist of pedicle, giving symptoms of acute appendicitis, 205.
Operations, anemia as a risk of, 225; caution before, 628; consent to, 354; gynecological and disease of, 225; gynecological and obstetrical, diagnostic value of the electrocardiograph before, 225.
Ophthalmia, gonorrheal, in Manila, 673.
Opsonic index, lecithin and, 31.
Optic nerve, bilateral pseudoneuritis of, in cranial injury, 13; neuritis of, hereditary, 860.
Organotherapy, 207.
Oroya fever, 954.
Orthocrasia, dyscrasia, idiosyncrasia, eucrasia, and naphylaxis, 299.
Orthopedics, and the sanatorium, 952; in general practice, 536; recent progress in, 1044.
Osteitis and periostitis of the skull, syphilitic, 780.
Osteoarthropathy, hypertrophic pulmonary, 675.
Osteochondritis dissecans, 997.
Osteoporosis and blue sclerotics, 121.
Osteosarcoma, *x*-ray treatment, 446.
Otitis, association of, with other diseases, 773; influenzal, 28.
Otorrhea, persistent, mated by postauricular drainage, 157.
Ovary, adenocarcinoma of, complicating labor, 178; autoplastic graft of, 724; cyst of, sudden severe hemorrhage into, following delivery, 732; functional testing of activity of, 769; Kruchenberg tumor of, 596.
Oxalic acid, decalcifying action of, 309.
Oxygen, administration of, to fetus, 112.
Ozena, paraffin in, 629; true, and the bacterium Perez, 623.
Ozone, 676.
Ozone, for public buildings, 530.

P

Pain, and sleeplessness, remedies for, 719; determination of changes in, 1159; remedies for, 584.
Palefski, I. O., a collapsible-weighted stomach-tube and a new gastric glass bulb, 564.
Palmer, F. A., is appendicitis ever catarrhal, 139.
Palpation, special technique in, 907.
Pancreas, insufficiency of, in children, 410; lesions, 430; necrosis of, causing sudden death, in labor, 124.
Pancreatitis, acute, 586.
Parabiosis rats, exchange of nutriment in, 262.
Paracelsus, a short study of the career of, 93.
Paraffin, embolism, removal of dangers, 587; in ozena, 629.
Paralysis, facial, partial, due to traumatism, 1030; intradural anastomosis of nerves for the cure of, 800; Landry's, 335; oculomotor, 134; pseudobulbar presenting facial spastic movements simulating laughter, 737; spastic, operative treatment of, 213; spastic, phylogenetic significance of, 217; parasyphilis of nervous system, neosalvarsan in treatment of, 131.
Paraplegia, congenital spastic, 1012.
Paratyphus-B, 32.
Paresis, 723; in the negro, 812; juve-

nile, 781; syphilitic infection from blood of patients with, 859; Virchow-Robin lymph spaces in, 781; without demonstrable anatomical findings, 135.
Parotid, ablation of, 608.
Parotitis, acute, and a fatal illness, 354; complicated by meningitis, 453.
Parturition, adenocarcinoma of ovary complicating, 178; clamping parametria for hemostasis following, 1181; mechanism at the pelvic brim, 307; meningeal hemorrhage during, 1128; missed, 32; pituitary extract in, 996; prolonged precipitate, 337; sudden death in, from pancreatic necrosis, 124.
Pathology, plant and animal, 309; of fossil animals, 631; of the living, 206.
Pedersen, V. C., a case of exploded urethrascopic lamp; removal for fragments without operation for subsequent symptoms or sequels, 158.
Pediatrics, as a special study, 1144.
Pellagra, experimental, in the monkey, 29; in England, 171; intestinal bacteria in, 593; nervous system in, 171; present knowledge of, 1131; surgical treatment, 307.
Pelvis, acute inflammatory disease of, conservatism in operations for, 731; floor of, operation for repair of, 224; infections of, from a general surgeon's point of view, 45; operations on organs of, newer methods of reducing the mortality of, 44; repair of floor of, 596.
Pemphigus, complicating typhoid fever, 549.
Percussion of the pulmonary apices, 858.
Pericarditis, adhesive, symptomatology of, 768; bacillary (tuberculous), 491; chronic adherent, 582; chronic adhesive, in childhood, 809; surgical treatment of, 31.
Pericardium, adherent, 689.
Pericecal membranes, 857.
Pericolic membrane, 1099.
Pericolitis, membranous, symptoms and diagnosis of, 37.
Peridental infections, 964.
Perineorrhaphy retractor, 897, 1089.
Periodicity, sexual, in the male, 18.
Periosteum, function of, in bone transplantation, 1188; preservation of, in bone transplantation, 37.
Peritoneum, fetal folds of, and their relation to postnatal acute and chronic occlusions of the large and small intestines, 37.
Pertussis, the bacillus of, 21; complement deviation in, 1001; pathology, 581; public control of, 409; suprarenal extract in, 414; treatment of, 736; vaccine in, 1125, 1136.
Petery, A. K., some early symptoms of dental disturbances, 1123.
Phagocytosis in acute infectious diseases, 1037.
Pharynx, inflammation of lateral columns of, 542; phlegmon of, 542.
Phenolsulphonepthalein test, 674; sources of error, 586.
Philippines, health officer in, 1089; politics and sanitation in the, 1083; sanitary problems of, 547.
Phillips, S. L., unilateral amblyopia and diplopia following suppressio mensium, 573.
Phillips, W. C., the treatment of persistent otorrhea in infants and young children by the establishment of postauricular drainage, 157.
Phillips, W. F. R., extreme enlargement of the cavum septipellucidi, 433.
Phlegmon of upper respiratory tract, 542.
Phosphates, excretion of, in infancy, 454.
Phosphorus in pulmonary diseases, 398.
Phototherapy and apparatus, 683.
Phthiriasis, complicated with impetigo, treatment of, 736.
Physician, and patient, 389; and social service, 414; intellectual standard of, 92; in the Philippines, 1176; services of, stepfather's liability for, 757; waiting room of, 598.
Pig skin used in extensive grafts, 822.
Pilcher, J. T., the diagnosis and prognosis of duodenal ulcer, 156.
Piles, see hemorrhoids.
Piorkowsky, turtle tuberculin of, 581.
Pituitary extract, causing uterine rupture, 448; in constipation, 1104; in labor, 996; in obstetrical country practice, 1081; in rheumatic arthritis, 608; in uterine inertia, 220.
Placenta, manual delivery of, 32; prævia, treated by cesarean section, 730.
Plague, and the Mongolian marmot, 490; cessation of, in Philippines, 673; human, traced directly to the rat, 950; increase of, in the Philippines, 120; tarbagans and rats, 535.
Pleura, examination of tuberculous fluids of, 1179.
Pneumococcus, infection in the rabbit, 660; septicemia, a case of, 1033.
Pneumolysis, 310.
Pneumonia, acute gastric dilatation in, 353; and bronchitis in children, 251; and heart lesions, 1048; causes of, 679; cause of death, 250; chemotherapy of, 448; chronic, fibrolysin in, 262; cerebral complications of, 76; ethylhydrocuprein in, 448; ethylhydrocuprein and pneumococcus serum in, 1046; heart weakness of, treated with venesection and saline infusion, with suprarenin, 814; lobar, observations and suggestions regarding, 201; croupous serotherapy of, 944; lobar, treatment of, with partially autolyzed pneumococci and pneumococcus extracts, 39; quinine treatment of, 170; rational treatment, 250; treatment of, by bacterial vaccines, 1157; treatment of, by specific serums, 39.
Pneumothorax, artificial, in treatment of pulmonary tuberculosis, 28; artificial, 131, 497, 976, 905, 583.
Pogue, G. R., specifies in the treatment of tuberculosis, 285.
Policy, life insurance, adapting the, 126, 218.
Politics and public health, 944.
Polioencephalitis, acute, 483.
Polycythemia, a hitherto undescribed form of, related to duodenal ulcer, chronic pancreatitis and a disturbance of internal secretions, 177, 701.
Polygraph, MacKenzie's modified ink, 452.
Polyorromenitis, chronic, 1179.
Polyposis, gastrica, 1091.
Porto Rico, diseases of, 30.
Postgraduate study in Vienna, 1020.
Potassio-mercuric iodide, 477.
Poxes, differential diagnosis of the, 124.
Poliomyelitis, and its periodicity, 207; atypical, 913; causation, 678; choreiform manifestations of, 955; histopathology, 712; pathology, 72; transmission, 399, 536; year's progress in research of, 913.
Polyneuritis in fowls, 1176.
Pregnancy, Abderhalden reaction in, see Abderhalden reaction; and Addison's disease, 491; calcium content of the blood during, 225; clinic, 1044; early ectopic, 688; ectopic, final results following operations for, 44; ectopic influence of, on the blood supply of the uterus, 223; elastic area in the isthmus of the uterus a positive early sign of, 80; labor, and the puerperium, conditions complicating, 731; serum diagnosis of, 29, 80, 99, 125, 216, 251, 318, 730, 1043; skin striations during, 222; toxicoses of, treatment of, 769; urinary complications of, 317; urine in, 364; vomiting of, 261.
Presidential address, American Climatological Association, 226; American Electrotherapeutic Association, 683; American Laryngological Association, 498; American Neurological Association, 131; Seventeenth International Medical Congress, 359; Southern Medical Association, 1143.
Privacy, right of, in photographing dead bodies, 389.
Proctoclysis, an experimental and clinical study, 36.
Proctoscope, children's, 272.
Prognosis, 360; and blood pressure, in abdominal operations, 224; mistakes in, 904.
Prostate and bladder, gumma of, 1028; and seminal vesicles, rôle of, in toxemia, 37; carcinoma of, 216; high frequency cauterization in obstruction from, 259; hypertrophy of, 401; pathology of, 1139.
Prostatism, operative treatment, 315.
Prostitution, social and medical aspects, 231.
Protein disintegration and acidosis, in diabetes, 75.
Pruritus, ani, pertinax, 891; vulvæ, treatment of, 1104.
Pseudocholecystitis of typhoid fever, 32.
Pseudodiphtheria organism in the urinary tract, 908.
Pseudoileus, due to intestinal nerve impulse disturbances, 130.
Pseudopélade of Brocq, 1048.
Psoriasis, as a constitutional disease, 538; syphilide or tuberculide, 356.
Psychiatry, Abderhalden reaction in, 679, 1181; preventive medicine in relation to, 76.
Psychoanalysis, 258; delusion of, 421; depreciation of, 116; example of, 909; scope and technique of, 973; transference in, 873.
Psychology, clinic for, 521.
Psychoses, acute, etiology, 262; Freudian conception of the, 967; histopathology of the cortex in, 782; kinetic neuroses and, 1177.
Psychogenetic disorders in detained immigrants, 58.
Psychoneuroses of children, 834.
Psychotherapy, evolution of, 857.
Ptosis, problem, 352.
Publicity and ethics in health education, 961.
Puerperium, eclampsia of, 861; infection of, emptying uterus in, 45; infection of, obliteration of cervix following, 688; infection of, surgery in, 124; infection of, treatment of, 20; infection of, use of salvarsan in, 909; streptococcemia of, treated with intravenous injections of magnesium sulphate, 720; tetanus of, recovery, 392.
Pulmonary tuberculosis, a new sign in the early diagnosis of, 668; advanced, climate and, 229; and "family clusters," 398; artificial pneumothorax in treatment of, 28, 497, 905; cases of tumor of

the lungs and mediastinum simulating, 888; decrease in mortality from, only apparent, 950; diagnosis, 585; early diagnosis and treatment, 260; fever in, 813; hospital care of subjects of, 949; in pregnant women and sanatorium treatment, 583; relation of influenza to, 123; relation of tonsils to, 229; rest and exercise for the child affected with or predisposed to, 875; rest and repair in, 399; sputum diagnosis of, 1120; subject treatment of, 951; treatment of progressive cases of, 159.
Pulmotor, infant, 221.
Pulpit, medicine and the, 1058.
Pulse, rate during sleep, clinical significance of, 899; venous, auscultation of, 92.
Pulsus durus, 261.
Purpura, fatal, following scarlet fever, 814.
Purse, B. S., treatment and pathology of appendicitis, 296.
Pyelitis, 131; acute primary, in children, 131; colon bacillus, relation of, to fecundity, 217; in infancy, 409.
Pyemia, cutaneous metastases of, 401.
"Pyemides," 401.
Pyloroplasty, 960.
Pylorus, congenital stenosis of, 386; congenital hypertrophic stenosis of, 488; pilleus ventriculi, and duodenum, physiology of, 583; stenosis of, 1097.
Pyocyaneus infection, chronic, 451.

Q

Questions, hypothetical, conclusions eliminated from, 874.
Quinine treatment of pneumonia, 170.

R

Rabies, 453; Pasteur treatment of, 991; research, present status of, 909; virus, cultivation of, 859, 1000.
Race betterment, the medical profession and, 1006.
Rachitis, cod liver oil, calcium and phosphorus in, 401; of nose and bronchial asthma, 1181.
Radioactivity, in certain waters, 760.
Radiography, see *x*-ray.
Radium, and inoperable cancer, 270; for London hospitals, 1134; in cancer, 490; in internal medicine, 812; in treatment of thyroid hypersecretion, 723.
Radius, congenital absence of, 1170.
Raynaud's disease, therapy of, 32.
Rectocele, operation for, 224.
Rectum, diseases of, diagnosis of, 868; feeding by, amino-acids and surgery in, 124.
Reed, A. C., Alaska and its health, 571.
Reflexes, and inhibitions, the development of new, 850.
Refrigerator problems, 630.
Rehfuss, M. E., radiography in pulmonary gangrene, 1080.
Reich, A., perineorrhaphy retractor, 897.
Rejections in life insurance, study of, 815.
Research, historical, results of, 1084; laboratory, the surgeon and the, 36.
Resorcin, sensitiveness to, 98.
Respiration, the tonsil, a vestigeal organ of, 756.
Respiratory tract, diseases of, blunders by nature in, 289; upper, phlegmons of, 542.
Rest and play, in school children, 1144.
Resuscitation, 259.
Retina, impaired activity of, 908.
Retractor, perineorrhaphy, 897, 1089; self-retaining, for superficial dissections, 666.
Reuben, N. S., infant mortality, 236.
Rheumatism, effect of climate, 23, 227; lesions produced by streptococcus group in, 1148; pathogenesis of, 355; treatment of, 703.
Rhinitis, acute, an anaerobic organism in, 77.
Rhinitis, atrophic, with ozena, 674.
Rhinoplasty, early, 743.
Richter, C. M., colds and their relation to the physics of the atmosphere, 1014.
Richter, G., the etiology of "blackwater fever," 297.
Rigg's disease, radio-active substances in, 32.
Risks, medical selection of, 402.
Robinson, B., high blood pressures and hardened arteries, 25; obsessions in medicine, 204.
Rocky Mountain fever and sheep grazing, 1171.
Roethlesberger, P., a new method for the determination of uric acid in minimum quantities of blood serum and other fluids of the body, 802.
Rosenbluth, B., partial facial paralysis due to traumatism, 1030; the neuroses and psychoneuroses of children; their mode of development and treatment, 834.
Roussel, A. E., acute phlegmonous cholecystitis, report of a case with gangrenous enteritis, 1075.
Rueck, G. A., a case of pneumococcus septicemia, 1033; a study of the bacteriemia in pneumococcus infection of the rabbit, 660; bacteriological study of a case of hemorrhagic myelomalacia, 146.
Rush, J. O., gumma of prostate and bladder; six intravenous and one intramuscular injections and salvarsan and twenty-six intravenous injections of neosalvarsan to patient sixty-six years old, 1028.

S

Saccharomycete infection of lungs, 386.
Sacrouterine ligaments, 722; utility of, 45.
Safety blade holder, hemostat as, 1034.
Salomon-Saxl reaction in cancer, 1034.
Salpingitis, tuberculous, 45.
Salvarsan, and neosalvarsan in treatment of syphilis, 984; in actinomycosis, 715; in congenital syphilis, 585; in gumma of prostate and bladder, 1028; in puerperal infection, 909; in syphilis, 811; intravenous injection, 527; localization of arsenic in the viscera after injection of, 1166; needle, 435; relapsing, 907; two years' experience with, 998.
Sanatorium, the, and orthopedics, 952.
San Diego, California, the climate of, with relation to renal disease, 227.
Sanford, A. N., results of intravenous injection of extracts of goiter in blood pressure in the dog, 378.
Sanitary administration of parts, 490.
Sanitary retrogression, 208.
Sanitation, rural, and country schools, 23.
Scalp, eczema of, in infants, treatment of, 230; seborrhea of, treatment of, 230.
Scaphoid, carpal, fracture of, 213.
Scarlet fever, and diphtheria, eye coloration in relation to, 1179; differentiated from German measles, 197; fatal purpura following, 814; inclusion bodies in, 319; neosalvarsan in, 319; pathogenesis of, 900; return cases of, 320.
Scars, a new method of dealing with, 1000; upon candidate for insurance, 726.
School, children, feeding, 166; country, and rural sanitation, 23; medical inspection, 1144; medical inspection and the general practitioner, 710; medical inspection in New York, 1117; medical inspection in rural schools, 1144; medical sociology in, 1177; open-air, architecture of the, 880; open-air, for healthy children, 209; open-air, in preventive medicine, 995; rest and exercise for the tuberculous child, at, 875; trachoma in, 530.
Sciatica, new view of, 124; kyphotic, 862.
Scleroderma, generalized, with severe muscular atrophy, 67.
Sclerosis, disseminated, transmitted to rabbits, 909; multiple, a case of, treated for incontinence, 873.
Sclerotics, blue, and osteoporosis, 121.
Scoliosis, Abbott treatment of, 31, 124, 724; spinal tumor with, 78; treatment of, 906.
Scorbutus, experimental, 398, 454.
Seborrhea of the scalp, treatment of, 238.
Secretin, 574; therapeutic value, 398.
Secretions, internal, and the female characteristics, 214, 1046, 1086; internal, effect upon development, 584; internal, in disease, 268; internal, oxytocic properties of, 900.
Selection, self, in life insurance, 770.
Sepsis, oral, 461.
Septicemia, tetragenus, 78; pneumococcus, a case of, 1033.
Serological tests, in cerebral hemiplegia, 1013; in croupous pneumonia, 944; in organic changes, 1043; in pregnancy, 125, 216, 730; see also Abderhalden reaction.
Serum, antistreptococcic, 39; and vaccines, federal control over manufacture of, 39.
Services, professional, stepfather's liability for, 757.
Sex, periodicity of, in the male, 18; amentia as related to, 753; diseases of, and society, 765; error of, 217; hygiene of, teaching of, 765, 805, 907, 990.
Shalet, tuberculosis and the von Pirquet test in children, 1032.

Thrombosis, and embolism, 1057; traumatic, of inferior vena cava, and life insurance, 172.
Thymus, causing tracheal obstruction, 777; physiology and pathology, 587; regeneration of, in mammalia, 725.
Thyroglossal cysts and fistulæ, 38.
Thyroid degeneration of, in relation to obstetrics and gynecology, 45; disease, 1113; hypersecretion radium in treatment of, 723; in infancy, 161; relation of, to alimentary toxemia, 68; surgery of, 37.
Tibia, epiphysitis of, 587.
Tin plate industry, chronic irritation in, 400.
Tobacco, question of its being a drug, 620; smoking and life insurance, 173.
Tomlinson, W. H., preventable deafness, 569.
Tonsil, a vestigeal respiratory organ, 756; complete removal of, in its capsule, by means of a new tonsillotome, 820; faucial, and systemic infection, 499; passage of bacteria through, 547; plasma cells on, 308, 544; surgery of, in relation to the voice, 964; surgery of, failures in, 1170; with special reference to the Sluder-Ballenger operation, 820.
Tonsillectomy, accidents of, 171; results of, 500.
Tonsilitis, meningitis following, 1181; surgical treatment of, 820.
Tonsillotomy versus tonsillectomy, 721.
Toxemia, rôle of prostate and seminal vesicles in, 37.
Toxins, thermostabile, use of, in urethral and bladder infections, 28.
Trachea, obstruction of, from thymus gland, 777.
Tracheotomy, accidental, 927.
Trachoma, control in schools, 530; status of question of, 943.
Transfusion, 714; accidents in, 1178; and hemopoiesis., 1136; by means of glass cylinders, 1090; prevention of dangers, 1094; simple syringe, with special cannulas, 775; theory and practice of, 38; therapeutic possibilities of, 38.
Transplantation of organs, 116.
Treponema pallidum, living, in the brains of paretics, 172, 591; transmitted from brain of paretics to rabbits, 169.
Trigger-knee, 243.
Tropacocaine, spinal anesthesia by, 79.
Trypanosomiasis, see sleeping sickness.
Tubercle bacillus, in the circulating blood, 80; progeny of, 1162.
Tuberculin, administration, 514; minute initial dose of, 353; treatment, 490; turtle, of Piorkowski, 581; use of in genitourinary diagnosis, 650; value of, 395, 399.
Tuberculosis, acquired through circumcision, 776; and cirrhosis, the liver in relation to, 851; and syphilis in German Southwest Africa, 217; and von Pirquet test in children, 1033; bone and joint, treatment of, 814; clinical, relation of laboratory work to, 229; differentiation between active and healed, by means of the cutaneous tuberculin test, 1057; dispensaries, 213; immunized milk in, 766; genital, in children, 1138; in infancy, prognosis of, and account of a ward epidemic, 775; in the United States Army, 214; in the United States Navy, 249; intestinal hemorrhage in, 471; isolation the only effective measure in combating, 950; laryngeal, relief of pain of, 860; of middle ear, 180; morbidity and mortality not decreasing, 949; myeloid leucemia and, 573; notification of, in France, 904; of epididymis, 28; of urinary tract, 354; of uterus, 767; physical exercise in the open air in the prophylaxis of, 788; primary of the gums, 163; prophylaxis of, rôle of physical exercise in, 230; public measures against, 999; resistance to, diminished by excess of carbohydrates, 755; specifics in, 285; surgical and milk, 447; surgical, outdoor treatment, 306; surgical, sunlight and *x*-ray treatment of, 400; two most important factors in treatment of, 230.
Tumor cells, experimental transference, 400; benign and malignant radiographic treatment of, 960.
Turbinotomy, 1128.
Typhlitis, chronic, pathogenesis, 491.
Typhoid carrier, perineal suppuration in, 401; problem, 168.
Typhoid fever, Besredka's method of vaccination against, 989; diagnosis, 398; gelatin and olive oil in, 307; diagnosis and treatment of, 678; immunized milk in, 766; in the Canal Zone, 104; measles complicating, 632; mixed infection in, 621; pemphigus complicating, 549; pseudocholecystitis of, 32; treatment of, 32, 866; ulceration of larynx from, 302; ulcer of, surgery of perforated, 678; vaccination, 121, 606, 622, 719; vaccination in civil communities, 894; vaccination in the army, 40; vaccination, limitations, 344; vaccine treatment, 518, 537, 720.

U.

Ulcer, varicose, treated by feeding it with cheese, 481; gastric, see stomach.
Umbilicus, solid tumors of, in adults, 260; stump of, care of, 45.
Ureter, repair of defects in, 954.
Ureterovesical cysts, 953.
Urethra, and bladder, infections of, thermostabile toxins in treatment of, 28; caruncle, high frequency cauterization in, 1138; prostatic, congenital stricture of, 260.
Urethritis, chronic non-gonorrheal, 29.
Urethroscope, direct view irrigating, 434; lamp of, exploded, 159.
Uric acid, mistaken for sugar, 633; new method for determination of minimum quantities of, in the blood serum, 802.
Urinary tract, the pseudodiphtheria organism in the, 908; upper, diagnosis of lesions of, 960.
Urine, antiseptics for, 631; Chetwood operation for retention of, 721; indications from the, in the treatment of certain diseases of the skin, 921; lipoids in, 437; practical observations from 8000 examinations of, 1151; pus in, 1177; sulphates of, and indicanuria, 248.
Uta, 954.
Uterus, adenoma, 595; and bladder, prolapse of, 821; and both adnexa, hernia of, 180; and vagina, prolapse of, 44; carcinoma of, 222, 595, 722, 1109; cancer of, and fibroid tumor, 732; cervix of, cancer of, 597, 722; elastic area in the isthmus of, a positive early sign of pregnancy, 86; emptying of, in puerperal infection, 45; fibroids of, 318; fibroids of, medicinal

treatment, 414; fibroids in the lower segment of, 733; hemorrhage from the non-pregnant, 489; inertia of, 220; inertia of, artificial delivery in, 220; inertia of, pituitary extract in, 220; influence of ectopic pregnancy on the blood supply of, 223; leucoplakia of, 363; maldevelopment of, causing dypmenorrhea, 480; malpositions of, treatment, 268; perforation by a foreign body, 448; prolapse of, 44, 130; rupture, following use of pituitary extract, 448; septate, causing fatal puerperal septicemia, 179; syndrome of, 333; tuberculosis of, 767.

V.

Vaccination, and smallpox, 207; antityphoid, Besredka's method of, 089; sensitized virus, in gonorrhea, 999.
Vaccines and serums, federal control over manufacture of, 39; gonococcus, and diagnosis of gonorrhea, 581; in acne pustulosa, 656; in pertussis, 1125; in pneumonia, 1157; in typhoid fever, 518, 537; preparation of pure cultures of, 1048; sensitized, in bacterial infections, 123; therapy of, 1044; typhoid in the army, 40.
Vaccinola, 623.
Vagina and uterus, prolapse of, 44.
